If the structure is indeterminate, as in the case of a closed conduit, the value of ΔM_a must be determined by elastic theory. Moment distribution offers a convenient method of obtaining this solution. The two quantities needed for the moment distribution computation are the "fixed-end moment" and the stiffness of the slab. The formula for the "fixed-end moment" can be obtained from Eq. 24*c* by setting $x = a$; thus:

$$M'_a = -\,C_a\,F\,\lambda \dots\dots\dots\dots\dots\dots\dots (26a)$$

in which

$$C_a = \frac{1}{2}\left(\frac{\sinh 2\,\alpha - \sin 2\,\alpha}{\cosh 2\,\alpha - \cos 2\,\alpha}\right) \dots\dots\dots\dots\dots (26b)$$

The coefficient C_a is represented graphically in Fig. 4 (curve 1). The stiffness of the slab may be obtained from Eq. 25*c* by setting $x = a$:

$$\phi_3(a) = S'_a\,\frac{E\,I}{\lambda} \dots\dots\dots\dots\dots\dots\dots (27a)$$

in which S'_a, the stiffness coefficient, is

$$S'_a = \frac{\sinh 2\,\alpha + \sin 2\,\alpha}{\cosh 2\,\alpha - \cos 2\,\alpha} \dots\dots\dots\dots\dots\dots (27b)$$

It is probably more desirable to express the stiffness in terms of $\frac{E\,I}{a}$ as given by Eq. 7. By comparing Eq. 7 and Eq. 27*a*, it becomes apparent that

$$S_a = \frac{a}{\lambda}\,S'_a = \alpha\,S'_a \dots\dots\dots\dots\dots\dots\dots (28a)$$

Substitution of Eq. 27*b* gives

$$S_a = \alpha\left(\frac{\sinh 2\,\alpha + \sin 2\,\alpha}{\cosh 2\,\alpha - \cos 2\,\alpha}\right) \dots\dots\dots\dots\dots (28b)$$

The coefficient S_a is represented graphically in Fig. 4 by curve 2. This coefficient reflects the effect of foundation rigidity upon the beam stiffness.

In a large proportion of base slab designs the only quantities needed for the actual design are the end shear, end moment, and center moment. The end shear is known. The end moment can be computed either from statics or by moment distribution. In either case the value of ΔM_a can be determined and the center moment computed from Eq. 10c by setting $x = 0$:

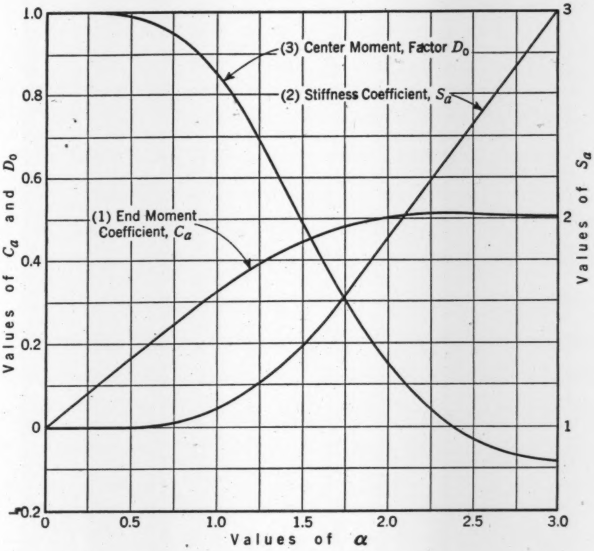

FIG. 4.—QUANTITIES USED IN MOMENT COMPUTATIONS

$$M_0 = M'_0 + D_0 \Delta M_a \qquad (29a)$$

in which

$$D_0 = \psi_3(0) \qquad (29b)$$

The term M'_0 is the center moment with ends fixed, and the factor D_0 is the change in center moment which accompanies a unit change in end moment. The formula for M'_0 can be obtained from Eq. 24c by setting $x = 0$:

$$M'_0 = v F \lambda \qquad (30)$$

The formula for D_0 can be obtained from Eqs. 11, 25c, and 27a:

$$D_0 = \psi_3(0) = \frac{\phi_3(0)}{\phi_3(a)} = \frac{2u}{S'_a} \qquad (31a)$$

Substitution of Eqs. 21*a* and 27*b* gives

$$D_0 = 2\left(\frac{\sin\alpha\cosh\alpha + \cos\alpha\sinh\alpha}{\sinh 2\alpha + \sin 2\alpha}\right) \qquad (31b)$$

The factor D_0 is represented graphically in Fig. 4 by curve 3.

PHYSICAL SIGNIFICANCE OF VALUES OF α

A conception of the practical significance of values of α can be gained by studying the curves for the fixed-end moment and stiffness coefficients. Referring to Fig. 4, curve 1, it may be noted that the initial slope of the graph is $\frac{1}{3}$ and that, for $0 < \alpha < 1$, the value of C_a is approximately $\frac{\alpha}{3}$. For $\alpha > 2$, the value of C_a is approximately one half. Consequently the following approximate formulas for the fixed-end moment can be written:
When $\alpha < 1$,

$$M'_a \approx -\frac{F\,a}{3} \qquad (32a)$$

and, when $\alpha > 2$,

$$M'_a \approx -\frac{F\,\lambda}{2} \qquad (32b)$$

For the range $0 < \alpha < 1$, the formula for M'_a may be converted to the well-known formula $\frac{W\,L}{12}$, in which W is the total base reaction and L is the span length ($W = 2\,F$, and $L = 2\,a$). For $\alpha > 2$ the value of M'_a is only slightly affected by the span length, being equal approximately to one half of the fundamental moment $F\,\lambda$. The three ranges of α might be classified as follows:

Range	Classification
$0 < \alpha < 1$	Rigid beam on flexible foundation
$1 < \alpha < 2$	Rigid beam on rigid foundation, or flexible beam on flexible foundation
$2 < \alpha < \infty$	Flexible beam on rigid foundation

An example of the first range of α is a reinforced concrete slab 3 ft thick and 20 ft long resting on soil. Examples of the second range are the same slab resting on shale, or a slab 1 ft thick and 20 ft long resting on soil. An example of the third range would be the latter slab resting on limestone.

Referring to Fig. 4, curve 2, and Eq. 7, the stiffness of the slab may be approximately expressed by the following formulas:
When $\alpha < 1$,

$$\phi_3(a) \approx \frac{E\,I}{a} \qquad (33a)$$

and, when $\alpha > 2$,

$$\phi_3(a) \approx \frac{E\,I}{\lambda} \qquad (33b)$$

Thus the stiffness, for $\alpha > 2$, is seen to be independent of the span length of the slab.

Another method of demonstrating the physical significance of values of α is to plot reaction diagrams. Reaction diagrams are shown in Fig. 5 for $\alpha = 1$ and $\alpha = 2$ with the ends of the slab fixed. The unit of reaction used in plotting the diagrams is the average reaction $\frac{F}{a}$. It may be seen that for $\alpha \leqq 1$ the reaction is approximately uniform, but for $\alpha = 2$ the variation from uniform distribution becomes a matter of practical significance.

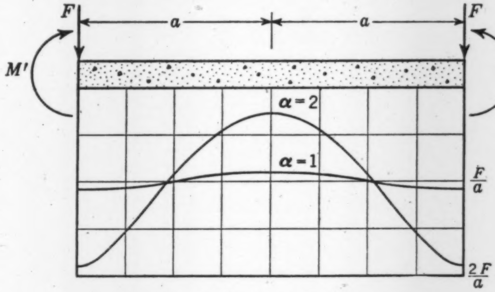

FIG. 5.—REACTION DIAGRAMS

ILLUSTRATIVE EXAMPLES

Fig. 6 shows a section of a water channel in which the floor slab is to be constructed without an expansion joint parallel to the direction of the channel. The weight of the slab itself has no effect upon moments or shears in the slab. The weight of the side-wall (12.4 kips per ft) has been computed using the weight of concrete as 150 lb per cu ft. The values of E for the concrete and k for the foundation are assumed as 4×10^6 lb per sq in. and 100 lb per cu in., respectively. The values of λ (= 138 in.) and α $\left(= \frac{240}{138} = 1.74 \right)$ may be computed. From the various figures in the paper the constants C_a, S_a, D_0, u, and v may be read as follows: $C_a = 0.48$; $S_a = 1.61$; $D_0 = 0.30$; $u = 0.14$; and $v = 0.195$.

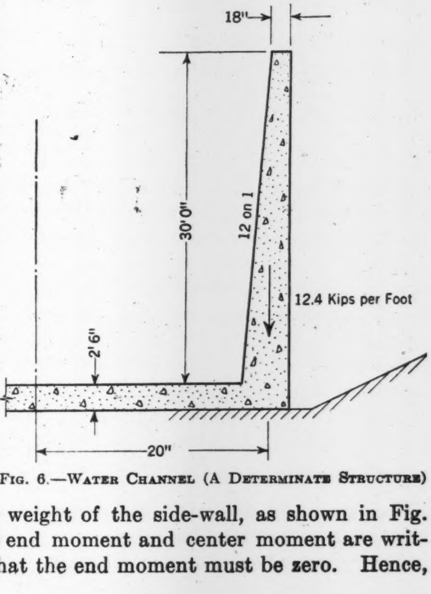

FIG. 6.—WATER CHANNEL (A DETERMINATE STRUCTURE)

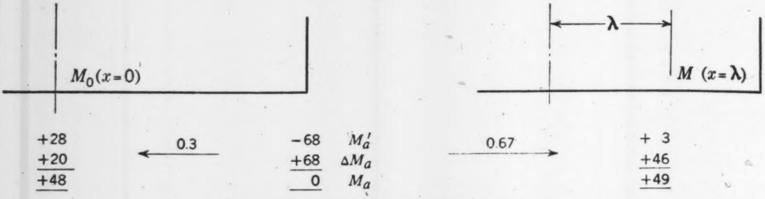
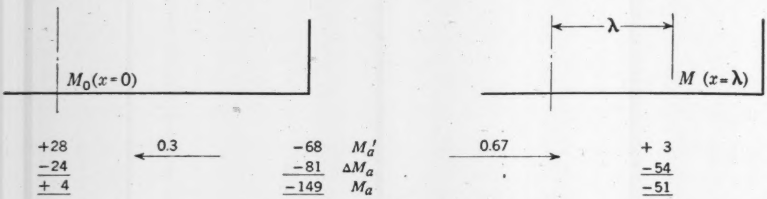
It is first desired to compute the center moment caused by the weight of the side-wall, as shown in Fig. 7(a). The fixed-end values of the end moment and center moment are written first. From statics it is seen that the end moment must be zero. Hence, when the artificial restraint at the end of the slab is released, the change in end moment which occurs will be equal in magnitude to the fixed-end value, and of opposite sign. This change in end moment is then multiplied by the moment factor D_0 to obtain the change in center moment which occurs when the artificial end restraint is released. The final value of center moment then is found by addition to be 48 ft-kips. It is interesting to compare this value with that which would occur with uniform reaction distribution as given by



(a) MOMENTS CAUSED BY WEIGHT OF WALL



(b) MOMENTS WITH BACKFILL IN PLACE

FIG. 7.—COMPUTATION OF MOMENTS

$$M = \frac{W\,L}{8} = \frac{F\,a}{2} = 124 \text{ ft-kips} \quad \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

Fig. 7(*a*) also shows the computation for determining the moment at an intermediate point $x = \lambda$, chosen for convenience. The fixed-end value of moment at this point was computed from Eq. 24*c*, and the moment factor, $\psi_3(\lambda) = 0.67$, was computed by using Eqs. 11 and 25*c*. The moment factor appears in the computations in a manner which resembles the carry-over factor of moment distribution.

It is also desired to compute the moments that will occur after the backfill is placed. This computation is shown in Fig. 7(*b*). The backfill has been assumed to be placed to the top of the wall and to exert a pressure equal to that of a liquid weighing 33 lb per cu ft. The moment at the base of the wall, which is also the moment at the end of the slab, may be computed from statics:

$$M = \frac{q\,H^3}{6} = \frac{33\,(30)^3}{6} = 149 \text{ ft-kips} \quad \ldots\ldots\ldots\ldots\ldots\ldots (35)$$

in which q is the density of the equivalent liquid and H is the wall height. Assuming an artificial restraint at the end of the base slab the fixed-end values of end moments and center moments are written first. When the artificial restraint is released the magnitude of the end moment will increase to 149. The change in end moment is then multiplied by the moment factor to obtain the simultaneous change in the center moment. A computation is made also for moment at the point $x = \lambda$.

In Fig. 8 a rectangular conduit is analyzed by moment distribution to illustrate an indeterminate structure. The relative I-values are assumed as shown on the left side of the center line. The stiffness values may be computed to be as shown on the right side. Due to symmetry the stiffness of the top slab includes the end-rotation constant $\frac{1}{2}$. This avoids the necessity of carrying across the center line in the moment balancing process. It has been assumed that the stiffnesses of the base slab and foundation are such as to give the value $\lambda = 24$ in. and hence to give $\alpha = 2$. The moments have been distributed in the usual manner after computation of the distribution factors. The total change in moment at the end of the base slab has been multiplied by a moment factor $D_0 = 0.15$ to obtain the change in center moment. A statical moment sign convention has been used in the moment distribution.

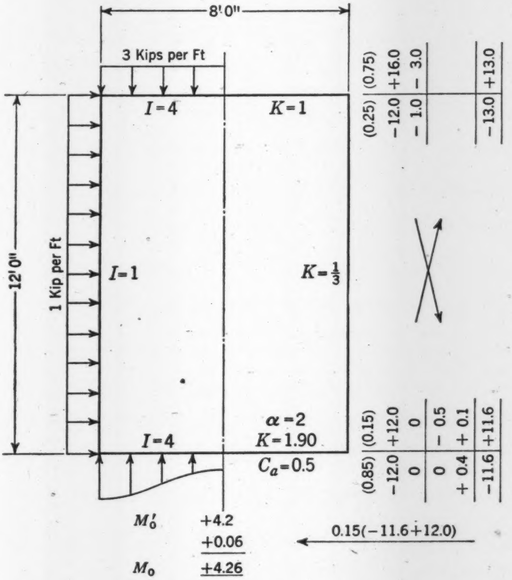


FIG. 8.—RECTANGULAR CONDUIT (AN INDETERMINATE STRUCTURE)

CONCLUSION

A method of determining shears and moments in a base slab resting on an elastic foundation has been developed by using a floating slab theory. Formulas have been developed for fixed-end moment and stiffness values to permit an analysis by moment distribution when the slab is part of an indeterminate frame. Graphs of those coefficients commonly needed in practice have been presented.

APPENDIX

NOTATION

The following letter symbols, used in the paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials,[4] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

A = an integration constant (also B, C, and D, see Eq. 17);
a = half-length of slab;
B = (see A);
C = (see A);
C_a = a fixed-end moment coefficient;
D = (see A);
D_0 = center moment factor;
E = modified modulus of elasticity $= \dfrac{E'}{1 - \mu^2}$;
E' = modulus of elasticity;
F = external force acting on a beam;
I = rectangular moment of inertia of a slab, per unit of width;
k = foundation modulus;
L = span length;
M = bending moment: M_a = bending moment at $x = a$;
S = stiffness function;
u = a convenient function of α defined by Eq. 21;
V = total shear;
v = a convenient function of α defined by Eq. 21;
W = total base reaction;
w = reaction pressure;
x = horizontal coordinate;
z = vertical displacement;
α = a fundamental ratio or angle, in radians, $= \dfrac{a}{\lambda}$;
θ = slope of elastic curve: θ_a = end slope or end-rotation angle;
λ = a fundamental length;
μ = Poisson's ratio;
ϕ = an end-rotation function: ϕ_0 = a beam stiffness $= \dfrac{E\,I}{a}$;
ψ = an end-rotation function.

Subscripts on z, θ, M, V, or S indicate the value of the functions when x equals the subscript. For example: z_a = displacement at $x = a$. Primes on z, θ, M, or V indicate the value of the functions when the ends of the beam are fixed.

---

[4] ASA—Z10a—1932.

DISCUSSION

Robert O. Jameson,[5] M. Am. Soc. C. E.—Although the subject of beams on elastic foundations has been treated at some length by other authors,[6,7] Mr. Benscoter has simplified the solution of this special case greatly by use of moment distribution. The formulas and graphs presented should prove valuable timesavers.

The complete formulas for slope, moment, and shear (compare Eqs. 24) are:

$$\theta(x) = \frac{dz}{dx} = \frac{F\,\lambda^2}{2\,E\,I}\left[(v - u)\sin\frac{x}{\lambda}\cosh\frac{x}{\lambda} + (u + v)\cos\frac{x}{\lambda}\sinh\frac{x}{\lambda}\right]$$

$$+ \theta_a\left[(v + u)\sin\frac{x}{\lambda}\cosh\frac{x}{\lambda} + (u - v)\cos\frac{x}{\lambda}\sinh\frac{x}{\lambda}\right] \ldots\ldots\ldots (36a)$$

$$M(x) = E\,I\,\frac{d^2z}{dx^2} = -\,F\,\lambda\left(u\sin\frac{x}{\lambda}\sinh\frac{x}{\lambda} - v\cos\frac{x}{\lambda}\cosh\frac{x}{\lambda}\right)$$

$$+ \frac{2\,E\,I\,\theta_a}{\lambda}\left(v\sin\frac{x}{\lambda}\sinh\frac{x}{\lambda} + u\cos\frac{x}{\lambda}\cosh\frac{x}{\lambda}\right) \ldots\ldots\ldots\ldots (36b)$$

and

$$V(x) = E\,I\,\frac{d^3z}{dx^3} = -\,F\left[(u + v)\sin\frac{x}{\lambda}\cosh\frac{x}{\lambda} + (u - v)\cos\frac{x}{\lambda}\sinh\frac{x}{\lambda}\right]$$

$$+ \frac{2\,E\,I\,\theta_a}{\lambda^2}\left[(v - u)\sin\frac{x}{\lambda}\cosh\frac{x}{\lambda} + (u + v)\cos\frac{x}{\lambda}\sinh\frac{x}{\lambda}\right] \ldots\ldots (36c)$$

Some designers prefer to plot two moment curves for a restrained beam: One representing positive moments due to vertical loads on the simply supported beam, and the other showing negative moments due to restraint at ends of the beam. The equations for finding these moments are as follows: Referring to Eq. 36(*b*) when $M_a = 0$,

$$\theta_a = F\,\frac{\phi_1(a)}{\phi_3(a)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (37)$$

Substituting Eq. 37 in Eq. 36*b*,

$$M(x) = C_1\,F\,\lambda \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (38)$$

in which

$$C_1 = \frac{1}{\lambda}\left[\frac{\phi_1(a)\,\phi_3(x)}{\phi_3(a)} - \phi_1(x)\right] \ldots\ldots\ldots\ldots\ldots (39)$$

[7] *Engineering News-Record*, Vol. 93, p. 881 (letter to the editor by C. W. Pantke).

Values of C_1 are plotted in Fig. 9. Eq. 38 is used in finding the positive moments on the beam.

With no external loads on the beam, $F = 0$ in Eq. 36*b*, and

$$\theta_a = \frac{M_a}{\phi_3(a)} \quad \text{(40)}$$

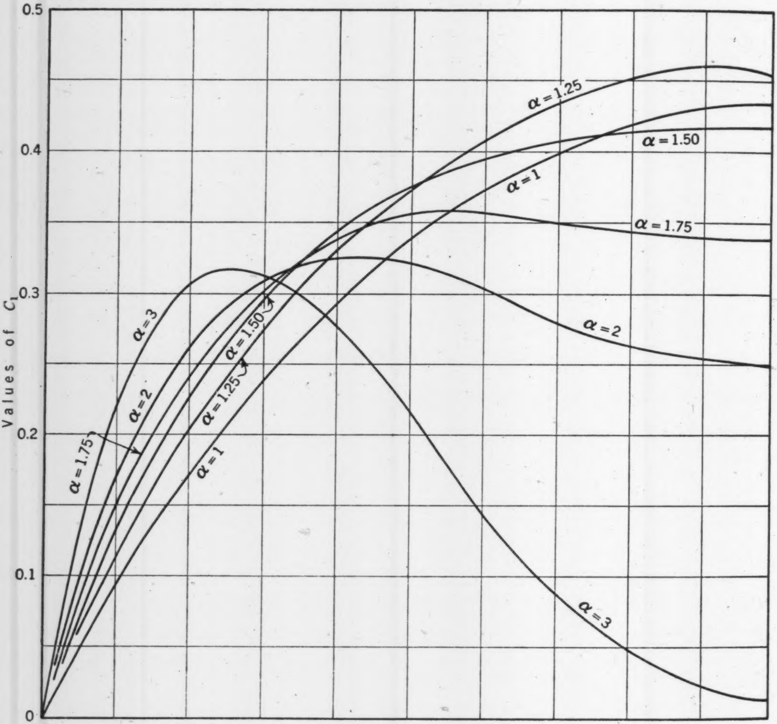

FIG. 9.—POSITIVE MOMENT FACTORS

Substituting Eq. 40 in Eq. 36*b* gives

$$M(x) = D(x)\, M_a \quad \text{(41)}$$

in which

$$D(x) = \frac{\phi_3(x)}{\phi_3(a)} \quad \text{(42)}$$

Values of $D(x)$ are shown in Fig. 10. These values may be used also in solving Eq. 10c. The moments due to end restraint only can be determined by Eq. 41.

The example shown in Fig. 7(a) in the paper is solved by use of Eq. 38 and Fig. 9 as follows: $\alpha = 1.74$; $x = 0$; $\lambda = 11.5$; $C_1 = 0.343$ (from Fig. 9); and—

$$M_0 = 0.343 \times 12.4 \times 11.5 = +48.9$$

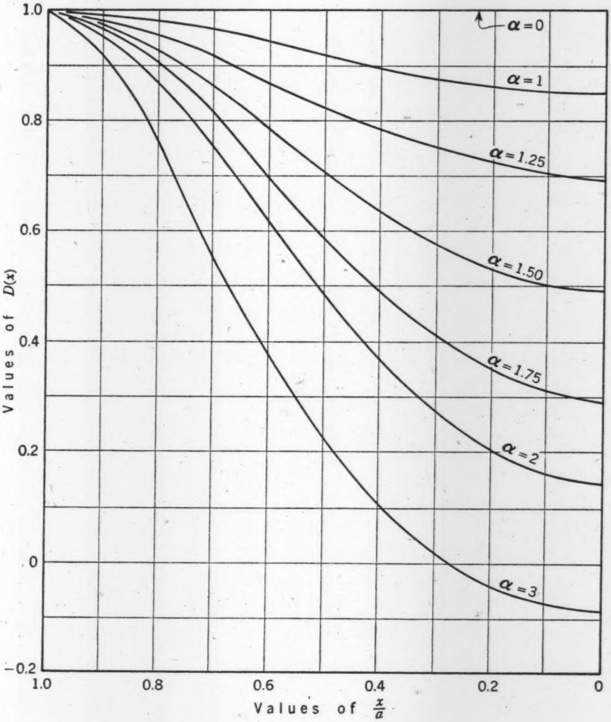

FIG. 10.—RESTRAINT MOMENT FACTORS

Again, for $x = \lambda$; and $C_1 = 0.347$:

$$M(\lambda) = 0.347 \times 12.4 \times 11.5 = +49.5$$

For solving the example shown in Fig. 7(b), Eq. 41 and Fig. 10 are used, thus: $\alpha = 1.74$; $x = 0$; $M_a = 149$; $D(x) = 0.306$; and—

$$\begin{aligned} -M_0 &= 0.306 \times 149 = -45.6 \\ +M_0 \text{ (from Fig. 7(a))} &= \underline{+48.9} \\ M_0 \text{ (net)} &= +\ 3.3 \end{aligned}$$

Also, $\alpha = 1.74$; $x = \lambda$; $D(x) = 0.673$; and—

$$\begin{aligned} -M(\lambda) &= 0.673 \times 149 = -100.3 \\ +M(\lambda) &= +49.5 \\ \hline M(\lambda) \text{ (net)} &= -50.8 \end{aligned}$$

For the example shown in Fig. 8, the center moment (for $\alpha = 2$; $C_1 = 0.248$; $D(x) = 0.144$; and $\lambda = 2$) is

$$\begin{aligned} +M_0 &= 0.248 \times 12 \times 2 = +5.95 \\ -M_0 &= 0.144 \times 11.6 = -1.67 \\ \hline M_0 \text{ (net)} &= +4.28 \end{aligned}$$

L. J. MENSCH,[8] M. AM. SOC. C. E.—Many able mathematicians have worked on the problem presented in this paper, and all of them have based their analyses on the assumption that Eq. 13 holds true. Any experienced engineer who seriously reflects on the requirements in such a case or makes the simplest kind of experiment with a card or wooden board must predict that this assumption plainly is not feasible except in rare instances. It did not apply in the case of a rail supported by ties as treated by the late A. N. Talbot,[9] Past-President and Hon. M., Am. Soc. C. E., although the error was probably less than 25%. Frost action will make k unsteady and reduce its value to possibly 30 to 50 lb per cu in. The mathematics are valid enough, but they do not prove the assumption.

Eq. 12 means neither more nor less than that the intensity of the forces acting on the slab per unit length equals w. It is identical with the fundamental equation of flexure in elementary textbooks:

$$E\,I\,\frac{d^2M}{d^2x} = w \qquad (43)$$

Once the computer can make a good guess at its distribution, the problem can be solved easily by simple mathematics familiar to busy structural engineers. The writer has shown elsewhere[10,11] that the distribution of w can be assumed as shown in Fig. 11(*a*) and that the deflection of the slabs will be approximately as in Figs. 11(*b*) and 11(*c*), and will rarely be as shown in Fig. 11(*d*). In most cases the slab will rise from contact with the soil in the central part, which makes Eq. 13 invalid.

The design of a water channel or large tank is by no means as simple as would appear from the paper, and serious mishaps with such structures have been encountered by engineers of standing in the profession. The engineer, experienced in this type of structures, will attack the problem in the author's "Illustrative Examples," as follows:

[10] "Joints for Concrete Pavements," by L. J. Mensch, Chicago, Ill., 1935.

[11] *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 1148.

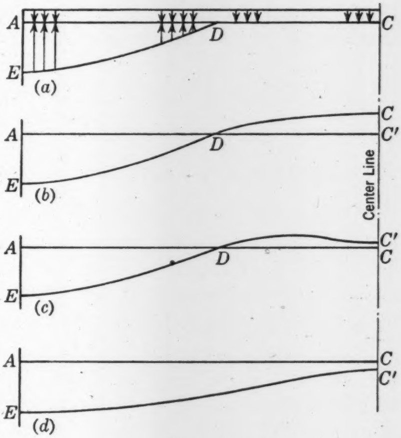

Fig. 11

1. He will ask himself what a heavy rainstorm of 2-in. to 6-in. precipitation in as many hours will do to the structure which is being constructed. Will the banks cave in at one or both sides of the channel at various places and trap the water so that an uplift is produced which may shove the structure sideways a few feet or lift it up entirely and break it? This phase of the project alone will involve quite some study and expense.

2. Suppose that the engineer is in a position to guard his structure against a highwater level not exceeding 15 ft above the subgrade. Then the base slab will have to be strong enough to withstand the moment of 148 ft-kips mentioned by the author, as the water pressure will just balance the weight of the structure.

3. Let it be now assumed that conditions are favorable and no hydraulic uplift has to be taken in consideration and that the engineer, induced by the paper, will proceed to investigate the stresses in the base slab due to the wall load alone. He or his assistants will not have the time or patience to check the mathematics of the paper, especially in the absence of any bibliography on this subject, and instead likely will make a simple test by laying a thin ruler about 1 ft long with the flat side on the pages of an open book and by pressing the ends down with a force of about 20 lb. They will notice a pronounced depression near the ends and a slight tendency of lifting up at the middle. Considering that it is good practice to cantilever the base slab beyond the wall from 6 in. to several feet, they may assume as a first approximation that the base slab deflects as shown in Fig. 12.

They may assume the line ED as a common parabola; line AE equals z_a in the author's nomenclature and, following the author's idea, they will assume the soil pressure, w, proportionate to the ordinates of the parabola on the length AD. The length of the half slab AC will be loaded by the uniform dead load of 375 lb per sq ft, the weight of the wall is 12,400 lb per lin ft; and therefore one can write, for the vertical loads—$12{,}400 + 26 \times 375 = \frac{2}{3} w_a \times 16$, from which $w_a = \dfrac{22{,}150}{10.67} = 2{,}070$ lb per sq ft or 14.4 lb per sq in.

The moments acting in the slab can be found by simple statics: $M_C = 22{,}150 \times (26 \text{ ft} - \frac{3}{8} \times 16 \text{ ft}) - 12{,}400 \times 22 \text{ ft} - 375 \times \dfrac{26^2}{2} = 43{,}000$ ft-lb (tension at bottom). The maximum negative moment will be found at the section where the shear is zero; it is considerably smaller than the positive moment. The point C′ closely approaches the point C.

No radical change will be found when the line of deflection is assumed to intersect the line AC nearer or farther from C than the 10 ft shown in Fig. 12.

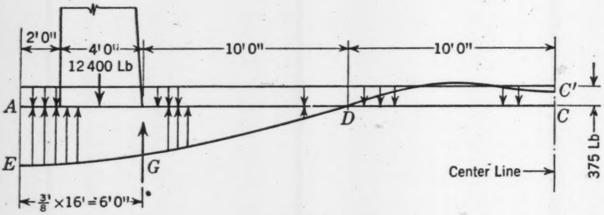

FIG. 12

4. The experienced engineer is accustomed to design the base of a water channel or tank for actual service conditions; namely, for the wall backfilled, and for the structure filled with water (in this example assumed to be to a height of 25 ft). When hydraulic uplift is not encountered, it is not economical in a structure of considerable width (sometimes several hundred feet wide) to make the base slab of uniform thickness, and, in order to avoid the use of piles in ground of medium carrying capacity, the experienced engineer most likely will assume the base slab to cantilever 4 ft beyond the wall and will make it 30 in. thick for only about 10 ft inside the structure. He will make the remaining slab only about 6 in., or perhaps 8 in., thick, and will connect it with the thicker part by a well-designed metal water stop, as shown in Fig. 13. The engineer is now confronted with a number of decisions before he can proportion the foundation slab of this structure. What assumption shall be made for the earth pressure acting on the wall? Shall he assume the customary value of 15 H^2 for the pressure per linear foot of wall, and the moment about the base as 5 H^3, or is the moment of 4 H^3 a better guess?

Some engineers, who have seen shrinkage cracks develop in backfills near the wall after heavy rains, claim that the earth pressure should not be counted upon to relieve the pressure on the wall from the water on the inside. Others go as far as to say that colloidal tension may exert a pull on the wall that will increase the effect of the water pressure. Others have observed considerable deflections in concrete walls, not tied on the top, and claim that passive earth pressure should be taken into account. When the backfill consists of good material, such as sand, gravel, stone, and slag, and is thoroughly rolled or tamped, it requires a movement of about $\frac{H}{200}$ at the top to develop a passive pressure about four times the active pressure, whereas when the fill simply is dumped from cars or grab buckets, it will take a movement of $\frac{H}{50}$ to $\frac{H}{100}$ to develop the aforementioned passive pressure. The movements given take into account time loading. Suppose the decision has been made that the combined water and earth pressure on the wall exerts a moment of 80,000 ft-lb at the base of the wall for each linear foot.

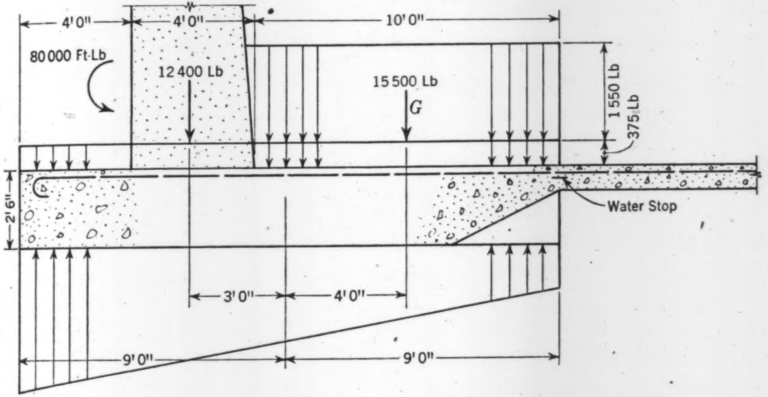

FIG. 13

The sum of all vertical loads on the foundation will be $12{,}400 + 375 \times 18 + 1{,}550 \times 10 = 34{,}650$ lb and the ideal distributed soil pressure $\frac{34{,}650}{18} = 1{,}925$ lb per sq ft. This pressure will be modified by the moment acting at the base of the foundation slab: $80{,}000 + 12{,}400 \times 3 - 15{,}500 \times 4 = 55{,}200$ ft-lb which produces an ideal plus-and-minus stress of $\frac{55{,}200}{\frac{1}{6} \times 18^2} = 1{,}022$ lb per sq ft, or the soil pressure at A $= 2{,}947$ lb per sq ft and that at D $= 903$ lb per sq ft. The differential pressure of 2,000 lb per sq ft will tilt the base about 0.14 in. for a soil modulus of 100 which will result in a horizontal movement of the top of the wall of about $\frac{1}{4}$ in. The elastic deformation of the wall will increase this movement to about $\frac{1}{2}$ in., or $\frac{H}{720}$, which will bring into action part of the passive pressure of the backfill.

5. When the structure is built on wet clay it is possible that the outward pressure of the water (diminished by the earth pressure) will cause a sliding of the foundations, as shown in Fig. 13. This outward pressure has been assumed at about 10,000 lb per lin ft, whereas the weight on the foundation slab is 34,650 lb; and the coefficient of friction required $\frac{10{,}000}{34{,}650} = 0.3$. Conservative engineers do not allow more than 0.2 as the coefficient of friction on wet clay. It will be necessary to run reinforcing steel from the 30-in. slab into the thin slab across the contraction joint, a practice that many engineers condemn but that

has been used on some of the largest and most successful reservoirs built in the United States.

Alfred L. Parmé,[12] **Jun. Am. Soc. C. E.**—Commendation is due Mr. Benscoter on the masterly style in which he has presented the problem of a slab on an elastic foundation. The information and ideas contained in the paper should lead to a more economical design of concrete channels and conduits and should serve to stimulate a more rational approach to the problem of designing reinforced concrete walls.

A further problem arising in the design of wide U-channels is that of determining how far the influence of the corner moments extends. For this purpose, the writer has utilized the work done by the Portland Cement Association on the design of circular tanks to develop a simple and easily applied formula. A comparison of the differential equations for circular walls and for beams on an elastic foundation reveals that both follow the same law. For an unloaded beam (see Table 1):

TABLE 1.—Analysis to Determine Influence of Corner Moments

Moment = coefficient $\times \left\{\begin{array}{l}\text{edge moment}\\ \text{edge shear} \times l\end{array}\right.$										
	0.9 *l*	0.89 *l*	0.7 *l*	0.6 *l*	0.5 *l*	0.4 *l*	0.3 *l*	0.2 *l*	0.1 *l*	0.0 *l*
Edge moment...	−0.001	−0.043	−0.112	−0.189	−0.311	−0.464	−0.638	−0.798	−0.944	−1
Edge shear	+0.0	+0.017	+0.034	+0.060	+0.083	+0.106	+0.117	+0.109	+0.077	+0

$$\frac{d^4 z}{dx^4} + \frac{4\,z}{\lambda^4} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

in which $\lambda = \sqrt[4]{\frac{4\,E\,I}{k}}$. On the other hand, for a circular tank, the equation

$$\frac{d^4 z}{dx^4} + 4\,\beta^4\,z = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

expresses the behavior of an unloaded tank. In Eq. 45, $\beta = \sqrt[4]{\frac{3}{r^2\,t^2}}$. For $\frac{H^2}{D\,t} > 2$ the upper boundary is slightly affected by operations at the lower boundary.[13] If the relationship between the parameters is then established, a convenient way of determining the effective length of the slab will be available. Therefore, setting $\frac{l}{\lambda}$ equal to $\beta\,H$ and making the proper substitution:

$$\frac{l}{t}\sqrt[4]{\frac{3\,k\,t}{E}} = H\sqrt{\frac{3}{r^2\,t^2}} \ldots\ldots\ldots\ldots\ldots\ldots (46a)$$

---

[12] Bronxville, N. Y.

[13] "Circular Concrete Tanks Without Prestressing," *Concrete Information Sheet No. ST 57*, Portland Cement Assn.

and therefore

$$\left(\frac{l}{t}\right)^2 \sqrt{\frac{k\,t}{E}} = 2\left(\frac{H^2}{D\,t}\right) \qquad (46b)$$

With $\frac{H^2}{D\,t}$ equal to 2, it follows that $\left(\frac{l}{t}\right)^2 \sqrt{\frac{k\,t}{E}} = 4$; or,

$$l = t\sqrt[4]{\frac{E}{k\,t}} \qquad (47)$$

To illustrate the applicability of the formula, a specific example will be computed. Assume $k = 100$ lb per cu in.; $t = 1$ ft; and $E = 3{,}000{,}000$ lb per sq in. Substituting these numerical values in Eq. 47, $l = 4 \times 1\sqrt[4]{\frac{3{,}000{,}000}{100 \times 12}}$ = 28.3 ft. The value of t inside the radical must be in inches to conform with the dimensions of the other terms. The variation of the moment along the base due to an edge moment or shear is presented as an aid to detail analysis.

At this point a word of caution against the indiscriminate use of the method should be voiced. The designer should check the pressures exerted on the slab. The existence of negative pressures greater than the weight of the slab creates a condition that cannot be met in the field. Hence, it would have been desirable if the author had included the displacements due to the applied shear and moment. The inclusion of these values would immediately disclose whether the assumed conditions could be realized. In the case where the width of the channel exceeds the effective length as computed by Eq. 47, a shear greater than $\frac{2.57\,M}{l}$ will provide positive pressures throughout the slab.

A. A. EREMIN,[14] ASSOC. M. AM. SOC. C. E.—The foundation pressures under an elastic footing vary according to the elastic properties of the soil and the footing. Interesting cases of pressure distributions under footings were illustrated by D. P. Krynine[15] in 1937. Mr. Benscoter has considered the case of a footing with decreased foundation pressures at the midspan. He has determined the stresses in the footing in terms of a constant α which varies with the elastic properties of footing and foundation material. However, the range over which the constant α varies is too wide for exact computation.

The writer has found that the approximate method of computing stresses for the assumed distribution of foundation pressures is often sufficient for practical purposes. The foundation pressures under the elastic footing may be assumed to vary according to the sine curve in Fig. 14. The average foundation pressure in Fig. 14 is w_o and the reduction of foundation pressure at the midspan is w_1. Assume that the footing slab in Fig. 14 is supported by hinged supports at the ends; then the bending moment at midspan will be

FIG. 15.—DISTRIBUTION OF MOMENTS IN RECTANGULAR CONDUIT

The example shown in Fig. 8 may be solved by applying Eqs. 48 as shown in

Figs. 14 and 15. The average foundation pressure in the footing slab (Fig. 14) is w_o = 3 kips per ft. Assume that the foundation pressures vary according to the sine curve, with a reduction of pressure at the midspan to w_1 = 2.1 kips per ft, or about 70% of the average pressure. The assumption that foundation pressures are reduced at the midspan may be verified easily by tests. The bending moments at the fixed ends of the footing slab (Fig. 14) computed by Eq. 48*b* are M' = 12.65 kip-ft. The bending moments in all members of the rigid frame were determined by the graphical method[16] as shown in Fig. 15. The difference between the resulting bending moments and those shown by the author is negligible.

Often the foundation pressures at midspan of the footing slab are increased, as shown by Professor Krynine.[15] In this case also the foundation pressures may be assumed to vary according to the sine curve, with the maximum pressure at the midspan, as shown by the dotted line in Fig. 15. Bending moments in the footing, in this case, may also be determined by Eqs. 48, except that the sign before the second term in the parentheses will be changed from minus to plus.

The author's approach to the problem under discussion appears to be more complex than is necessary. In order to find a solution, the author makes use of slope deflections, moment distribution, and elastic theory based on the differential equation of the elastic curve of the deflected slab. Actually, the problem can be solved by the elastic theory alone with considerably less mathematical work than is involved in the author's solution.

The load condition represented by Fig. 7(*a*) was solved years ago. It is a problem involving a beam resting on a yielding foundation and loaded with two concentrated loads symmetrically placed with respect to the center line. This is just a special case of the problem of the railroad tie which was the principal subject of the early investigations of E. Winkler (Reference 1), J. W. Schwedler (Reference 2) and others. The only difference between Fig. 7(*a*) and the railroad tie is the fact that the concentrated loads on the tie are some distance in from the ends of the tie, whereas the loads in Fig. 7(*a*) are at the ends of the beam. However, the problem with the loads at the ends of the beam has been solved and the complete solution was given by K. Hayashi (Reference 7).

Fig. 7(*b*) refers to the more complicated condition when the backfill is in place and there are various forces and moments acting on the base slab. In order to solve this problem as represented by the force diagram of Fig. 2, the author has introduced slope-deflection equations, beam functions, fixed-end functions, and end-rotation functions. None of these is needed for the solution of this problem, as it is possible to solve the entire problem at one stroke by means of the differential equation of the elastic curve of the beam.

The general solution of Eq. 13 is Eq. 17 which contains four arbitrary constants of integration. The author has chosen to set two of these constants equal to zero for reasons of symmetry and he has then determined the other two constants by the boundary conditions in Eqs. 19. It is this procedure that necessitates the introduction of all those other functions into the analysis. Actually, it is possible to solve the entire problem by means of Eq. 17. To do this, it is only necessary to find the four boundary conditions that will determine the four constants A, B, C, and D. For this purpose the following four boundary conditions are available:

(1) By symmetry, the elastic curve of the deflected slab has a horizontal tangent at the center line. Therefore:

$$\left[\frac{dz}{dx}\right]_{x=0} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(49a)}$$

(2) The bending moment at the right-hand end of the slab is $-M_a$. Therefore:

$$\left[\frac{d^2z}{dx^2}\right]_{x=a} = -\frac{M_a}{E\,I} \ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(49b)}$$

(3) The shear at the right-hand end of the slab is $-F$. Therefore:

$$\left[\frac{d^3z}{dx^3}\right]_{x=a} = -\frac{F}{E\,I} \ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(49c)}$$

(4) The summation of vertical forces must be zero. Therefore:

$$-F = \int_0^{0.5L} w\,dx = -k\int^{0.5L} z\,dx \ldots\ldots\ldots\ldots \text{(49d)}$$

When the four integration constants of Eq. 17 have been determined by means of these four boundary conditions, the resulting equation will be a complete solution of the problem. This equation will contain all of the external forces shown in Fig. 2, and it will contain the elastic coefficients of the soil and the slab. The amount of mathematics required to present the solution would be about the same as that involved in the author's Eqs. 12 to 22, inclusive. The slope-deflection equations, beam functions, fixed-end functions, and end-rotation functions are all unnecessary. The problem of superimposing that external bending moment on the general solution of Eq. 13 is quite simple. Hayashi (Reference 7) devotes only a short paragraph to the subject and merely remarks that the external bending moment can be included in the solution without difficulty.

The author has not offered any explanation as to why he solved this problem on the basis of the incomplete force diagram shown in Fig. 2. A structure of the type under discussion, with the channel empty and with the backfill in place outside the walls, is shown in Fig. 16(*a*). The horizontal thrust, *P*, is combined with the vertical force, *F*, into a resultant, *R*. At the middle plane of the slab, the resultant, *R*, is resolved into a vertical force, *F*′, and a horizontal force, *P*′. These forces are equal, respectively, to *F* and *P*. Since any force may be replaced by a force and a couple, the force *F*′ may be replaced by *F* and M_a. The author has done this in the force diagram of Fig. 2, but the question arises as to what disposition has been made of the horizontal force, *P*′.

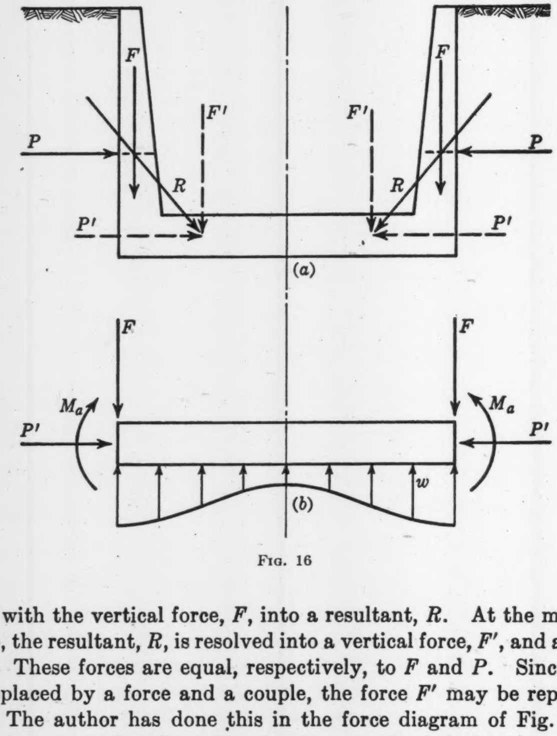

FIG. 16

This horizontal thrust, *P*′, is the force that can cause a retaining wall or a dam to fail by sliding even though the structure may be safe against overturning due to the eccentric force, *F*′. In the design of the side-wall itself, this force,

P', is taken into account because it produces a shearing stress on the horizontal plane where the base of the wall rests on the slab. The design of the bottom of the wall includes an investigation of three kinds of stresses: (*a*) The direct compression produced by F, (*b*) the flexural stresses produced by M_a, and (*c*) the shear produced by P'. Accordingly, when the structure as a whole is being considered, the diagram of external forces should include two equal and opposite horizontal thrusts, P', applied to the edges of the slab as shown in Fig. 16(*b*).

The probable importance of the forces, P', would depend on the dimensions of the structure. In a shallow structure with a thick base slab, the effect of P' would be negligible in comparison with the effects of F and M_a. In a deep structure with a thin base slab, the force, P', might materially increase the bending moments in the slab. In all cases, these forces will exist in any actual structure of this type and they should not be discarded unless it can be demonstrated that their effect is negligible. Furthermore, it should be kept in mind that the slab is bent by transverse loads and bending moments so that these horizontal thrusts are applied to the edges of an already deflected slab.

Eq. 13 is not satisfactory for this problem because it does not include the effect of the horizontal forces, P'. In order to include these forces, it is necessary to start with the differential equation:

$$\frac{d^4z}{dx^4} + \frac{P'}{E\,I}\frac{d^2z}{dx^2} + \frac{k}{E\,I}z = 0 \qquad (50)$$

This is a linear differential equation of the fourth order with constant coefficients. Methods of solving the equation are well known (24) and the general solution may be written in the form

$$z = \sum_{n=1}^{n=4} A_n\, e^{xp_n} \qquad (51)$$

in which A_n represents the four arbitrary constants of integration, p_n represents the four roots in the characteristic equation, and e is the Napierian log base. The four values of p_n are obtained from the equation

$$p^4 + \frac{P'}{E\,I}p^2 + \frac{k}{E\,I} = 0 \qquad (52)$$

After these values of p_n are substituted into Eq. 51, the four values of A_n are determined by means of the boundary conditions given in Eqs. 49. The solution of Eq. 50 is somewhat more laborious than that of Eq. 13, but the use of Eq. 50 with the proper boundary conditions will yield a complete solution without the aid of slope deflections or moment distribution or any other form of structural analysis.

When a mathematical analysis of this kind is applied to an engineering problem it is desirable to keep in mind the fact that the mathematics is only a part of the solution of the problem. All problems of this type involve important practical considerations which are easily overlooked in the maze of mathematics with which the problem is surrounded. Any one contemplating the use of some of these equations as design formulas should understand that this entire analysis is based on certain definite assumptions which may or may not be fulfilled in the actual structure. For example, in connection with Eq. 1, the author has defined the foundation modulus, k, as the constant of proportionality between the upward reaction, w, and the downward displacement, z. Nowhere in the paper is there any mention of the fact that k is supposed to work both ways. In other words, if the bending stresses in the slab tend to lift the slab from the ground, the mathematics require a tensile stress to be generated between the soil and the underside of the slab. This tensile stress is a downward reaction which is proportional to the upward displacement of the slab and the constant of proportionality is the same k that is in Eq. 1.

This idea can be expressed mathematically by the following statement: There is no restriction on the sign of z in Eq. 17. Positive values of z refer to downward displacements, and negative values of z refer to upward displacements. The stress between the soil and the slab may be either tension or compression in direct proportion to the displacement and the constant of proportionality is the foundation modulus, k, in either case. The mathematical analysis therefore requires that k must be able to act in tension or compression.

In contrast with this mathematical requirement, practical considerations lead to the conclusion that the soil cannot exert tension on the underside of the slab in the prescribed manner. If the slab were supported by a pile foundation, the piles would provide anchorage against uplift as well as resistance to downward displacement. However, even under such conditions the elastic behavior of piles subjected to uplift forces would not necessarily be the same as their elastic behavior under downward forces. The analysis of a slab supported by piles which could also act as anchors would require two different values of k. When the slab simply rests on earth or rock, there is no restraint to hold it down if the external forces try to bend it up off the ground.

The author has remarked (see heading, "Design Formulas") that "a practicing engineer instinctively prefers to deal entirely with bending moment values in a structure analysis." In the problem under discussion, it is not safe to trust entirely to instinct and to stop the investigation after the bending moments are determined. The displacements must be investigated also because the entire mathematical analysis is useless if there is any part of the slab for which the value of z is negative. This is a matter of considerable practical importance and it has been discussed thoroughly by other writers, particularly by Hayashi (Reference 7). The author's analysis does not include the final equation for the elastic curve of the deflected slab. However, this equation should be derived and used in the investigation of the structure.

Another practical aspect of this problem is the numerical value of k. The author has suggested load tests to determine the value of k but he recommends a value of 100 lb per cu in. for design purposes in cases where load test results are not available. The writer finds it difficult to accept such a recommendation for several reasons. In the first place, it is quite a problem to get a suitable value for k even when careful load tests are made. The literature in the foregoing list contains numerous demonstrations of this fact. A series of load tests with different sizes of bearing areas on the same soil would give a different value of *k* for each bearing area. The choice of *k* for the full size structure would therefore be a matter of judgment at best. In the second place, the numerical values of *k* that are obtained from load tests on different types of soil will vary over a considerable range. There appears to be no justification for the assumption that 100 lb per cu in. would be a suitable value for all soils merely because no load tests were made. Furthermore, an arbitrary assumption of this kind is hardly compatible with the powerful mathematical analysis the author has applied to the problem.

In conclusion, it seems desirable to make the following observations: Problems of this kind have engaged the attention of engineers for many years and complete mathematical solutions are already available for many of them. In general, these mathematical solutions are much more concise and elegant than the cumbersome procedure used by the author. The real need in connection with these problems is a better understanding of the physical significance of the equations and a considerable number of field measurements on actual structures to find out how accurately the mathematics can predict the behavior of the structure. As the matter stands now, the abstract mathematics has run far ahead of the practical side of the problem.

HARRIS EPSTEIN,[18] ESQ., AND JAMES R. AYERS, JR.,[19] ASSOC. M. AM. SOC. C. E.—The assumption of the proportionality between distributed soil reactions and the deflection of the distributing medium has been used by the writers since 1920.

A particular application of this assumption was made recently, at the suggestion of Ben Moreell, Hon. M. Am. Soc. C. E., to the design of graving docks which consist of two concrete side-walls connected by a floor slab resting either directly on the underlying soil, or on bearing piles, depending on the foundation conditions at a particular site. The side-walls are usually backfilled with earth. A typical cross section appears in Fig. 17, which is quite similar to that of the water channel in Fig. 6.

The side-walls of the water channel, as well as those of a dry dock, are of such height that, in comparison with the floor thickness, they possess almost infinite stiffness in the vertical direction and cannot, therefore, have a curved elastic line. This fact leads to the logical conclusion that the parts of both the force and displacement diagrams, directly under the walls, should be straight lines tangent to the curved part of these diagrams for the floor proper at the intersection of the floor with inner faces of side-walls and extending to the outer faces, as shown in Fig. 17. This contrasts with Fig. 2 in which the curved lines of the force and displacement diagrams extend under the side-walls and terminate at their centers. The omission of the forces on the outer halves of the wall width is certain to influence the magnitude of the moments in the floor slab, the influence increasing with increase in the width of the walls. Therefore the force and displacement diagrams should extend across the entire width of the structure.

---

[18] Prin. Designing Engr., Bureau of Yards and Docks, U. S. Navy Dept., Washington, D. C.

[19] Senior Designing Engr., Bureau of Yards and Docks, U. S. Navy Dept., Washington, D. C.

Let: W_s = weight of the part of the side-wall above the top of the floor slab; and a' = distance from the inner face of the side-wall to the center of gravity of the wall. The effect of the downward distributed load of the side-wall may be incorporated in the solution of the author's fundamental differential equation by applying to the slab, at the inner face of the side-wall, a concentrated load, W_s, and a moment of magnitude $W_s\, a'$. Since the reaction diagram under the wall is a straight line, the shear and moment, as well as the slope of the elastic curve, at the inner face of the side-wall may be expressed in terms of the foundation reactions at the inner and outer faces of the wall. These three expressions, combined with the conditions of symmetry and the expression for foundation reaction at the inner face of the side-wall, are sufficient for evaluating the constants for the general solution of the fundamental differential equation as applied to structures of this shape. Then the expressions for moment, shear, and foundation reaction at any point may be written and used to compute values of these quantities directly, thus eliminating the necessity for balancing the moments by the indirect method suggested by the author.

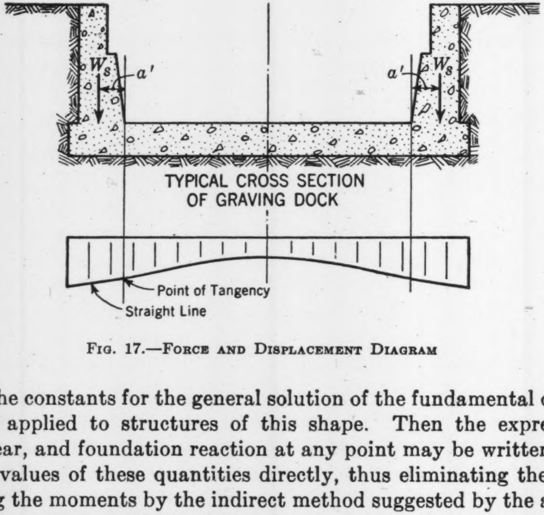

Fig. 17.—Force and Displacement Diagram

In the illustrated example of the water channel, the writers check the author's value of 48 kip-ft for the moment at the center of the slab, assuming a side-wall width of zero; whereas, if the force diagram extends across the entire wall width as a straight line, the moment at the center of the slab reduces to 40 kip-ft, the difference being about 16%.

The maximum value of the negative moment (tension in the top of floor slab) does not always occur at the center of the slab width. In many cases, for large values of α, there are two points of zero shear in the slab in addition to the one occurring at the center. The negative moment, which extends across the entire slab between side-walls, then has a minimum value at the center of the slab, and equal maximum values on either side of the center at the other two points of zero shear. This is due to the fact that the computed distributed reaction acts downward for a part of the slab adjacent to the center of the structure, thus requiring a force to prevent lifting of the slab from the foundation. The dead weight of the slab is usually more than enough to supply this force in the case of a dry dock.

STANLEY U. BENSCOTER,[20] **JUN. AM. SOC. C. E.**—The comments and information in the discussions are appreciated by the writer and will render useful service to the future reader as viewpoints gained from varied experience. The proper assumption as to reaction distribution in the design of a flexible base slab has always been a controversial issue. The writer has seen several types of broken-line diagrams which give a minimum value of base reaction at the center and a maximum value at the edge. Mr. Mensch has illustrated the use of a parabola over part of the half span; and Mr. Eremin, the use of a sine curve. None of these approximate methods of treating the problem contains any rational association with a physical measure of the foundation rigidity. Likewise, none of these approximate methods gives any suggestion as to the increased stiffness of the base slab, which is caused by the foundation and which must be used in an elastic indeterminate structural analysis.

Since the foundation modulus is a readily obtainable measure of the rigidity of the foundation, a method of analysis should be employed which gives results that are directly associated with this modulus. Thus, a rational analysis of the structure is obtained.

Various methods of analysis should be recorded so that calculated results can be compared with experimental field measurements whenever such measurements become available. A stress analyst can only express a plea that future plans for reinforced concrete structures include the installation of strain gages and pressure cells for measuring both reactions and acting earth or water pressures.

Inconsistently, Mr. Mensch objects to using the foundation modulus in a rational analysis of the slab, yet proceeds to use it in calculating the angle of rotation of the side-wall in Fig. 13. The writer wishes to recommend that structural engineers acquire the habit of calculating the angle of rotation of a retaining wall as presented by Mr. Mensch. The acting pressures are closely related to this angle. Although Mr. Mensch neglects the shear through the base slab at the section of the water stop, this shear affects the base reaction and the angle of rotation of the wall. Inclusion of this shearing force permits a reduction in the length of the heel. The writer has never found the loading condition mentioned by Mr. Mensch critical. Stresses are usually at a maximum after the backfill has been placed and before water has been allowed to enter the channel. The critical condition for stability occurs with the channel partly full and must be determined by trial and error. The writer does not extend the base slab beyond the side-wall as illustrated by Mr. Mensch in Fig. 12 when the wall and slab are constructed as a monolithic frame.

The graphs of moment factors presented by Mr. Jameson are a valuable addition to the paper. The writer is inclined to believe that the majority of designers will prefer to calculate internal moments as suggested by Mr. Jameson rather than as presented in the paper. Calculating the simple beam moments and correcting them for the effect of total end moment will resemble more closely the usual analysis of beams with fixed loading. The moment factors for a simple beam would be more instructive if they were plotted as coefficients of the moment $F\,a$ rather than as coefficients of $F\,\lambda$. Thus, the coefficients of $F\,a$ would reflect completely the effect of the foundation rigidity, and the curve for $\alpha = 0$ would be the well-known parabola for uniform loading. A complete set of design information would consist of three families of graphs for z, V, and M for a simple beam and a similar set of three graphs for the effect of a unit end moment.

---

[20] Associate Engr., Bureau of Aeronautics, Navy Bldg., Washington, D. C.

Mr. Parmé has recalled the close relationship between the floating slab theory of an elastic slab on an elastic foundation and an element of an elastic cylinder. The use of moment distribution in cylindrical tank analysis is illustrated in the reference[13] given by Mr. Parmé. The writer has used moment distribution for the analysis of cylindrical tanks and elastic base slabs for several years. In cylindrical tanks, bottom moments and shears generally produce little effect at the top of the cylinder. However, many thick-walled water tanks, built in army camps, designed to conserve steel, showed considerable effect at the top due to bottom moments. It is rather uncommon to find a base slab in which the edge moments and shears produce only a negligible effect at the center.

Mr. Eremin's analysis shows the error of neglecting the effect of foundation rigidity on the stiffness of the base slab. The sine curve gives a reasonable shape for the reaction distribution. The minimum ordinate of the diagram should be associated in some rational manner with the foundation rigidity.

The purpose of the paper is to demonstrate that an indeterminate structure resting on an elastic foundation can be analyzed by moment distribution. The mathematical development was planned and completed with this objective in view. An illustration of the analysis of an indeterminate structure was given in Fig. 8. As a matter of secondary importance, since the solution is well known (as explained by Mr. Cummings), it was shown in Fig. 7 that a determinate structure can also be analyzed by using the same graphs and formulas that are required for the indeterminate case. This inclusion of a determinate case appears to have sidetracked the attention of Mr. Cummings from the primary accomplishment of the paper. The methods of analysis which he presents as being preferable deal only with the determinate case.

Mr. Cummings opens and closes his discussion with statements that "The author's approach to the problem under discussion appears to be more complex than is necessary" and "these mathematical solutions [existing solutions] are much more concise and elegant than the cumbersome procedure used by the author." His entire discussion, which lies between these two criticisms, deals only with a determinate structure and offers the designer no suggestion as to how an indeterminate structure might be analyzed. This fact is particularly significant for the reader who may wish to evaluate the validity and applicability of the criticisms. A more concise method of analyzing the indeterminate case is not to be found in so far as the writer is aware.

Mr. Cummings explains that the complicated functions of the paper arise because the author "has chosen to set" two of the integration constants, C and D, equal to zero. Actually, the solution is unique and the writer had no personal choice in the matter. Eqs. 49, offered by Mr. Cummings in defense of his claim actually disprove it because they show immediately that C and D must be zero. To prove this statement, it is desirable to simplify Eq. 49*d*. With the assistance of Eq. 49*c*, Eq. 49*d* may be reduced to:

$$\left[\frac{d^3z}{dx^3}\right]_{x=0} = 0 \qquad (53)$$

Eq. 53 is recognizable as a condition of symmetry which should be used in place of Eq. 49*d* since it involves considerably more mathematical labor to integrate than to differentiate a sum of products of transcendental functions. Also the third derivative must be computed for use in Eq. 49*c* and thus is available for use in Eq. 49*e*. Substitution of the general formula for z, as given by Eq. 17, into Eqs. 49*a* and 53, which are equations of symmetry, or into Eqs. 49*a* and 49*d* gives,

$$C + D = 0 \qquad (54a)$$

and

$$C - D = 0 \qquad (54b)$$

Eqs. 54 show that C and D are zero. The remainder of the solution for the determinate case consists of solving Eqs. 49*b* and 49*c* simultaneously for A and B, corresponding to the procedure used by the writer for solving the indeterminate case. For that particular determinate case in which V_a and M_a are known, Eqs. 49*b* and 49*c* are correct. For the indeterminate case which should be solved by moment distribution, Eqs. 19*a* and 19*b* give a correct statement of the boundary conditions. There are six possible ways of stating the boundary problem, since there are six combinations of four things taken two at a time. In all six cases C and D must be zero because of symmetry.

The effect of thrust on bending was purposely omitted to conform to standard practice in the design of rigid frames of reinforced concrete. Since the eccentricity of the thrust is several hundred times the maximum relative deflections, the effect of thrust on bending is commonly regarded as negligible in the design of concrete frames. This matter becomes of considerable importance in thin, flexible structures such as those used in the monocoque construction of airplanes.

Mr. Cummings expresses concern over the tensile reactions which may occur at the center of the slab. He states that "the entire mathematical analysis is useless if there is any part of the slab for which the value of z is negative." The writer considers this to be a serious exaggeration of a trivial matter. Tensile reactions occur with flexible beams on rigid foundations, that is, with $\alpha > 2$. Such a case is a concrete conduit on a limestone foundation when the rock has a modulus of elasticity of several million pounds per square inch. The negative calculated reactions must exceed the weight of the slab before a theoretical error occurs. Actually, on such rigid foundations, floating slab theory can only give an approximate value for maximum moments. The error is not due to the slight tensile reactions at the center of the span but, rather, to the need for a more accurate influence relationship between deflections and reactions than that given by floating slab theory.

This paper should be regarded as an introduction to the use of floating slab theory in indeterminate structures. Extension of the concepts to more complicated cases remains for future study.

ILLINOIS WATER LITIGATION, 1940-1941

BY LANGDON PEARSE,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. WILLEM RUDOLFS, L. R. HOWSON, A. M. BUSWELL, LLOYD M. JOHNSON, H. P. RAMEY, AND LANGDON PEARSE.

SYNOPSIS

In 1940–1941, hearings followed a petition to the U. S. Supreme Court by the State of Illinois for a temporary increase in diversion from Lake Michigan. The inquiry was directed to ascertain the effect of odors from a large pool in the heart of Joliet, Ill., on health, the remedial measures available, and the condition of the sewage treatment works of The Sanitary District of Chicago. The Special Master held that no menace to health was proved and that no remedial measures were available as effective or as promptly as the proposed completion of the sewage treatment works of the Sanitary District. The U. S. Supreme Court denied the petition.

GENERAL

Considerable interest was aroused by the petition of the State of Illinois, dated January 11, 1940, for a temporary relaxation of the diversion order restricting the flow of water from Lake Michigan to relieve the condition existing in the upper Illinois Waterway, particularly at Joliet (see Fig. 1). The litigation was somewhat unique in that it involved the question: "When is pollution a menace to health" rather than the well-defined problem of the abatement of a nuisance. Curiously the attorneys on both sides admitted that no cases could be cited as legal precedent.

Prior to July 1, 1930, the War Department Permit of March 3, 1925, limited the diversion to an annual average of 8,500 cu ft per sec, with an instantaneous maximum of 11,000 cu ft per sec. This permit expired on December 31, 1929. A new permit was then issued authorizing an annual average diversion of 7,250 cu ft per sec, or such lesser annual average diversion as would restrict the average annual flow measured at Lockport, Ill., to 8,500 cu ft per sec, until July 1, 1930. The actual diversion in 1929 was 7,699 cu ft per sec, and in 1930, 6,658 cu ft per sec.

NOTE.—Published in December, 1942, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

FIG. 1.—GENERAL PLAN AND PROFILE, ILLINOIS WATERWAY

This litigation was a result of the decree of the Supreme Court of the United States issued April 21, 1930, which provided that the annual average diversion at Chicago, Ill., from Lake Michigan should be reduced in three steps:

Step	Date	Total diversion (cu ft per sec)
1	July 1, 1930	6,500
2	December 31, 1935	5,000
3	December 31, 1938	1,500

These allowances are in addition to the domestic pumpage of Chicago, which amounts to approximately 1,700 cu ft per sec. A controlling works was also to be built at the mouth of the Chicago River on or before December 31, 1935. The diversions were made on schedule and the controlling works were built.

The 1930 decree simply limits the flow of water. It does not specify the type of sewage treatment works to be built or when they shall be completed, although this was discussed by the Special Master, the Hon. Charles E. Hughes, in his report on Re-Reference.

The Court did not foresee the depression which retarded tax collections in 1931–2–3 and thereby stopped The Sanitary District of Chicago from selling bonds because of the technical default of its then outstanding issues. Consequently the timing of the completion of the sewage treatment works gradually fell out of step with the reduced diversion after 1935, with resulting difficulty in 1939, after the final reduction was made. The Sanitary District took the position that it should follow the decree to the letter. After the first two steps the sewage treatment works still provided enough cushion to show some improvement in the condition of the upper Illinois Waterway until 1938, when the third step reduced the flow so greatly that conditions were created that were worse than at any time in the preceding 30 years.

The late Chief Justice William Howard Taft had instructed the Special Master to determine the diversion required for the Port of Chicago. This was interpreted to include the Main Channel at Lockport. Thus, by the Taft instructions, conditions below Lockport were ignored in preparing the Report on Re-Reference and the 1930 decree, because, when Mr. Taft was Chief Justice, the Des Plaines River from Lockport to its junction with the Kankakee River, and thence the Illinois River to Utica, Ill., were not navigable waters of the United States. By the River and Harbor Act of July 3, 1930, the entire waterway from the Chicago River to Utica became a navigable waterway of the United States, more than two months after the decree.

The "Illinois Waterway" is the term now applied to the waterway from Lake Michigan to the Mississippi River. In July, 1930, the United States took over the upper waterway from Utica to Lockport, then under construction by the State of Illinois, and completed the work (7).[2] In the spring of 1933, the waterway was opened for through navigation. In this plan of slack-water navigation a number of pools were created by the dams at Brandon Road, Dresden Island, Marseilles, Ottawa, Peoria, and La Grange, all in Illinois. This paper is concerned principally with the happenings in the upper pool, known as the Brandon Pool (Fig. 1), which extended from Lockport to the Brandon Road dam, a distance of about 4.84 miles, through the heart of Joliet, a city of 42,365 population (1940 census). The pool varies in width from 200 ft to 1,400 ft, with a maximum depth of 27 ft. Prior to the closing of the Brandon Road dam in 1933, the flow passed through Joliet down river with considerable rapidity, and consequently with a high rate of re-aeration. To the end of 1938, however, little was heard of conditions in the pool, although sludge was accumulating in it.

---

[2] Numerals in parentheses, thus: (7), refer to corresponding items in the Bibliography, in the Appendix.

With the reduced diversion, in 1939, conditions changed rapidly for the worse. The 5-day biochemical oxygen demand (B.O.D.) at Lockport rose rapidly. The dissolved oxygen disappeared not only at Lockport (Table 1), but upstream for 30 miles into the South Branch of the Chicago River at Damen Avenue (Table 2). The conditions along the Main Channel were the worst known for more than 30 years.

Five-day B.O.D.	6.3	8.2	6.8	32.7	8.3	33.0	13.5	34.2

In the summer of 1939, the outcry from Joliet became so great that on January 11, 1940, the State of Illinois applied for a modification of the 1930 decree to permit a temporary increase of the diversion to 5,000 cu ft per sec in addition to domestic pumpage, until December 31, 1942. After a hearing on this application, the Court, on April 30, 1940, ordered that the petition of the State of Illinois and the return of the Complainant States be referred to Monte M. Lemann as a Special Master

> "* * * with directions and authority to make summary inquiry and to report to this Court with all convenient speed with respect to the actual condition of the Illinois Waterway by reason of the introduction of untreated sewage, and whether, and to what extent, if any, that condition constitutes an actual menace to the health of the inhabitants of the Complaining Communities, and also with respect to the feasibility of remedial or ameliorating measures available to the State of Illinois without an increase in the diversion of water from Lake Michigan."

(In this paper the petitioner, the State of Illinois, is referred to as "Illinois"; the Complainant States, Michigan, Minnesota, New York, Ohio, Pennsylvania, and Wisconsin, are referred to as "Opposing States"; and the Special Master, Mr. Lemann, is referred to as the "Master."

The hearings were held in Chicago over a period of months. The case was argued in New Orleans, La., in February, 1941, before the Master, who rendered a report to the Court on March 31, 1941. On May 26, 1941, the Court denied the petition.

The original petition (January, 1940) requested a temporary increase in diversion to 5,000 cu ft per sec until December 31, 1942. After the completion of the hearings the petition was modified. In its revised petition, Illinois requested a temporary increased diversion during the warmer months of 1941 and 1942 sufficient to maintain a minimum of 1 ppm of dissolved oxygen in the Brandon Pool. The expected need for increased diversion was set up as follows:

Month	1941	1942
April	1,000	....
May	3,000	2,000
June	5,000	4,000
July	6,000	5,000
August	5,000	3,000
September	3,000	1,000
October	1,000	....
Annual average increase	2,000	1,250

The annual average increase in diversion thus requested was 2,000 cu ft per sec in 1941 and 1,250 cu ft per sec in 1942. The earlier records in the case and the findings of Special Master Hughes indicate that the lowering effect of such temporary diversions would not be more than ½ in. in 1941 and ⅓ in. in 1942 in Lake Michigan, Lake Huron, and Lake Erie.

Minimum Dissolved Oxygen

F. W. Mohlman and the writer testified that in the absence of sludge deposits at least 1 ppm of dissolved oxygen is necessary to prevent nuisance. Referring to New York vs. New Jersey, 256 U. S. 296, 311, decided in 1921, the Master expressed his belief that the weight of opinion is that the presence of any dissolved oxygen is sufficient. In that case, however, the Court held that

25% to 50% of saturation is the dissolved oxygen necessary to prevent offensive odors from decomposition of organic matter deposited in the body of water under consideration. As Lake Michigan contains about 8 ppm dissolved oxygen in the summer months, this yardstick would require 2 to 4 ppm of dissolved oxygen in the warmer months in Brandon Pool.

The evidence shows that the most important factor responsible for the foul conditions of the Main Channel and Brandon Pool is undoubtedly the deposits of putrefactive sludge that formed since the diversion was reduced on January 1, 1939. In Brandon Pool, this deposit has accumulated since 1933, from residual solids in the effluents of the various works of the Sanitary District, from raw solids, the discharge of sludge at Stickney (the site of the West and Southwest works of the Sanitary District), and from the storm-water solids.

The accretions of prior years and the preceding winter, which lay dormant through cold weather, exerted a potent effect with the onset of warmer weather and a water temperature of 62° F or higher.

The engineering witnesses on both sides of the case agreed that such sludge deposits are potent in their avid demand for oxygen, and are the most important factor in the production of the foul condition in the Main Channel and Brandon Pool. All agreed that the discharge of settling suspended matter, whether in sewage partly treated or as sludge, should be stopped as soon as possible. This is what the Sanitary District program contemplates doing. Thus the Opposing States and Illinois were agreed that the solids must be kept out of the channels of the Sanitary District and that the sewage must be treated to as high a degree as practicable, as quickly as possible.

The conditions in the Main Channel and Brandon Pool during 1939 and 1940 continued through 1941 and 1942 and will continue thereafter although on a gradually diminishing scale, until the sewage treatment works of the Sanitary District are completed.

The sludge deposits require a long time to lose their putrefactive character or potency. Mr. Mohlman testified that a test of the oxygen demand of sewage sludge overlaid by Illinois River water showed consumption of oxygen for more than 1,100 days. For the first 400 days, this was confirmed by W. Rudolfs, M. Am. Soc. C. E. (1). The results show that during the first summer, for a period of 120 days, the loss of oxygen demand may range from 50% to 55%. During the winter the sludge lies dormant. The following spring possibly 20% to 25% more of the B.O.D. is destroyed. Reference was made to studies of Karl Imhoff, M. Am. Soc. C. E. (2), and the report of the Committee on Sewage Disposal of the Engineering Board of Review (3) which found that the sludge deposits in the Upper Illinois River practically doubled the effect of pollution during the summer.

The condition of the waterway, from Damen Avenue in Chicago to Brandon Road Dam below Joliet, was bad in 1939 and somewhat better in 1940, because of the increased treatment due to the starting of the Southwest works in the summer of 1939. By April, 1940, all the sewage in the Sanitary District was picked up for treatment in its plants except for about 70 mgd and by October, 1940, for about 35 mgd.

From testimony of laymen and experts, there is no question but that hydrogen sulfide was set free. There was controversy over the concentration in the atmosphere, the possible zone of effect, and the presence of other ingredients such as mercaptan, indol, skatole, and cadaverin. One expert witness, C. W. Muehlberger, indicated that persons might become accustomed to hydrogen sulfide but not to fecal odors.

The Health Problem

The proceedings before the Master were clearly divided into three parts, considering—

1. Complaints and the health conditions along the Waterway;
2. Status of sewage treatment by the Sanitary District and the outlook for the summers of 1941 and 1942; and
3. Available remedial or ameliorating measures.

Illinois contended that the present condition of the Illinois Waterway in the Joliet-Lockport area constitutes not only an actual menace to health but also a definite injury to health. Thus, whether or not the Waterway caused the effects alleged to the health of the inhabitants is the initial question in determining whether the conditions, as disclosed by the proof, constitute an actual menace within the meaning of the Court. The evidence shows a two-fold health problem:

(*a*) The actual detriment to health caused by the inhalation of gaseous odors emanating from the Waterway; and
(*b*) The potential hazard, danger, or menace to health occasioned by the present highly polluted and foul condition of the Waterway.

The Opposing States contended

> "* * * that the phrase 'actual menace to health' as used in the order of the United States Supreme Court means that the effects on the health of the people residing near the Waterway must be real and exist in fact, as opposed to any potential, speculative, hypothetical views on what might happen, unsupported by any real cases or actual happenings."

Thus the Opposing States maintained that the evidence falls far short of establishing a menace to health and at most shows only annoyance, discomfort, and inconvenience suffered by some people.

Complaints of Lay Witnesses at Joliet.—The complaints as to the Waterway emanated entirely from residents of Joliet and Lockport, and chiefly from those in Joliet residing alongside the pool and near it. The population of Joliet was reported to be 42,365 in 1940. The Health Commissioner of Joliet estimated 50,000 people were affected, living in and around Joliet. Through Joliet, the Waterway is crossed by eight bridges.

No water from the Waterway is used for drinking purposes. There is no swimming in it. All complaints were based on the offensive odors from the pool, and the effects ascribed to them.

A total of 127 witnesses testified at Joliet, made up as follows:

Lay residents of Joliet	81
Physicians residing in Joliet	15
Nurses and employees of St. Joseph's Hospital	24
Lay residents of Lockport	7
Total	127

It was stipulated that if 200 additional witnesses were called, their testimony would be substantially the same. Three fourths of the witnesses resided within four blocks of the canal, and more than half within two blocks.

The complaints generally were that the pool in the hot summer months of 1939 gave off extremely offensive odors, which in many cases caused nausea, lack of appetite, or inability to sleep. The character of the odors was described variously as the odor of sewers or outhouses or of rotten eggs. Some called it a "stink," others a "terrible" or "unbearable" odor.

All the witnesses agreed that the pool had always given off objectionable odors, but in 1939 the odors were much more offensive than theretofore. The weight of the evidence was that in 1940 the conditions were somewhat better.

The nurses at the hospital (one and one-half to two blocks from the pool) complained of the odors. Many of the patients suffered nervousness, nausea, vomiting, sleeplessness, and headache. Some of the patients were anxious to go home early. However, the average period of stay during 1939 was about one day less than the average for general hospitals in the United States.

The superintendent of grade schools at Lockport (eight blocks from the Waterway) and the principal of an elementary school at Joliet (600 ft from the Waterway) testified as to the type of odor and its nauseating effect on the children in 1939, and to a lesser extent in 1940.

The percentage of sick leaves of the employees in the U. S. Engineer office from Lockport to Starved Rock was somewhat higher in 1939 than in 1938. However, it was but little less than in the Chicago area. In 1940, the percentage in the Joliet area was less than in 1939.

The Health Commissioner of Joliet received hundreds of complaints in June, July, and August, 1939. He stated that there was danger of an epidemic from flies and mosquitoes alighting on the scum; that the stench was nerve wracking; and that the odorous gases irritated the mucous membrane of the nose, throat, and sinus. However, the health conditions in Joliet were good. The only difference in 1939 was the odor.

The other fourteen Joliet physicians considered the pool a menace to health for similar reasons. One was a government surgeon who noted skin diseases attributable to the foul water. Another noted an increase in impetigo along the Waterway from year to year.

The Master concluded that no cases of specific illness clearly attributable to the pool were cited by the physicians.

The statistics on reportable diseases in Illinois show that the case rate per 100,000 inhabitants in 1939 was less in Will County (in which Joliet lies) than the average for the state except for poliomyelitis, malaria, and influenza. In

1939, the death rate was lower in Will County for all reportable diseases than the average for the state. The typhoid rate in Will County in 1939 was 0.9 per 100,000 as compared with an average of 1.8 for the years 1930 to 1938, and a rate of 1.4 for the state. The statistics for the cases and deaths from typhoid show lower rates for counties adjoining the Waterway than for those that do not.

Testimony by Opposing States on Health Conditions.—Casual tests on August 3, 1940, disclosed no trace of hydrogen sulfide in the air over the pool. The bacterial tests on July 16, 1940, disclose only the usual bacteria found in air. Various experts testified that there was no possibility of an epidemic in the adjoining community due to the transmission of germs or bacteria by air from the Waterway. On September 17, 1940, the number of bacteria found over the pool was about one tenth that of other stations. On September 28, 1940, samples of water from the pool showed hydrogen sulfide from 0.1 to 0.2 ppm with an air temperature ranging from 34° to 74° F.

W. H. McNally, M. D., a toxicologist, testified that hydrogen sulfide in the air, concentrated as low as 50 ppm, may produce nausea. A concentration of 100 ppm may cause local irritations and depression of the nervous system. He doubted if such a concentration could occur in the atmosphere over the pool. A concentration of 25 ppm might discolor paint. He quoted Alice Hamilton and Philip Drinker as stating that not more than 20 ppm should be tolerated in industry. The sensitivity of individuals varies. He knew of no recorded instance of damage to health from hydrogen sulfide in a waterway like the Illinois Waterway.

All the physicians, health authorities, and sanitary experts (nine in all) who appeared as witnesses for the Opponents agreed that the Waterway did not constitute a menace to the health of persons living along it.

Testimony for Illinois on Health Conditions.—Mr. Muehlberger, an expert toxicologist, testified that the complaints of nausea, headaches, insomnia, and loss of appetite "may have been caused by hydrogen sulfide." He could not refer to any record in medical literature where an individual was overcome in the open air from a polluted waterway. Upon exposure to more than 20 ppm but less than 50 ppm, the average person would complain of irritation of the mucous surfaces of the eyes, nose, and throat. As stated, decomposing sewage produces organic sulfide compounds, including indol, skatole, mercaptan, and cadavrin, all having offensive odors. Mr. Muehlberger considered the conditions of the Waterway a very definite menace to the health of the inhabitants in the region of Joliet. People may not have died or required hospitalization, but they may have been uncomfortable and unhappy. They are entitled to a decent living condition with good, healthy air. Any contamination of the air is a menace, if a sound state of health is upset. Mr. Muehlberger testified that the odor of the pool in 1939 irritated his throat and nasal passages. However, he had noticed odors in prior years.

A. J. Carlson, M.D., a physiologist, testified that on October 13, 1940, "the present condition is more than a menace to health, it is inimical to health." His conception of a menace to health was typified by conditions which, through accidents or any ordinary course of human events, can lead to injury to health. He regarded such a polluted pool as a menace even if the water is not used for drinking or cooking or bathing. In his opinion, the fact that the communicable disease rate in Joliet is no higher than in other places is no factor whatever in determining whether the pool is a menace to health. Either the inhabitants of Joliet are lucky or the medical statistics are not what they are supposed to be.

Dr. Carlson stated that the Waterway has been a menace since 1934, but that now the menace has been increased. He used the words "menace to health" in a scientific sense as a theoretical danger which cannot be measured in any statistics or in any outward observation by a physician. The restoration of the diversion to 5,000 cu ft per sec was a lessened menace. A. C. Ivy, M. D., a physiologist, corroborated Dr. Carlson, holding that the disturbances reported due to the odor showed an unhygienic condition working as a detriment to the health of the people so affected. He knew of no recorded case of an individual being overcome by hydrogen sulfide from a waterway. H. A. McGuigan, M. D., a pharmacologist, agreed with Drs. Carlson and Ivy, pointing out that hydrogen sulfide was not the only odor in the air from the Waterway.

General Authorities on Sewage Odors

Reference was made to a report of the American Public Health Association which stated (4):

> "A long prevalent theory that sewage odors are directly responsible for disease has been definitely refuted. It is now realized that the physiological effect, if any, is indirect. Odors, by causing worry, loss of sleep, loss of appetite, etc., may be a contributory cause of ill health, and certainly cause discomfort. The courts, in general, have held that the creators of an odor nuisance are responsible therefor, and as far as municipal sewage disposal is concerned, the odor hazard appears to have been shifted from the public health to the public pocketbook."

M. J. Rosenau, M. D., was quoted (5):

> "While odors may be unpleasant, they are not known to seriously influence health. Contrary to common opinion, they are not by any means a reliable sign of danger. * * *
>
> "The effect of odors upon health is not well understood. * * * Odors influence the nervous system in various ways; some stimulate, others depress."

Condition of Waterway in Earlier Years

In weighing the claims of Illinois that the situation in Joliet and Lockport presents a menace to health which makes imperative an increase in diversion, the Master assembled all the available references to the earlier conditions in the Canal and Des Plaines River, which he cited as evidence of gross pollution. This analysis, however, failed to emphasize the changes brought about by the treatment works of the Sanitary District, and the marked improvement in the upper Waterway to the end of 1938. The conditions he cited as of 1872, 1891, 1911, 1919, 1921, 1922, and 1927 had been radically changed for the better.

CONCLUSIONS AS TO HEALTH CONDITIONS

For many years there have been odors from the Des Plaines River at Lockport and through Joliet. In 1925 when the river flowed over rapids at Joliet, the odors were offensive. From 1930 to 1938 conditions at Joliet improved, notwithstanding the reductions in the flow from Lake Michigan because of the added treatment which the Chicago sewage gradually received. The people at Joliet had become accustomed to this improvement. When the flow from Lake Michigan was reduced on December 30, 1938, conditions retrogressed and complaints ensued from the residents, who compared the 1939 conditions with those prevailing in 1938 and immediately prior to 1938. They had either forgotten the conditions prevailing prior to 1930, or, not unnaturally, felt that the improvement should continue. The nuisance conditions in 1939 were much worse than in 1938. They were not as bad in 1940 as in 1939.

The Master stated that this summary disclosed the facts as he found them. In deciding whether these facts constitute a "menace to health" within the meaning of the instructions of the Court, he indicated he lacked a certain guide. The dictionary definitions of menace he considered of no avail, because the Court itself will determine what it meant.

The Master concluded that the Court did not use the expression "menace to health" in the sense which Drs. Carlson and Ivy ascribed to it. If the Court had so intended, it would not have been necessary to refer the case to a Master, because the facts were clear in the papers in the case. If the test be that urged by Drs. Carlson and Ivy, it is clear that a menace would be found to exist. Accepting this definition, the increase of the flow to 5,000 cu ft per sec would not eliminate the menace. Within the suggested definition the stream would continue a menace as long as any untreated sewage is discharged into it.

The Master then stated that

> "It is obvious that the presence of untreated sewage in an open stream is not in accordance with proper standards of sanitation and should be abated. * * *
>
> "The record leaves no reasonable doubt as to the safety of the water supply of Joliet and Lockport. Nor can the effect of odors upon invalids and persons of less than average health be accepted as any test of health menace; even in cases of private nuisance the test is the effect of the acts complained of upon persons of ordinary sensibilities and in normal health. In the present case it is Illinois itself which is creating the nuisance of which it complains and of which it seeks to be relieved by water which has in effect been adjudged by the Court to belong to the opposing States. * * *
>
> "My conclusion is that the facts proven do not establish any menace to the health of the inhabitants of Joliet and Lockport or elsewhere along the Waterway requiring an increase in diversion in water from Lake Michigan."

PRESENT STATUS OF SEWAGE TREATMENT BY SANITARY DISTRICT

The Sanitary District comprises 442 sq miles in area, including Chicago and 59 other municipalities. H. P. Ramey, M. Am. Soc. C. E., testified that this is divided into four main projects, with sewage treatment works as specified:

1. North Side Works.—This is an activated sludge plant, with a present average capacity of 250 mgd. It went into service on October 3, 1928. The effluent goes to the North Shore Channel. The excess sludge and the preliminary settling sludge are pumped 17.5 miles to the Southwest works for ultimate disposal.

[a] Annual average percentages. [b] The old Calumet Plant was shut down from May 9 to September 13,
Calumet plant. [c] The North Side plant was placed in operation October 3, 1928, and the North Branch
The remaining months of the year were averaged to extend the total to 12 months. In a six-month period
B.O.D. record for Calumet is for the settling in the old Imhoff tanks. After 1935 the record is for activated

2. Calumet Works.—This is an activated sludge plant, with a present average capacity of 136 mgd and a maximum of 200 mgd. Sewage was pumped first on December 3, 1935. Treatment with activated sludge began on December 16, 1935. The excess sludge is conditioned, de-watered, dried for burning, or sold for fertilizer.

3. West Side Works.—This is an Imhoff tank plant, designed for an average flow of 472 mgd and a maximum of 700 mgd. The sludge is pumped to open-air drying beds.

4. Southwest Side Works.—This is an activated sludge plant, nominally designed for an average flow of 400 mgd and a maximum of 600 mgd. The first battery of aeration tanks went into service on June 27, 1939. Sludge disposal apparatus has been in operation since August 28, 1939. On March 20, 1940, the Racine Avenue Pumping Station went into service, thus completing the pickup of sewage except for some minor sewers with a flow of about 70 mgd. By September 26, 1940, all but 35 mgd was connected.

The equivalent population of the Sanitary District is as follows (exclusive of the Corn Products Refining Company):

Population	1930	1940	1941
Human (U. S. Census)	3,901,569	3,962,514	3,962,514
Industrial equivalent	1,486,000	2,237,000	2,549,300
Total	5,387,569	6,199,514	6,511,814

The industrial equivalent population for 1930 was estimated. That for 1940 is the actual value for the period from April to December, inclusive. The peak month in 1940 was November, with a population equivalent of 3,065,000.

Expenditures.—To December 31, 1941, about $166,300,000 had been spent by the Sanitary District for the intercepting sewers, pumping stations, and treatment works. It was estimated that $11,756,900 was required to complete the program. The principal items to be built were at the West-Southwest works—namely, the aeration and final settling tanks and completion of the blower house and sludge handling plant.

in 1928. It suspended operations September 15, 1935, and beginning with 1936, records are for the new pumping station began operating June 28, 1930.[c] [d] The Southwest plant began pumping May 23, 1939. 28 mgd were pumped. [e] Complete treatment on approximately 60% of the total flow. [f] Prior to 1936 the sludge. [g] Six months.

PROGRESS IN TREATMENT

Table 3(*a*) shows that the flow of sewage treated increased from 67.9 mgd in 1928 to 929.9 mgd in 1940. Of the latter, 123 mgd was reported untreated in 1940. The total sludge and grit discharged to the Main Channel aggregated 53,970 tons in 1939 (see Table 3(*b*)). In 1938 it was 44,198. On and after September 16, 1940, no sludge and grit was so discharged, because of the provision of some temporary lagoons in addition to the permanent sludge handling

TABLE 4.—DRY VOLATILE SOLIDS DISCHARGED INTO THE CANAL
(Tons per Year)

Solids	1936	1937	1938	1939	1940
Sludge	21,432	24,613	22,450	33,865	14,937

equipment. The efficiencies of the various plants are shown in Tables 3(*c*) and 3(*d*). The 1941 data are from actual records and were not before the Master.

The volatile solids entering the Main Channel decreased from 145,572 in 1936 to 76,472 in 1940 (see Table 4). Briefly for 1938, 1939, and 1940, the percentage reduction in B.O.D. was as shown in Table 5. The Southwest works lacks blowers and sludge handling equipment. Activated sludge treatment was given only to sufficient sewage to produce solids within the capacity of the dewatering and drying equipment. The remainder received preliminary settling treatment only.

[a] This is only an Imhoff tank plant.

Periods of Flow.—For a clearer understanding of the problem in the Main Channel and Brandon Pool, the time factors of flow must be visualized. The actual periods of flow (in hours) from Damen Avenue to Brandon Road dam, with the average velocities in the Main Channel, are shown in Table 6.

TABLE 6.—FLOW DATA, MAIN CHANNEL AND BRANDON POOL

Month (1939)	Flow (cu ft per sec)	DAMEN AVE. TO SUMMIT		SUMMIT TO LOCKPORT		BETWEEN BRANDON ROAD DAM AND:

PROBABLE CONDITIONS AT LOCKPORT AND JOLIET IN THE SUMMERS OF 1941 AND 1942

At the request of the Master, the experts on both sides submitted estimates on the probable conditions at Lockport and Joliet in the summers of 1941 and 1942. A principal factor was the oxygen demand of sludge deposits in the Main Channel and Brandon Pool. This was difficult to estimate.

The difference between the two sides was enlarged by an over-optimistic viewpoint of the Opposing States as to the date of completion of the remaining Sanitary District works. This viewpoint went so far as to assume that equipment could be delivered long prior to the dates set under contract and the works completed in 1941. As a matter of fact, under the present conditions (November, 1942) of National Defense, it is clear that the works cannot be completed in 1942, and unless priorities are granted, not until after the war. At least two years will then be required, after construction is actively resumed.

The Master concluded that the conditions in Brandon Pool would be better in 1941 and 1942 than in 1939. He noted that in the summer of 1938 there was only 0.2 ppm of dissolved oxygen, and that no special complaints were heard. However, he believed that there would be no dissolved oxygen in the pool in 1941 and that offensive odors were likely to recur.

AVAILABLE REMEDIAL MEASURES

The contention of Illinois was that the only immediate, feasible, remedial or ameliorating measure available for relief of the critical situation at Brandon Pool is an increased diversion of water from Lake Michigan.

The writer testified that a diversion of 5,000 cu ft per sec would improve the conditions over those existing prior to 1939, and that no temporary measures are available which can be applied quickly to obviate the conditions in Brandon Pool other than an increased diversion. Messrs. Calvert and Mohlman concurred. Messrs. A. M. Buswell and Enslow were confident that chlorination would provide more certain relief at Brandon Pool than the diversion of 3,500 cu ft per sec additional; yet Mr. Buswell admitted that dilution reduces the B.O.D. more certainly than chlorine.

Clarence R. Andrew, Assoc. M. Am. Soc. C. E., stated that an additional diversion would reduce the odors. The only two feasible methods known to him were the removal of the pollution at its source or the addition of sufficient water to prevent the odors. Dr. Carlson noted that an increased diversion would lessen both the odors and the menace to health.

As the witnesses for both sides agreed that the critical period of nuisance and health hazard occurs during the warmer months (from early April through October), and as no complaint or health hazard arises with the 1,500 cu ft per sec diversion in the colder months from November through March, the budgeting of the diversion appeared logical on a graduated scale, with a maximum in midsummer and tapering off into spring and fall, with a minimum in the winter.

Mr. Enslow stated the critical temperature of flow to be 62° F. As the temperature rises above this, bacterial action is stimulated, thus increasing gasification from decomposing organic matter. The temperature record of the water at Lockport, in degrees Fahrenheit, is as follows:

Month	1939	1940	Month	1939	1940
January.....	41°	35°	July........	76°	74°
February....	38°	41°	August......	77°	73°
March......	45°	42°	September...	75°	72°
April.......	56°	50°	October.....	64°	65°
May........	64°	58°	November...	53°	52°
June........	71°	70°	December...	46°	39°

Mr Ramey stated that since December 31, 1938, the Sanitary District has budgeted the water diverted from Lake Michigan in a manner to best meet the needs of sanitation, with a diversion limited to an annual average of 1,500 cu ft per sec. This includes the rainfall runoff from the Chicago and Calumet rivers, amounting to 550 cu ft per sec. There remains a dependable dry-weather diversion of approximately 1,000 cu ft per sec. In 1939, from May to October, the dry-weather diversion averaged 1,090 cu ft per sec.

For the protection of the water supply of Chicago, Mr. Ramey did not consider it safe to maintain a flow of less than 2,400 cu ft per sec in the Main Channel at Lockport. Domestic pumpage amounts to 1,650 cu ft per sec and the storm-water runoff equals 550 cu ft per sec, making a total of 2,100 cu ft per sec. This leaves only 300 cu ft per sec to come from Lake Michigan.

To provide greater flow during warmer months, dry-weather flows from 2,400 to 2,600 cu ft per sec were budgeted and attained in the cooler months of 1939 and 1940. Operating results can be improved but little with the present limit on the diversion.

Various remedial or ameliorating measures were proposed by the Opposing States. Illinois contended that these were unsound in principle, effective only to a negligible degree, and available too late to serve the emergency in 1941 and 1942. Illinois further believed that the practicability of the suggestions should be tested from the four standpoints of (*a*) proven reliability and soundness, (*b*) degree of relief effected, (*c*) the time required for installation, and (*d*) the cost.

The suggestions may be divided into temporary and permanent classes, as indicated in Table 7.

TABLE 7.—SCHEDULE OF REMEDIAL OR AMELIORATING MEASURES

No.	Program	Opposing States (temporary)	Illinois (permanent)
1	Chemical treatment at West Side works	✓	....
2	Activated sludge treatment for West Side Imhoff tank effluent	....	✓
3	Eliminate by-passing of Southwest preliminary settled effluent	✓	✓
4	Keep all sludge out of Main Channel	✓	✓
5	Chlorinate the flow in Main Channel	✓	....
6	Chlorinate the effluent of the West Side works	✓	....
7	Double the air used at the North Side works; increase the aeration period from 5 hr to 7 hr to produce 5 ppm of nitrogen as nitrate	✓	....
8	Build cascades at the controlling works at Lockport to aerate the flow above Brandon Pool	✓	....
9	Increase the diversion in summer, in accordance with the results of analyses, to provide a minimum of 1.0 ppm of dissolved oxygen in Brandon Pool	....	✓ (temporary)

The Opposing States urged that the first step to improve the Waterway would be to discontinue the discharge of sludge into it. This was actually done at the end of September, 1940. However, considerable putrescible material is carried over in partly treated effluents. Other suggested remedial measures follow.

Dredging, Draining, or Flushing Brandon Road Pool.—The pool is about 4.84 miles long, with a maximum width of 1,400 ft. Its surface area totals about 12,409,500 sq ft. The water depth varies from 10 to 20 ft. The original volume was approximately 151,000,000 cu ft, which was reduced by 1939 to 120,000,000 cu ft. Mr. Andrew of the U. S. Engineer office estimated about 1,250,000 to 1,500,000 cu yd of deposited material, from 2 to 10 ft deep. He stated that increasing the flow would not remove this deposit, but hydraulic dredging could do so, at a cost of between $500,000 and $700,000, in a period of from 6 to 9 months. Louis R. Howson, M. Am. Soc. C. E., thought the cost might be $400,000 and that any nuisance in lagooning the material could be controlled by chlorine.

Experts on both sides agreed that the denser material has largely lost its potency to cause nuisance, and that hydraulic dredging would remove chiefly material no longer the cause of offense. Mr. Howson doubted the practicability of such dredging as compared to chlorination and other methods. Mr. Mohlman and the writer regarded dredging as an impractical proposition.

Draining the Pool.—Draining the pool was regarded as impracticable by the U. S. Engineer office for a variety of reasons. The Chief of Engineers declined to allow it. From the discussion finally emerged a plan for permitting a flow of 10,000 cu ft per sec in addition to domestic pumpage for 10 days beginning December 2, 1940. To this both sides and the Court agreed.

Experimental 10-Day Flushing.—During the 10-day test beginning December 2, 1940, the total flow at Lockport averaged 9,973 cu ft per sec. The net diversion was 8,430 cu ft per sec. The level of the Brandon Pool was lowered 0.5 ft at first and later an additional foot. The flushing scoured out the Main Channel and deposited in the Brandon Pool more solids than were discharged (see Table 8). However, the solids washed out of the Pool were slightly higher in percentage organic matter than those which entered, as the incoming total solids contained 32.4% volatile matter and the outgoing solids contained 35.6%.

TABLE 8.—RESULTS OF EXPERIMENTAL 10-DAY FLUSHING OF BRANDON POOL

Description	TOTAL SUSPENDED MATTER		VOLATILE SUSPENDED MATTER	
	Tons	%	Tons	%
Delivered to pool	84,010	....	27,067	....
Discharged from pool	21,123	25.2	7,512	27.7
Remainder deposited in pool	62,887	74.8	19,555	72.3

During the test the velocities in the pool averaged from 0.47 to 0.55 ft per sec. The maximum velocities were from 1.33 to 1.58 ft per sec, and the minimum near the banks from 0 to 0.07 ft per sec. Mr. Mohlman estimated about 524,000 cu yd of material were swept in. All the witnesses agreed that in the Main Channel and Brandon Pool a considerable benefit was accomplished, as a whole, by removing sludge from the Main Channel. Mr. Mohlman doubted if this effect would offset the effect of the additional sludge deposited in the pool.

Chlorination of Waterway.—The Opposing States urged the use of chlorine to eliminate odors at Lockport and Joliet.

Mr. Enslow considered the sludge at Brandon Pool to create a bad situation, which would require from three to four times the chlorine necessary if the sludge deposits were removed. In his opinion there is no parallel case in existence for the use of chlorine to prevent septicity for such long periods of flow in a deep river underlaid by sludge, and chlorination at present would be a failure at

Brandon Pool. However, he suggested chlorination at the Southwest plant and at Lockport. Assuming that no new sludge came into the pool his opinion was that 3 ppm of chlorine was required at the Southwest works and 6 ppm at Lockport, although 3 ppm might suffice. If sludge continued to enter, 12 ppm or more, even 15 or 25 ppm, might be required. He considered the attempt speculative, and estimated the cost roughly at $700 to $3,000 per day, based upon chlorine at $43.20 a ton. The equipment might cost $115,000.

Mr. Buswell deprecated the effect of the sludge deposits. He believed 2 to 3 ppm of chlorine at Lockport would be sufficient, with a chloro-boat in the pool to apply 1 ppm if sludge were no longer discharged, and if sludge discharge was continued maybe 5 ppm would be needed. To obtain an authoritative opinion, he admitted, would require tests for at least three months. Mr. Enslow stated that Mr. Buswell's estimate of 1 ppm was too optimistic, but perhaps 3 ppm would be safe, if applied at two points.

Joseph W. Ellms, M. Am. Soc. C. E., estimated that the cost of a 150-ton chlorination plant would not exceed $300,000 and would require six or seven months to build. He felt that chlorine should be applied before septic conditions developed, and at several points. He stated that chlorine could reduce, and perhaps eliminate, odors from hydrogen sulfide, but that hydrogen sulfide would persist as long as organic matter is fed into the pool.

L. F. Warrick testified that chlorine would have a decided beneficial effect upon the Waterway. As a rough estimate he thought the effect of chlorine applied at the Southwest plant might last from 30 min to 2 hr or longer. (The time of flow in June, 1939, actually varied between 24 hr and 76 hr from the Southwest works to Lockport.)

Mr. Howson testified generally that chlorination "is a very effective and positive method of controlling odors." He considered it practicable and effective to relieve the conditions at Joliet and Lockport, and estimated that 6 ppm of chlorine would suffice. With a total flow of 3,130 cu ft per sec, this would amount to 50 tons of chlorine per day. His testimony on the subject of chlorination was based chiefly on Mr. Enslow's testimony.

The Illinois experts conceded that, in many situations, chlorine is used effectively to prevent odors; but, in view of the sludge deposits in the Main Channel and Brandon Pool, they believed that chlorine could not be used effectively to eliminate the odor conditions, even if large quantities were used at great expense.

Mr. Mohlman indicated that at least three points of application would be needed—Damen Avenue, Summit, and Lockport. This might require about 150 tons per day or about $6,000 to $7,000 per day during the summer months. The writer called attention to the fact that chlorine does not dispose of the organic matter that causes the nuisance at Joliet.

Cecil Kirk Calvert, Affiilate Am. Soc. C. E., presented a disappointing experience in 1930, at Indianapolis, Ind., in which an average of 10 ppm of chlorine was applied to the plant effluent. The reduction in B.O.D. was about 10% or 2 ppm of B.O.D. per part per million of chlorine. Usually the chlorine disappeared as soon as the effluent mixed with the river water. On only one occasion was any residual chlorine found farther away than 2,000 ft. He believed that the estimate of 150 tons per day for the Chicago-Joliet situation was very moderate and the application would be required for five or six months. He did not consider that the expenditure was justified, because the nuisance would not be measurably reduced.

Thus the amounts of chlorine required per day were variously estimated between 50 and 150 tons, with very doubtful assurance that the money would be well spent even as an emergency measure. Witnesses on both sides agreed that there is no water or sewage plant in the United States with a capacity for applying chlorine greater than the Detroit (Mich.) Sewage Works with 27 tons per day, and even this plant has not actually applied as much as 10 tons per day.

Cascades at Lockport.—The flow of the Main Channel passes through the turbines at the power house below Lockport and generates electric power which is worth about $1,500 per day to the Sanitary District.

Mr. Howson proposed that this flow be run over a cascade instead of generating power, thereby picking up 6.75 ppm of dissolved oxygen or about 113,000 lb of dissolved oxygen, equivalent to that contained in 2,650 cu ft per sec of lake water. He estimated the cost at between $50,000 and $100,000 for a wooden structure and a period of three to six months for construction. He based the pickup on the experience at the Hastings Dam in the Mississippi River and in the North Side effluent at Chicago.

Mr. Warrick believed that such cascades would have a beneficial effect, inasmuch as at Hastings Dam, in 1933 and 1934, about 7.8 ppm of dissolved oxygen was obtained. He stated that the B.O.D. in the water at the Hastings Dam was only 7 ppm as compared with 30 or 40 ppm in the flow at Lockport. He declined to express any opinion as to how long such pickup could be retained and doubted whether any dissolved oxygen would be carried through.

Mr. Calvert testified that such cascades would improve conditions but slightly, and that they would create a local odor nuisance.

Mr. Mohlman and the writer conceded that some dissolved oxygen would be picked up, not to exceed 3 ppm, but that the effect would be lost before the flow reached the pool because of its anaerobic condition. (As a matter of fact, actual tests made in October, 1924, showed a pickup over the old Bear Trap Dam of 4.1 ppm, which practically disappeared in the flow of 5 miles to the upper end of Brandon Pool.) The writer admitted that the pickup of dissolved oxygen at the North Side works averaged about 6.7 ppm from 1934 to 1939, but he doubted if all the dissolved oxygen so entrained was effective.

Mr. Howson contended that such dissolved oxygen would not be lost because of the 15-ft fall in the flow from the cascade to the pool. Mr. Enslow agreed with Mr. Mohlman that the re-aeration obtained by cascading would not last long under summer conditions and would not justify the cost. If chlorine were added to the cascade, he felt that some benefit would accrue. Otherwise, it would be just a local odor nuisance.

The writer conceded that, if the suggestion of cascading had merit, the effect could be accomplished over the existing control dams at the power house with very small expenditure. He did not consider that enough was gained to justify the loss of $1,500 per day to the Sanitary District. The Opposing States argued that Illinois should be required to try every measure that might possibly ameliorate conditions even at considerable expense, before diverting any additional water from the Lake.

Supply of Additional Oxygen through the Production of Nitrate by Increased Use of Air at North Side and Calumet Works.—Mr. Howson suggested that 40,500 lb of additional oxygen might be developed in the effluents of the North Side and Calumet works by using more air in the activated sludge process, at an operating cost of $89,000 for a 5-month period, or $216,000 for a 12-month period. Messrs. Warrick, Ellms, and Buswell agreed in general. Mr. Buswell stated that he knew of no streams with nitrites and nitrates present in the flow where septic conditions occurred, as nitrates tended to oxidize hydrogen sulfide and prevent its formation. Under existing conditions Mr. Buswell admitted there would be odors even if nitrates were present.

Messrs. Calvert and Mohlman agreed with the writer that such nitrate production would be of little ultimate value. The production of nitrates would require an increase in detention period in the aeration tanks from the present basis of 4.5 or 5 to 7 hr. Such capacity does not exist at the North Side works. Mr. Mohlman indicated that algae and green plants would form a secondary growth in the North Shore Channel which would create a secondary source of B.O.D. He testified that, if an attempt were made to control the odor situation by purchasing sodium nitrate, the cost might reach $17,000 per day.

Chemical Treatment at West Side Works.—Messrs. Buswell and Howson proposed the installation of chemical treatment on the effluent of the Imhoff tanks at the West Side works. This was intended to supplant the treatment by activated sludge which is a part of the Sanitary District permanent program and approved by Messrs. Ellms, Enslow, Howson, and Warrick. Such chemical treatment would reduce the B.O.D. by 21 ppm or, on a flow of 437 mgd, a reduction of 76,000 lb of B.O.D. Mr. Howson estimated that the construction would cost $1,300,000, with an operating expense of from $200,000 for five months to $481,700 for twelve months. (This was substantially the Sanitary District estimate of $1,300,500 (6).) Mr. Howson claimed in September, 1940, that this could be completed by the summer of 1941. According to the Sanitary District report of April, 1940 (6), two and one-half years would be required. Mr. Mohlman and the writer both stated that chemical treatment would not be satisfactory, since it would reduce the B.O.D. at the West Side from 57 to 36 ppm, whereas activated sludge treatment should reduce it to 10 ppm. The Sanitary District estimated that the chemical plant would cost $555,800 per year to operate at the West Side, whereas the activated sludge plant for equivalent purification would only cost $320,600 per year, with a first cost of $3,662,000.

Inasmuch as the Sanitary District has adopted the activated sludge treatment, the Master saw no reason to accept the suggestion that chemical treatment be adopted as a temporary or emergency measure to care for the summer of 1942, at the cost involved, when it would be almost immediately superseded by the superior activated sludge plant.

Chlorination of West Side Imhoff Tank Effluents.—Mr. Howson also described the application of chlorine to the West Side effluent as an alternative to chemical treatment, as suggested by Mr. Enslow. He estimated that this would reduce the B.O.D. by 50,000 lb instead of 76,000 lb by chemical treatment. The cost of the equipment was estimated at $100,000 and the time for construction at six to nine months. The operating expense was estimated at $105,000 for a period of 150 days. Mr. Mohlman and the writer did not consider chlorination of the West Side effluent a practical measure to ameliorate conditions in the Brandon Pool.

The Master concluded that it was obvious that the suggested work could not be done before 1942 and that the extent of amelioration was limited.

Planned Use of Water.—The decree of April 21, 1930, permits a variation in the diversion, which the Sanitary District has utilized to endeavor to provide more flow in the summer. Mr. Howson suggested that the present arrangement be adjusted to provide 4,200 cu ft per sec flow at Lockport during four summer months.

Illinois conceded the merit of this suggestion but indicated that it was limited by the necessity of providing for storm runoffs to prevent reversal in the Calumet River and flooding of basements in the Chicago Loop area. Hence the Sanitary District carries a reserve for use in the event of storm.

In its revised petition, Illinois proposed to take only 1,150 cu ft per sec of water for January, February, March, November, and December. Assuming that this is adequate, the aggregate difference between 1,500 and 1,150 cu ft per sec for five months is 1,750 cu ft per sec. If distributed over four summer months an additional flow of approximately 437 cu ft per sec is provided for each month, or 1,935 cu ft per sec. If this is added to the domestic pumpage of 1,700 cu ft per sec, the total is 3,635 cu ft per sec, as compared with 4,200 cu ft per sec suggested by Mr. Howson.

The Master indicated that this suggestion would only contribute about 22,000 lb of oxygen to meet the B.O.D. situation at Lockport. The lesser amount possible upon the admission of the Sanitary District is not substantially ameliorating. To quote: "In view of the paramount importance to the health of Chicago of avoiding any reversals of the river" the Master hesitated "to make a finding that the Sanitary District should be required to go further in budgeting than in its modified petition it admits to be possible."

Metering of Chicago Domestic Water Supply.—The Opposing States offered in evidence a table showing that the Chicago per capita consumption was 214% more than the average of nineteen other American cities. In Chicago, of 412,228 water services in 1940, only 115,025 were metered.

Illinois offered evidence through Loran D. Gayton, M. Am. Soc. C. E., then city engineer of Chicago, showing that to provide universal metering would require 300,000 meters, costing in excess of $10,000,000 and requiring more than six years to install, at the rate of 50,000 meters per year. In the 10-yr period from 1930 through 1939, the city installed an average of 4,165 meters per year. The greatest number ever placed in one year in Chicago was 16,864 in 1931. No money had been appropriated for their purchase. Under the circumstances, Mr. Gayton stated that he did not believe that any meters installed in 1941 and 1942 on the South Side area (in connection with the new filtration plant) would appreciably reduce the use of water therein.

Should the domestic pumpage be reduced, the Master found no evidence to enable him to appraise the extent of the resulting benefit.

Activated Sludge Treatment at Southwest Works for West Side Imhoff Effluent. —Mr. Howson suggested that a large part of the Sanitary District program for the activated sludge treatment at the Southwest works of the West Side Imhoff effluent could be speeded up, covering an estimated cost of $3,267,200. The writer testified that this sum was inadequate without the addition of certain essential items, totaling approximately $700,000, thus raising the total to $4,048,000. The Sanitary District estimate for the entire extension of the activated sludge plant was $4,878,500. Furthermore, of the program advocated by Mr. Howson, certain conduits and appurtenances costing about $600,000 would be of no value when the plant was completed.

The Comments of the Master

The Master indicated that the contention of the Opposing States is that the Sanitary District might complete its program before the summer of 1942 by proper effort. He commented that

> "The record indicates that the Sanitary District has been influenced, not so much by the desire to make speed, as by the purpose ultimately to complete an efficient system at as little expense as possible to its taxpayers. These are praiseworthy motives when considered from the standpoint of the Sanitary District alone, but they may not place the emphasis upon expedition to which the legitimate protection of the interests of the opposing States entitles them."

The Master also noted that "the record contains numerous references by representatives of the District to the importance of saving the taxpayers' money as a controlling consideration."

Illinois tried to impress on the Master that with the funds available to the Sanitary District for construction and operation, in accordance with its legal limitations, the engineers of the Sanitary District had endeavored to spend such funds to best advantage to produce permanent results, instead of frittering the money away on expensive makeshifts and thereby injuring the operation of the existing works and delaying the construction of the program which the experts on both sides agreed was the only real solution of the problem, the treatment to a high degree of all the sewage and the handling of all the solids so removed, so that a minimum of residual pollution in solution and in settling solids entered the Illinois Waterway.

Recommendations of the Master

On the basis of his conclusions (see Appendix) the Master recommended that a decree be entered dismissing the petition and the modified petition of the State of Illinois for a modification of the decree of April 21, 1930, and taxing the costs of the litigation against the State of Illinois. The Court then dismissed the petition without comment on May 26, 1941.

Acknowledgment

The writer wishes to acknowledge herewith the free use of the report of the Special Master as well as the record and exhibits in the case, from which liberal quotations have been made.

APPENDIX

Conclusions of the Special Master

After hearing all the testimony and inspecting the upper Illinois Waterway from Brandon Road to the Power House, the Master presented the following conclusions to the Court:

> "(1) The actual condition of the Illinois Waterway by reason of the introduction of untreated sewage creates in the summer months a nuisance through offensive odors at Joliet and Lockport, but does not present a menace to health. No nuisance conditions were proven to exist along the Waterway at any other points.
>
> "(2) With respect to remedial or ameliorating measures available to the State of Illinois without an increase in the diversion of water from Lake Michigan, my findings are as follows:
>
> "(*a*) The dredging of Brandon Road Pool would remove chiefly old accumulations of sludge which have completely or largely lost their potency as causes of nuisance and would therefore be of extremely doubtful efficacy. It would cost between $400,000 and $750,000, plus the cost of providing spoil banks and lagoons. It would present problems as to possible nuisance from such spoil banks and lagoons and require further expense for chlorination. I do not think this is a feasible ameliorating measure.
>
> "(*b*) The draining of Brandon Road Pool cannot be accomplished without some interference with navigation, to which the War Department, which has sole jurisdiction over navigation problems, will not consent. For this reason I do not think this suggestion feasible. There would also be presented problems with respect to the water intake pipes of several industries which take water for industrial purposes from the Pool.
>
> "(*c*) Chlorine is an effective measure to reduce and eliminate odors, but owing to the size of the Brandon Road Pool and the large sludge deposits therein and the continuing discharge into the Waterway of incompletely treated sewage, it is impossible to make a reasonably certain estimate of the amount of chlorine which would have to be applied to produce a substantial result.
>
> "In order to have a reasonable prospect of substantially controlling offensive odors, it would be necessary to spend from $3,000 to $4,000 a day for chlorine, plus several hundred thousand dollars for chlorinating equipment.
>
> "(*d*) Cascading the water at Lockport or sending it over the dam there would be remedial to the extent of producing some oxygen at Lockport. How much oxygen would be produced and how much of it would reach Joliet and the Brandon Road Pool is uncertain and could only be determined by actual trial. The use of the water in this way would cost the Sanitary District $1,500 a day in the loss of power and it would be necessary to use an undetermined amount of chlorine to prevent an odor at the point of cascading.
>
> "(*e*) The supply of additional oxygen through production of nitrates by increase of air on the North Side and Calumet plants is not a feasible ameliorating suggestion for the summer of 1941. The evidence before me is not sufficient to prove that it is feasible for 1942, in view of the testimony of the Sanitary District experts that it would require an increase in aeration tank capacity. The proof before me is insufficient to support a conclusion that this suggestion, if it could be put into effect for the summer of 1942, would be substantially ameliorating.
>
> "(*f*) Chemical treatment at the West Side plant would involve a very large permanent expenditure, which could not be made effective in 1941

and if it could be installed by 1942 would be almost immediately superseded by the activated sludge treatment which is provided for by the District's permanent program. This does not seem to me a feasible ameliorating measure.

"(*g*) The estimates as to cost of chlorinating West Side Imhoff tank effluents are too uncertain and the opinions of the experts too conflicting as to the extent of amelioration which it would afford, to enable me to make any finding that such chlorination is a feasible ameliorating measure.

"(*h*) It is feasible for the Sanitary District to budget the 1,500 c.f.s. of water now permitted to be diverted in addition to domestic pumpage so as to divert only 1,150 c.f.s. in the months of January, February, March, November and December, and to allocate the aggregate saving in diversion in those months to the summer months. This ameliorating measure will not, however, materially reduce the BOD at Lockport, and will not, therefore, substantially relieve the odor nuisance.

"(*i*) The adoption of compulsory water metering by Chicago is an ameliorating measure, but the evidence before me is not sufficient to enable me to make any finding as to the extent of amelioration which it would afford or the time within which it could be made available.

"(*j*) The provision of activated sludge treatment at the Southwest plant for the West Side Imhoff tank effluent is a very important and feasible ameliorating measure to which the Sanitary District is committed, and toward which it has made some progress. The extent of the progress will depend upon the industry and enterprise of the Sanitary District. There is no prospect that this ameliorating measure will be operative in the summer of 1941. It is possible, but doubtful, that by special diligence it might be made operative in the summer of 1942 instead of only by the end of 1942, as claimed by the District.

"(*k*) As additional equipment is installed, it will become possible to give complete treatment during the course of 1941 and 1942 to increased quantities of sewage at the Southwest plant. The progress which will be made during these years and the gradually declining influence of sludge deposits from past years will be operative in the summer of 1941 to improve conditions at Lockport and Joliet as compared with 1939 and 1940, and will be operative to a further extent in 1942. The extent of relief from offensive odors which will be afforded at Lockport and Joliet in the summer months of 1941 is very doubtful, but there is a better outlook for the summer months of 1942. Weather conditions will have an important influence.

"Notwithstanding every effort on my part to press the hearings and consideration of this case, one of the three years for which Illinois originally petitioned for relief (1940) has already passed. The people in Joliet and Lockport have submitted to the conditions which prevailed in the summers of 1939 and 1940 without serious consequences to health. If relief is denied for the years 1941 and 1942, the authorities of the Sanitary District may be spurred to increased efforts in the treatment of Chicago sewage. The hearings before me have already resulted in the putting into effect of provisions as to lagooning of incompletely treated sewage which had not previously been adopted."

DISCUSSION

Willem Rudolfs,[3] **M. Am. Soc. C. E.**—Experience revealed by the Illinois Water Litigation in 1940 and 1941 touches three questions of general interest on which more information is needed:

(1) What is the minimum dissolved oxygen required to prevent odor nuisances?

(2) What is the B.O.D. of sludge on prolonged storage?

(3) How long does deposited sludge exert an influence on the overlying water?

Odor nuisances in polluted streams are primarily of two types: Those musty odors related to sewage and sewage effluents, frequently modified by industrial wastes; and the putrid odors (mainly hydrogen sulfide) associated with actively decomposing organic matter. The latter odors are the most objectionable and cause nuisances most frequently, although the former may be disagreeable. Active decomposition of deposited sludge proceeds whether or not the overlying water contains dissolved oxygen. Anaerobic decomposition—and hence gas formation—increases with higher temperatures, resulting in greater activity during summer than winter. The increased biological activity causes the deposited sludge to become gas laden and the sludge rises to the surface in the form of "islands" or is distributed through the overlying water. Under these conditions the available oxygen in the water is used up quickly.

Water containing considerable quantities of oxygen but flowing rapidly over actively digesting sludge banks may be deprived only partly of the available oxygen while gas bubbles escape from the surface. Results obtained have shown that the water may have a dissolved oxygen saturation of 25% or more with appreciable H_2S odors present. In sluggish streams the oxygen nearly always is exhausted when odors are present. It is clear, therefore, that the minimum of dissolved oxygen necessary to prevent odors in the presence of sludge deposits will vary with the character of the stream and the type and quantity of sludge present.

In the absence of sludge deposits, the odors produced come from organic materials in solution or suspension during the course of their decomposition. The gases formed may go into solution or may be released in tiny bubbles. As long as a minimum of dissolved oxygen is present in the water, gross odor nuisances will be prevented. The minimum amount of oxygen required will vary, but the minimum of 1 ppm given by Mr. Mohlman in his testimony probably will suffice in most cases when no sludge deposits are present.

The B.O.D. of sludge is reduced comparatively rapidly during the first nine months of storage. Thereafter the rate of reduction decreases, and finally the material becomes stabilized. Some results obtained from long-time experiments on three types of sewage will illustrate the changes:

---

[3] Chf., Dept. of Water and Sewage Research, New Jersey Agri. Experiment Station, New Brunswick, N. J.

1. Fresh solids, material subjected to anaerobic digestion, not disturbed except when samples were taken for analysis;

2. Fresh solids, material subjected to anaerobic digestion, and the supernatant removed at intervals; and

3. Digested sludge, material previously digested anaerobically for a period of ten years.

The sludges used in the experiments were under observation for a period of from six to sixteen years.

The concentration of the sludges at the beginning and after 2,195 days were as listed in Table 9, Cols. 1 and 2. Values in Cols. 3 and 4 indicate the relatively rapid rate of B.O.D. reduction and the demand on the stream which may be expected over a long period.

TABLE 9.—LONG-TIME EXPERIMENTS WITH SEWAGE SLUDGE

Days	Fresh Solids, Subjected to Anaerobic Digestion								Digested Sludge			
	(a) Undisturbed				(b) Supernatant Removed				(c) Previously Digested for Ten Years			
			B.O.D.				B.O.D.				B.O.D.	
	Total solids (%) (1)	Volatile matter (%) (2)	Parts per million (3)	Milligrams per gram of volatile matter (4)	Total solids (%) (1)	Volatile matter (%) (2)	Parts per million (3)	Milligrams per gram of volatile matter (4)	Total solids (%) (1)	Volatile matter (%) (2)	Parts per million (3)	Milligrams per gram of volatile matter (4)
0	1.80	1.31	7,060	537	1.82	1.33	7,000	526	3.54	3.52	2,400	171
1,050	....	....	295	90	....	....	235	94	....	....	1,290	106
2,195	0.65	0.24	210	89	0.54	0.21	50	24	1.41	1.27	1,080	84

After sixteen years of digestion the unit B.O.D. of the volatile matter remaining is the same as after six years. The sludge residue has become stabilized, but it still exerts an influence on the overlying water as indicated by the further reduction of B.O.D. when the supernatant liquor is removed periodically (see Cols. 4, Table 9). The washing-out effect may be considered similar to the condition in a stream. The quantity of volatile matter remaining in the washed material is only slightly less, but the degree of stabilization is greater, than when the sludge is stored; hence, there is a continuous effect of the sludge on the overlying water.

Summarizing, it appears that:

1. Odor nuisances may be caused when actively decomposing sludge is present, even when several parts per million of oxygen are available in the stream;

2. In the absence of actively decomposing sludge, a minimum of oxygen must be present to prevent odor nuisances;

3. Stabilization of sludge requires a number of years; and

4. Even so-called "stabilized" sludge has a B.O.D. and exerts its influence on a stream. The magnitude of the effect is reduced steadily.

L. R. Howson,[4] M. Am. Soc. C. E.—In all of the litigation regarding diversion at Chicago, extending over a period of fifteen years, the experts for the Opposing States have never been critical of the engineering or construction of the Chicago Sanitary District's works. They have testified repeatedly of the high character of both the design and execution of that work. It is also only fair to state that some of the procedures eventually incorporated into the Sanitary District's program were first urged by the experts for the Opposing States. Such steps include:

(*a*) The recommendation that the Southwest, West Side and Calumet plants be of activated sludge rather than trickling filter type;
(*b*) That the Southwest and West Side projects be consolidated on the West Side site; and
(*c*) That provisions be made for lagooning sludge at the Southwest Side plant in case of breakdown in the sludge drying plant.

To secure a proper perspective of the contentions of the parties in the recent litigation covered by Mr. Pearse's paper, reference is made to the opinion of the U. S. Supreme Court delivered by Chief Justice Taft on January 14, 1929:

> "The Sanitary District authorities relying on the argument with reference to the health of its people, have much too long delayed the needed substitution of suitable sewage plants as a means of avoiding the diversion in the future. Therefore, they cannot now complain if an immediately heavy burden is placed upon the District because of their attitude and course. The situation requires the District to devise proper methods for providing sufficient money and to construct and put in operation, with all reasonable expedition, adequate plants for the disposition of the sewage through other means than lake diversion."

The Supreme Court then instructed the Special Master, the Hon. Charles Evans Hughes, "to determine the practical measures needed to effect the object just stated and the period required for their completion." After an exhaustive series of hearings in which the experts for the Sanitary District estimated that the sewage disposal program would require the expenditure of $176,000,000 and fifteen years in which to build it, and the engineers for the lake states estimated $76,000,000 to $82,250,000 and four to eight years for construction, the Master adopted a construction period of nine years from the date of the order. The project is now (1943) substantially completed. Approximately $80,000,000 have been expended for the sewage disposal program set up in the Master's report. Due to the economic depression delaying the start of construction, most of the program was condensed into a six-year construction period.

Attention is called to Table 3 which discloses that, during 1939, the Sanitary District discharged 53,970 tons of sludge and grit (on a dry basis) into the drainage canal, and that the total volatile solids discharged into the canal in the same year (Table 4) was 115,658 tons. Expressed in another way, from two to three million tons of liquid sludge which had been removed in the treatment plants were dumped back into the channel during 1939 in addition to the solids necessarily carried by the plant effluents. The surprising thing is not that the channel did smell but that it did not smell worse.

---

[4] Cons. Engr. (Alvord, Burdick & Howson), Chicago, Ill.

Some of the hearings were held in the city hall in Joliet. This building is near the drainage channel. The hearings were conducted during the hottest week that has ever been recorded in the Joliet weather records so that the setting was perfect for severe odors. During the period when witnesses were testifying as to the intensity of the odors, the wind was frequently blowing into the court room directly from across the channel. There is such a thing as "judicial notice."

The Special Master records his impressions of the odor situation as he observed it on a boat trip over the Brandon Pool one evening when the hotel thermometer after his return at 9:00 p.m. registered 92°. The following excerpt is from the Master's report:

> "After returning from this inspection trip I noted at 11:30 P.M. in my room at the hotel (which was about 4 blocks from the Waterway) an odor which lasted a minute or two; a few minutes later I got another odor for a minute or two, and then detected no more odors. I slept four nights at Joliet and was not troubled by odors. The only trouble I had in sleeping was due to the heat, which was so great that I kept an electric fan constantly going all night. The City Hall, in which the hearings were held, was about three blocks from the Canal on the east side; I detected an odor only on one day and then only for a few minutes. The four days I spent in Joliet were the hottest of the summer, the temperature reaching 103 degrees on July 25th."

In referring the matter to Monte M. Lemann as Special Master, the Supreme Court in its per curiam opinion (309 U. S. 569) prefaced the quotation referred to by Mr. Pearse with this statement:

> "The State of Illinois has failed to show that it has provided all possible means at its command for the completion of the sewage treatment system as required by the decree as specifically enlarged in 1933 (289 U. S. 395, 710). No adequate excuse has been presented for the delay. Nor has the state submitted appropriate proof that the conditions complained of constitute a menace to the health of the inhabitants of the complaining communities or that the state is not able to provide suitable measures to remedy or ameliorate the alleged conditions without an increase in the diversion of the rights of the complainant states as adjudged by this court."

Accordingly, the position of the Opposing States in this litigation was that their function was simply to suggest various "remedial or ameliorating measures" and that in view of the aforementioned earlier Supreme Court opinions, the cost of such measures was not a consideration. The Opposing States were not concerned as to what steps Chicago or the State of Illinois might take so long as they did not involve increased diversion from Lake Michigan. All engineers were agreed that the Sanitary District should complete its construction program at the earliest possible date. If the State of Illinois considered the Joliet nuisance sufficiently acute or inimical to health, the Opposing States contended that it was obligatory upon Illinois to adopt any or all "remedial or ameliorating measures" at its expense and without detriment to the Opposing States. It should be recalled that the Opposing States did not initiate the 1941 hearings. The State of Illinois was plaintiff.

It is noticed, in Table 7, that Illinois takes credit for No. 4; namely, keeping all sludge out of the Main Channel. At the time of the hearing approximately half of the sludge that had been separated out in the treatment processes was being discharged back into the drainage channel. The experts for the Opposing States, in their suggestion of remedial measures, recommended the immediate cessation of that discharge and that the sludge be deposited in lagoons until the dryers were adequate. Initially the Illinois experts testified that lagooning of sludge was impracticable and could not be adapted to Chicago conditions. Subsequently, however, that position was changed and lagooning, in fact, was provided by the Sanitary District before the Master's report was completed.

Table 7 does not include No. 2, "Activated sludge treatment for West Side Imhoff tank effluent," as a remedial measure in the "Opposing States" column. However, this was one of the measures urged by the Opposing States experts for immediate undertaking and opposed by Illinois as requiring more time than estimated by the Opposing States. In commenting on these opposing views the Master quoted from Special Master Hughes,

> "Much time can be saved or lost in large building operations according to the attitude which is taken as to the importance of early completion. In the present case the Court has already laid down the requirement that the work shall proceed 'with all reasonable expedition.' "

Remedial Measure No. 9 "budgeting of the diversion" was also the initial suggestion of the experts for the lake states. This, too, was a matter on which all parties came to agreement during the progress of the case.

As to most of the other "remedial or ameliorating measures" suggested as available the Master considered them as not "feasible," worth while, or necessary. His report stated:

> "The people in Joliet and Lockport have submitted to the conditions which prevailed in the summers of 1939 and 1940 without serious consequences to health. If relief is denied for the years 1941 and 1942, the authorities of the Sanitary District may be spurred to increased efforts in the treatment of Chicago sewage. The hearings before me have already resulted in the putting into effect of provisions as to lagooning of incompletely treated sewage which had not previously been adopted."

From the fact that there have been four Supreme Court hearings on the diversion of water from Lake Michigan for sewage disposal purposes, it is evident that there have been some divergent views. However, in all of these cases the argument of Illinois has been for diversion. Previous cases have seen much testimony relative to diversion for power, diversion for navigation in the Illinois Waterway, and even the Mississippi River, but in this case the diversion was asked as a direct health measure. The Master recommended against, and the Supreme Court denied, the petition for increased diversion. The Master stated "Every increased diversion from the lakes removes a stimulus to Illinois to speed the work." The Master reported a nuisance but no menace to health.

A. M. **Buswell,**[5] **Esq.**—It is fortunate that Mr. Pearse has prepared for record a summary of the rather unique litigation which, as he states, involved the question, "When is pollution a menace to health" rather than a question of nuisance abatement.

---

[5] Chf., State Water Survey Div., Urbana, Ill.

Although much of the testimony related to evidences of nuisance and the relative effectiveness of various means of relieving odors, the plea was that the situation was so extreme as to have an actual effect on health. On this, the main point of the controversy, the Court stated that (see "Conclusions as to Health Conditions"):

> "In the present case it is Illinois itself which is creating the nuisance of which it complains and of which it seeks to be relieved by water which has in effect been adjudged by the Court to belong to the opposing States.* * *
>
> "My conclusion is that the facts proven do not establish any menace to the health of the inhabitants of Joliet and Lockport or elsewhere along the Waterway requiring an increase in diversion in water from Lake Michigan."

Since one of the principal reasons for increased diversion was to flush out sludge deposits which it was contended had accumulated as a result of decreased diversion, it is of importance to note (Table 3) that the discharge of sludge to the channel increased from some 30,000 tons in 1934 to some 50,000 tons in 1939. As a result of the hearings, this was reduced to 20,000 tons in 1940 and to 0 in 1941. This elimination of the discharge of sludge to the channel was urged by the opponents of diversion as the most effective immediate remedial measure, and it is gratifying to note that the suggestion was acted upon so promptly.

The presentation of these and other suggested ameliorating procedures by Mr. Pearse may be misleading to some readers. The Opposing States did not contend that any one item in their program (Table 7) would completely relieve the situation. They did submit that the effect of combining the permanent cessation of sludge discharge with such temporary measures as chlorination and chemical precipitation at certain plants to improve efficiency, and chlorination where dissolved oxygen deficiencies were imminent, would give greater relief than increased diversion. This contention was supported amply by the results of the 10-day flushing test (see discussion of Table 8) that swept some 500,000 cu yd of sludge into Brandon Pool, increasing the pollution at that critical point.

The page and a half of testimony on chlorination may confuse persons not familiar with the subject. The hesitancy of those offering testimony to state definite requirements and predict quantitative results was due to their realization of the complicated nature of the chlorination reaction. Complete or "break point" chlorination requires relatively large amounts of chlorine but hydrogen sulfide and other odorous compounds are chlorinated far below the break point. It is important to note that all agreed that chlorination was an effective means for odor control. Under the heading, "Available Remedial Measures," the writer is quoted as admitting that "dilution reduces the B.O.D. more certainly than chlorine." Actually the writer's testimony was that the reduction of B.O.D. by dilution can be calculated more accurately in the light of present knowledge than the reduction by chlorine can be calculated. The writer is further quoted (heading, "Supply of Additional Oxygen through the Production of Nitrate by Increased Use of Air at North Side and Calumet Works") as admitting that "there would be odors even if nitrates were present." He wishes here to state that the presence of nitrates is incompatible with putrefactive odors. If the nitrates are not present in sufficient quantity they would be reduced, after which odors would appear.

The summary of testimony on cascades fails to point out that the increase in dissolved oxygen after aeration is not a true measure of the results accomplished. Septic compounds are largely volatilized or oxidized by aeration, thus reducing the B.O.D. by several times the amount of actual oxygen increase. There is no question that aeration is effective, although it may not be worth "$1,500 per day to the Sanitary District."

Emphasis should be placed on the fact that there was no criticism of the final program of the Sanitary District of Chicago for relieving the situation permanently. Both parties to the litigation urged a speeding up of this program as the best solution of the problem. It is apparent that the Special Master came to the same decision. This is brought out forcefully in the final paragraph of his conclusions quoted in the last paragraph of the Appendix to Mr. Pearse's paper.

LLOYD M. JOHNSON,[6] ESQ.—Mr. Pearse's paper records clearly the proceedings in this case. It seems unfortunate that it was necessary for Illinois to prove a menace to health in the conditions existing in the Waterway, in order to obtain a temporary increased flow. To the layman the existence of nuisance would warrant such increase to relieve the conditions.

In view of the accumulations of sludge in the Waterway, and the persistence in oxygen demand of these deposits over several years, a temporarily increased diversion greater than 1,500 cu ft per sec appears extremely desirable during the summer months until the Sanitary District sewage treatment construction program can be completed. This increase would be most effective if taken during the summer months on a schedule similar to that outlined in the modified petition.

A plant of the unprecedented size and complications of the Southwest works of the Sanitary District requires a lengthy "tuning up" period. Scarcity of materials and the priority situation have worked against keeping the plant at maximum operating capacity. Due to limitations in sludge handling capacity the plant has operated so that the reduction of B.O.D. has been approximately 60%. The war has stopped work leading to construction of additional facilities for the complete treatment of all sewage from the Southwest area, and the activated sludge treatment of the West Side Imhoff tank effluent.

Under conditions in 1940–1941 the over-all B.O.D. reduction was approximately 60% for the sewage flow of the four major sewage treatment works of the Sanitary District. In 1938 (the last year of the diversion of 5,000 cu ft per sec and before the Southwest works was placed in operation) the over-all reduction was roughly 35%. With activated sludge treatment for 400 mgd at the Southwest works the reduction would average about 80%, and with such treatment for the West Side flow also, which is now only settled in Imhoff tanks, the value would be 90%. These figures do not take account of the effect of storm flows.

---

[6] Commissioner of Streets and Electricity, City of Chicago, Chicago, Ill. (formerly, Engr. of Maintenance and Operation, The Sanitary District of Chicago).

Table 10 shows a comparison of the residual sewage untreated, on a population basis, and the dilution afforded before and after the reduction in diversion, based on a total population equivalent (human plus industrial equivalent) of 6,512,000, which actually occurred in 1941. The value was probably less in preceding years, but 1941 was the first full year for which data were available.

TABLE 10.—COMPARISON OF RESIDUAL SEWAGE UNTREATED, ON A POPULATION BASIS

Year or condition	Percentage treatment	Residual population untreated	DIVERSION, IN CU FT PER SEC	
			Total population	1,000 population
1938	35	4,220,000	5,000	1.18
1941	60	2,605,000	1,500	0.58
Treatment[a]	80	1,302,000	1,500	1.15
Treatment[b]	90	651,000	1,500	2.30

[a] Activated sludge treatment for 400 mgd at Southwest works and Imhoff tank treatment at West Side works.

[b] Activated sludge treatment for the flow of the entire Sanitary District.

Thus, it is seen that in 1940–1941 the dilution available was about one half that in 1938, before the reduction in diversion. The fact that the lower diversion contained a much higher proportion of direct runoff is disregarded.

Regarding the suggested remedial measures it is fortunate that funds were not used to install chlorinating apparatus or chemical treatment at the West Side works. Any other funds expended for temporary measures would have been largely wasted. In the light of developments since the hearings it is fortunate that the use of chlorine was not adopted, as the war conditions would probably have made it impossible to obtain chlorine for such purpose.

In closing the comments on Mr. Pearse's paper, it is now clear that the most prompt and effective method to ameliorate the condition would have been increased diversion. Unless an emergency order is issued granting increased diversion, the condition of the Illinois Waterway must remain as it is for the duration of the war and for some time thereafter.

H. P. RAMEY,[7] **M. AM. SOC. C. E.**—In Table 7, Mr. Pearse indicates that remedial measure No. 9 was the initial suggestion of the State of Illinois. There was some agreement as to the desirability of budgeting the diversion, but the initial suggestion for it did come from the experts for the State of Illinois. Budgeting of the diversion was started long before the 1940 hearings. As assistant chief engineer of The Sanitary District of Chicago, the writer testified on September 9, 1940, that the flow began to be budgeted very carefully in January, 1939, when the diversion was reduced to 1,500 cu ft per sec. At the same time a tabulation was introduced as Illinois exhibit No. 40, which showed the budgeting, by months, from January, 1939, through 1940, and actual results through July, 1940.

---

[7] Asst. Chf. Engr., The San. Dist. of Chicago, Chicago, Ill.

The representatives of the lake states presented their first testimony regarding remedial measures on September 12, 1940.

Langdon Pearse,[8] M. Am. Soc. C. E.—Following the denial of the petition, work on the additional final settling tanks at the West-Southwest works progressed to about 85% completion, before coming to a stop. Of the three turbo-blowers under contract on August 29, 1940, only one unit was delivered late in 1941 and erected in 1942. However, it was not operated until April, 1943, because of the impossibility of securing necessary gate valves. Twelve contracts were let in 1940–1941 on the construction program to enlarge the Southwest works and provide facilities for treating the effluent of the West Side works. This group of contracts as a whole was only about 22% completed in the fall of 1941, when World War II began. At the end of 1943, construction practically ceased. On some contracts, nothing had been done. As yet (1944) there is no sign of relaxation in priorities, allowing work to be resumed. The completion of the necessary permanent facilities to dispose of the entire production of sludge appears to be postponed indefinitely, until peace comes.

To provide temporarily for the handling of the excess sludge from the West-Southwest plants, plans were drawn for a 16-in. force main and seventy-eight acres of lagoons, about 16 ft deep, divided into sixteen units. The lagoons are located about 4.75 miles down channel from the Southwest works, between the Des Plaines River and the Main Channel. On January 22, 1942, a contract was let for 1,300 tons of cast-iron pipe. This was delivered in May, 1943.

TABLE 11.—Percentage Removal from Four Major Sewage Treatment Works

Period	Yearly Average, Percentage Removal			Average Percentage Removal in June, July, and August		
	Population equivalent (1)	5-day B.O.D. (2)	Suspended solids (3)	Population equivalent (4)	5-day B.O.D. (5)	Suspended solids (6)
1939	....	78.2[a]	82.0[a]	....	76.9[c]	82.0[c]
1940	6,200,000[b]	67.8	72.5	5,735,000	66.6	72.7
1941	6,512,000	60.6	67.5	6,540,000	61.3	69.9
1942	6,693,000	61.5	65.7	6,336,000	65.7	69.5
1943	6,594,000	57.5	62.1	6,417,900	56.0	60.1

[a] Includes Southwest works, July to December, inclusive. [b] April to December, inclusive. [c] Includes Southwest works, July and August only.

Other contracts were let in 1942 for the valves, sludge pumps, and lagoon construction; and, in 1943, for the pipe laying. The pipe line and lagoons were ready for service on November 1, 1943.

Until additional equipment and the requisite structures can be built to complete the Southwest works and supplement the West Side works, there is little chance of meeting the desired goal of a high-grade effluent from all the sewage treatment works of the Sanitary District.

---

[8] San. Engr., The San. Dist. of Chicago, Chicago, Ill.

The load reaching the four major treatment works of the Sanitary District is shown in Cols. 1 and 4, Table 11, based on population equivalents derived from the B.O.D. actually reaching the works. The 1940 census population of the Sanitary District was 3,962,514. From a total of 4,581,111 in 1940 (Cook County representing 4,063,342) the U. S. Census Bureau estimates a decrease of 32,113 (approximately 0.7%) in the population of Cook, Du Page, and Lake counties in Illinois and Lake County, Indiana, between April 1, 1940, and March, 1943.

The results of this population decrease on the Southwest works (Table 3) and the effect on the over-all efficiency of the four major works are explained in Table 12 which shows the apportionment of incoming flow to sewage receiving preliminary settling only and to sewage receiving complete treatment. Under present working conditions, the sewage receiving activated sludge treatment at the Southwest works is limited to that producing the required sludge for dewatering and drying for fertilizer, when added to the North Side sludge.

The over-all efficiency of the four major sewage treatment works of the Sanitary District is illustrated by the data in Cols. 2 and 3, Table 11. The averages for the three months of June, July, and August in Cols. 5 and 6, Table 11, are but slightly different.

TABLE 12.—APPORTIONMENT OF FLOW (IN MILLION GAL PER 24 HR), SOUTHWEST WORKS

Year or period	Preliminary only	Activated sludge	Total
1939[a]	0	282	282
1940	121	192	313
1941	184	154	338
1942	188	143	331
1943	209	143	352

[a] July to December, inclusive.

The condition of the flow from the Main Channel as it enters the Brandon Pool is reflected by the analyses at Lockport. The yearly averages are shown in Table 13(*a*) and the averages for June, July, and August are given in Table 13(*b*). Samples are not collected at the outlet end of the pool.

From September 15, 1940, to November, 1942, no sludge was discharged from the treatment works into the channels of the Sanitary District or into the tributary rivers. Because of the 10-day test in 1940, a large amount of previously deposited sludge was swept down into the Brandon Pool. Apparently conditions in the pool were somewhat worse in the summer of 1941 than in 1940; 1940 was better than 1939 or 1941. In 1942, the condition was somewhat improved over that in 1941, except that an early spring in 1942 caused nuisance conditions at Lockport in April and May, whereas in 1941, the worst month was June. In 1942, from April through November, there was no oxygen (or only a trace) present in the flow at Lockport. In 1943, the dissolved oxygen disappeared in May, and reappeared in October.

Because of the cessation of all construction, an allowed diversion of 3,500 to 5,000 cu ft per sec for the duration of the war is the only measure that is immediately available to alleviate the existing conditions in the Main Channel and Brandon Pool. Such a flow would also be helpful in the lower Illinois River below Peoria, Ill., and Pekin, Ill., where greater activity in the manufacture of alcohol from grain has increased the pollution in the river by an equivalent population of about 750,000 to 1,000,000. As a result, during the summer of 1943, the river was reported almost devoid of dissolved oxygen for a distance of 46 miles below Peoria.

TABLE 13.—Diversion from Lake Michigan and Discharge and Analyses at Lockport, Ill., 1936 to 1943, Inclusive

Year	(a) Yearly Average				(b) Average, June, July, and August			
	Cubic Feet Per Second		Parts Per Million		Cubic Feet Per Second		Parts Per Million	
	Diversion	Discharge	Dissolved oxygen	5-day B.O.D.	Diversion	Discharge	Dissolved oxygen	5-day B.O.D
1936	4,862	6,607	2.9	19.7	4,999	6,838	0.3	20.1
1937	4,989	6,677	3.1	19.0	5,448	7,247	0.1	19.5
1938	4,999	6,648	2.5	18.4	4,891	6,752	0.2	17.3
1939	1,499	3,132	0.4	26.0	1,545	3,336	0.0	30.2
1940	1,681	3,319	0.5	20.1	1,666	3,469	0.0	20.6
1941	1,496	3,341	0.2	22.8	1,929	3,795	0.0	27.7
1942	1,528	3,269	0.4	23.6	1,621	3,429	0.0	21.5
1943	1,500	3,472	0.4	24.4	2,014	3,945	0.0	24.0

Incidentally, it is of interest to note that the level of Lake Michigan has been rising since 1934 and, in August, 1943, averaged 581.47 above mean tide at New York, N. Y., as compared with a previous high monthly average of 583.49 in July, 1876.

In March, 1944, Congress had before it a resolution introduced by the Hon. A. J. Sabath, Representative from Illinois, to allow a diversion of 5,000 cu ft per sec. Hearings have been held before the Rivers and Harbors Committee of the House of Representatives.

From an entirely different angle, the Attorney General of Illinois, George F. Barrett, recently petitioned the United States Supreme Court, on behalf of Illinois, to enjoin the State of Indiana and the cities of East Chicago, Gary, Hammond, and Whiting from polluting Lake Michigan, the source of the Chicago water supply. The Court refused to dismiss the petition and on March 7, 1944, appointed a Special Master, Luther E. Smith. The polluted condition of the lake and the Grand Calumet River in Indiana has been a source of worry to sanitarians since 1909.

The moral of this story has been pointed by the poet, Robert Burns, in his saying:

> "The best laid plans o' mice and men
> Gang aft a-gley."

Certainly, periods of panic and depression and war stress have wrecked the prophecies of optimists and upset the plans for a rational program of construction and operation.

In his testimony, Mr. Buswell stated definitely that there could be odors even if nitrates were present (Record, page 1894). He also stated that "sludge banks, therefore, may prove offensive even though overlaid by a liquid containing some dissolved oxygen" and that "the Drainage Canal would become deoxygenated just as quickly if nitrates were present as if they were absent." His statement, in the discussion of this paper, that "It is important to note that all agreed that chlorination was an effective means for odor control" should be qualified since the witnesses for Illinois limited their opinion on the value of chlorine for odor control to sewage treatment works.

Mr. Howson states that "some of the procedures eventually incorporated into the Sanitary District's program were first urged by the experts for the Opposing States." The engineering staff of the Sanitary District, both regular and consulting, was well aware of the various alternatives available, but did not attempt to decide which was best, under the stress of litigation. Naturally, the staff was gratified to know that the experts for the Opposing States would not oppose certain procedures. The late Harrison P. Eddy, Past-President, Am. Soc. C. E., the late George W. Fuller and the late T. Chalkley Hatton, Members, Am. Soc. C. E., had recommended lagooning of excess sludge in 1923, antedating Mr. Howson's expression of the same idea as of 1941.

Mr. Howson compares the 1927–1928 estimates for a sewage treatment program on the basis of $176,000,000 for the Sanitary District and $76,000,000 to $82,250,000 for the lake states. The record clearly shows that such estimates are not comparable since the lake states omitted more than $46,800,000 of work, including intercepting sewers and pumping stations essential to operation. This is manifestly an incomplete program.

The intercepting sewer system is largely completed (except for the South Side and miscellaneous sewers), the North Side works are practically completed, and the Calumet works nearly completed. However, the Southwest and West Side works are not completed in the sense inferred by Mr. Howson. Lack of funds postponed vital work, so that the efficiency in removal of B.O.D. of the four major plants has averaged about 60% for 1941–1943, instead of 90% or better.

The expenditures for sewage treatment have been as follows:

Period	Actual expenditure
Prior to December 31, 1928 (as reported to U. S. Supreme Court, First Report)	$ 81,917,602.83
December 31, 1928, to December 31, 1938 (as reported to U. S. Supreme Court, Final Report, December 1, 1938)	77,877,728.87
December 31, 1938, to December 31, 1943	11,705,000.00±
Total to December 31, 1943	$171,500,000.00±

The estimated cost of the remaining work is as follows:

Types	Estimated cost
Essential (including completion of Southwest works and addition of activated sludge plant to West Side)	$ 10,500,000.00
Postponed (including South Side intercepting sewers and miscellaneous sewers)	22,940,000.00
Total	$ 33,440,000.00

Contrary to Mr. Howson who states that "Remedial Measure No. 9 'budgeting of the diversion' was also the initial suggestion of the experts for the lake states," budgeting had already been practiced by the Sanitary District as shown by Mr. Ramey's discussion.

The outcome of the litigation was happy in that certain very experimental temporary measures were vetoed by the Master, who favored the permanent work. The writer agrees heartily with the two closing paragraphs of the discussion by Mr. Johnson. To those who have contributed to the discussion the writer is grateful.

Paper No. 2222

CHARACTERISTICS OF HEAVY RAINFALL IN NEW MEXICO AND ARIZONA

By Luna B. Leopold,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. Lawrence Pratt, L. L. Harrold and A. J. Dickson, James Girand, Clarence S. Jarvis, Paul V. Hodges, Edgar E. Foster, R. W. Davenport, A. K. Showalter, Walter B. Langbein Emil P. Schuleen, and Luna B. Leopold.

Synopsis

Seasonal differences in storm types are typical of New Mexico and Arizona. Summer storms ordinarily are of small areal extent and are characterized by high-intensity rainfall in a well-defined pattern with relation to time. Winter storms cover large areas and usually are of low intensity. In this paper, results of frequency analyses of one-day rainfalls are presented for all stations in New Mexico and Arizona, the records of which exceed 15 years in length. The relation of rainfall frequency to geographic position and topographic relief are discussed, and recommendations are made for the use of these data for design purposes.

Introduction

In 1935 when the late David L. Yarnell, M. Am. Soc. C. E., published[2] an analysis of rainfall intensity-frequency data, there were only five rainfall-intensity gages in and near the states of New Mexico and Arizona, the records of which were sufficiently long to be used in the analysis. That number represented one intensity gage per 47,000 sq miles. Since then the U. S. Weather Bureau has launched an extensive program for the collection of intensity records in these, as well as in other, states, which eventually will furnish data needed for engineering designs. The data from these newly installed gages have been published consecutively since January, 1940, and have supplied basic information for studies of intensity patterns, but the records are too short for frequency studies.

To help fill the urgent need for detailed recurrence-interval data on rainfall in New Mexico and Arizona, the present study was made of the records of rainfall collected by standard nonrecording gages of the Weather Bureau.

Note.—Published in February, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Aviation Cadet, U. S. Army Air Forces, Los Angeles, Calif.

[2] "Rainfall Intensity—Frequency Data," by David L. Yarnell, *Miscellaneous Publication No. 204*, U. S. D. A. August, 1935.

In addition to data on frequency of heavy rainfalls, it usually is necessary, in the design of certain engineering structures, to assume values of area covered by the design storm and to determine a pattern of rainfall intensity before a hydrograph of runoff can be constructed. With these requisites in view, some data on areal patterns of summer storms and rainfall-intensity records were included to add to already published data pertinent to the adoption of a design storm, with particular reference to a small watershed. Due to the limited areal extent of summer-type rainfall in New Mexico and Arizona, large watersheds usually are capable of producing the largest floods as a result of prolonged rainfall covering large areas, or in these states, a typically winter-type storm.

STORM TYPES

The normal rainy seasons in the Southwestern States are July to September, inclusive, and December to March. Valley areas usually receive the highest monthly precipitation in July, August, and September, whereas in the high mountain areas the greatest monthly precipitation occurs from December through March, mostly in the form of snow. These seasonal variations in rainfall amounts are related to storm characteristics and sources of moisture.

Winter precipitation generally is the result of frontal activity associated with influx of cold air masses, modified Polar-Pacific or Polar-Continental. Polar-Pacific air picks up moisture from the ocean and moves into the Southwestern States usually as a relatively moist and cool mass that tends to underrun the warmer dry air. If the moist air mass is forced upward over the mountain ranges, continuous showers or nearly steady precipitation in the form of rain or snow is recorded over a period of 48 hr or more.

Modified Polar-Pacific air may move into Arizona and New Mexico from the south, west, or northwest. Invasion from the south or southwest often results in a relatively stationary east-west front which causes widespread, low-intensity rainfall in these states. If the moist air comes from the northwest, heavy snowfall may be recorded on the north rim of the Grand Canyon and on San Francisco peaks, followed by squalls in southeastern Arizona and southwestern New Mexico.

Polar-Continental air usually comes from the northwest and it tends to lose its moisture in northern Utah or Colorado. Such air masses are relatively dry and cold when they reach New Mexico and Arizona, and they do not constitute an important source of moisture in these states.

The Mogollon Rim, a southwest-facing escarpment extending diagonally across central Arizona, receives most of its winter precipitation from the modified Polar-Pacific air masses. This conclusion is borne out by the flood history of the Gila River which drains the Mogollon escarpment and the mountainous country of west-central Arizona and southwestern New Mexico. Generally, high winter rainfalls in the headwaters of the Gila River are preceded by rain along the southern coast of California.

The source of winter precipitation at least partly explains the fact that winter storms generally affect large areas which receive rainfall at low intensities for periods of two or three days or even a week. Although, in a general way, the total winter precipitation increases with elevation, it is influenced to a great extent by the topographic relief.

These characteristics of winter rainfall contrast with those of summer rainfall, which ordinarily is not the direct result of frontal activity. Summer storms usually are of the thunderstorm type with high intensities covering relatively small areas. Ordinarily the moisture is derived originally from the Gulf of Mexico and is carried to Mexico by subtropical easterlies where convection causes the warmth and moisture to rise to high levels over the Mexican Plateau. This air mass is deflected northward and enters the Southwestern States as a moist tongue at high levels, crossing the Mexican border usually west of El Paso, Tex., and east of Yuma, Ariz. Analyses by H. Wexler and J. Namias[3] show that the path of this moist tongue varies from one season to another, and its position is reflected in the summer rainfall in New Mexico and Arizona.

The mechanism by which this vapor is precipitated usually is a combination of convection caused by local heating of the lower layers of air, and orographic influences of topographic relief. Surface heating of the ground and adjacent layers of air during a summer day tends to increase the steepness of the lapse rate (vertical temperature gradient), and convective instability may result in local precipitation. This process usually results in instability above a mountain slope more quickly than above a valley plain, because the temperature of the ground at the two locations increases at about the same rate. Owing to the higher elevation of the point on the mountain, the vertical temperature gradient above that point is greater than that above the valley floor, and it is more probable that rain will fall on the mountain slope than over the valley.

Infrequently, sections of New Mexico and Arizona experience a general summer storm characterized by moderate rainfall over large areas and scattered local areas of heavy precipitation. Whereas the local summer storms are mostly of the convective orographic type, the general storm usually is associated with frontal activity. The effect of topographic relief is relatively small, although, together with convective lifting, it may tend to promote local high intensities in the area of general rain. Data on intensities and short-period isohyetal maps of storms of this type are meager. The most adequate discussion of such a storm is the report of the U. S. Engineer Office on the storm of August 13–14, 1940.[4]

Storms of the general type caused the floods of the Pecos and Gila rivers in September, 1941, the Bill Williams River flood of September, 1939, and the San Pedro River flood of September, 1926. In general, the available records indicate that the average intensities for durations of 1 hr or less are considerably less in the general storm than in the local summer storms. In the former type, however, the area covered by intense rainfall tends to be somewhat greater, and the rainfall extends over a longer time period. One of the main points of difference apparently lies in the importance of frontal activity as a causal factor.

[3] "Mean Monthly Isentropic Charts and Their Relation to Departures of Summer Rainfall," by H. Wexler and J. Namias, *Transactions*, Am. Geophysical Union, Pt. I, 1938, pp. 164–170.

[4] "Hydrologic Data—Storm of August 13–14, 1940, Arizona and New Mexico," mimeographed September, 1941, Los Angeles Dist., U. S. Engr. Office, Los Angeles, Calif.

Because of the relative infrequence of important storms of the general type, most of the high rainfalls experienced in 24-hr periods in summer and comprising the point-rainfall data analyzed in the present study may be assumed to be of the local storm type. Because of the lack of data, adequate analyses of the area covered by the different storm types are not included in this paper, and thus the recurrence-interval data presented subsequently in Tables 2 and 3 are primarily applicable for design purposes to small watersheds.

AREAL PATTERN OF SUMMER STORMS

The relatively great instability in mountainous country at least partly explains the areal distribution of summer rains in the basin and range topography typical of many parts of New Mexico and Arizona. Rainfall records show that summer rainfall in the valley areas and at the base of the mountains is erratic and spotty, whereas at the crest of the higher mountains the total summer rainfall tends to be similar at all points of a given elevation and tends to increase with elevation. Field observations indicate that in any one summer storm the center of greatest precipitation usually is near the base of the mountain slope.

The areal extent of ordinary summer thunderstorms in New Mexico and Arizona is extremely variable, but the center of high intensity is usually about 5,000 acres. It is important to note, however, that many storms of relatively small area occur nearly simultaneously at widely separated points within an area as large as the State of New Mexico. Storms at any particular location evidently are associated with relatively widespread instability, or the influx of moisture into the entire region. Inspection of any monthly summary of precipitation published in *Climatological Data*[5] shows the regional coincidence of rainfall, but studies of the storms at any given station demonstrate that the storms were separate entities of small areal extent.

There is some evidence that the area covered by rainfall in a given summer storm increases with the total precipitation in the storm center, but only a few good isohyetal maps of individual storms are available. It appears certain that the storms occurring in east-central and southeastern New Mexico in the Pecos River basin cover larger areas than storms in any other section of the two states, and also any given amount of storm rainfall occurs there more frequently than in other sections of these states. This presumably may be attributed to the proximity of the Pecos River basin to the source of summer moisture, the Gulf of Mexico, and to the fact that the Pecos area sometimes is subject to the marginal effects of tropical hurricane disturbances that move into Texas from the Gulf.

Samples of the depth-area data available for local summer storms are presented in Table 1. Storm movement and lack of intensity data for various points within the storm area render this type of depth-area data inadequate for making assumptions of the depth-area-time pattern for a design storm, but in most sections of the Southwestern States no better data than the samples

in Table 1 are available. A complete report of depth-area-time relations of storms of these states must await the collection of more records.

RAINFALL INTENSITY

Winter-type storms in New Mexico and Arizona usually produce rainfall at relatively low intensities. Summer rainfalls of the thunderstorm type characteristically are intense and of short duration, with the period of highest intensity at, or soon after, the beginning of rainfall. Except in unusual cases, the periods of high intensity are separated by lulls in the downpour, the period of uninterrupted intense rain lasting less than one-half hour. In practically all cases the intensity decreases more or less gradually to the end of the rain. Mass curves of the most intense rainfalls on record at recording gages in New Mexico and Arizona are plotted in Fig. 1(*a*). Many summer rains have some low intensity fall prior to the most intense portion, but in general the curves in Fig. 1(*a*) are representative of the heaviest rains recorded in the Southwest. It is important to note the general similarity of pattern of mass curves of storms from widely separated localities.

From the records of beginning and ending of rainfall observed at Weather Bureau stations where standard rain gages are used, it is possible to collect additional records of heavy rainfalls of short duration. Fig. 1(*b*) presents the results of a systematic search through the original records of 162 stations in New Mexico, comprising 4,656 station-years and certain additional Arizona records, in an effort to determine the minimum duration of heavy rainfalls. The key to numbered points is given in Table 2. No rain less than 2.00 in. or of durations greater than 14 hr is platted, and many 4-in. rains of duration greater than 6 hr are omitted. The envelope curve drawn in Fig. 1(*b*) indicates the maximum rainfall of a given duration that might reasonably be expected in the Southwestern States.

The mass curves of Fig. 1(*a*) indicate the type of intensity pattern that probably comprised the rainfall totals shown in Fig. 1(*b*), and from these two graphs an approximate rainfall histogram can readily be taken for purposes of hydraulic design of engineering structures. It is important to note that none of the rains platted in Fig. 1(*b*) occurred in midwinter, and relatively few occurred outside the season of summer rains, July to September. It may be surmised from this fact that most of these intense rains covered relatively small areas, typical of summer-type storms.

SEASONAL DISTRIBUTION OF HIGH RAINFALLS

A separate analysis furnishes additional information on the seasonal distribution of high rainfalls. A tabulation was made of all rainfalls exceeding 2.00 in. in a 1-day period for 268 stations in the two states, comprising a total of 7,048 station-years of record. Stations were grouped into eight general regions by dividing each state approximately into four quadrants. For each region, rainfall depths were platted against the day of the year on which each occurred. An index was thus derived that weights both the frequency and magnitude of high rains, and is platted for the four regions in New Mexico and four regions in Arizona in Fig. 2.

The index was derived by dividing the year into periods of ten consecutive days, and the rainfall magnitude into categories of half inches, beginning with 2.00 to 2.50 in., 2.50 to 3.00 in., and so forth. For a given 10-day period including all stations, the number of rainfalls that fell in each magnitude category was multiplied by the average value of the magnitude category, and the sum of the products times 100, divided by the station-years of record for the region, was used as the index of magnitude-frequency. For example, in the upper Gila River and southeastern Arizona area, 35 stations were used, comprising 976 station-years of record. Between January 1 and January 10, there were five rains between 2.00 in. and 2.50 in. in magnitude, and one rain between

	(a) New Mexico; Number of:	Stations	Station-years

8	Upper Gila River watershed and southeastern Arizona	35	976

Index Derived from Rains Exceeding 2.00 In. in One Day)

5.50 in. and 6.00 in. The index platted at the midpoint of the period January 1 to 10 was $100 \times \frac{(5 \times 2.25) + (1 \times 5.75)}{976} = 1.74$.

It was necessary to divide by the number of station-years of record to make the computed indexes of the various regions comparable for platting, and the multiplication by the arbitrary value 100 was simply for the purpose of making the platted indexes whole numbers to facilitate platting and comparison.

The platted indexes in Fig. 2 show that the eastern section of New Mexico experiences high rainfalls more frequently than the western section of the state; but all sections receive high rainfalls predominantly in the summer and fall seasons, whereas November through March is comparatively free of heavy rainfalls. The heaviest rainfalls in western New Mexico occur between the first of July and the middle of August, and again in mid-September.

In Arizona, however, all regions except the northeast quadrant have a high index in summer, whereas in winter only the southeast and northwest quadrants have high indexes. These differences can be explained by the relation of topography, geographic position, and source of moisture. It was stated previously that summer moisture originates in the Gulf of Mexico and moves into New Mexico and Arizona primarily from the south, and that the Pecos Area in southeastern New Mexico sometimes is affected by tropical disturbances that cause great rainfalls in southern and central Texas. It may be expected, therefore, that the eastern section of the state would experience more high rains than the western because of the proximity to the source of moisture.

The southwestern section of New Mexico has a higher frequency-magnitude index than the northwest, since the latter is in the rain shadow of the mountainous southwestern section.

The index for regions in Arizona in summer is highest in the mountainous southeast and northwest quadrants, which can be related to the effect of topography. The index for southwestern Arizona is high in midsummer—July and August—because of the convective storms that are common over the desert at that season. Northeastern Arizona is on the plateau in the rain shadow of the Mogollon Rim and the mountainous central belt, and probably for this reason the index is low.

In winter, when moisture is derived from the Pacific Ocean and moves in primarily from the Southwest, the frequency-magnitude index should be high only for the mountainous sections of Arizona, the southeast and northwest quadrants, and relatively low in other areas and in New Mexico. The present study supports this hypothesis.

Frequency of High Rainfalls

Recurrence-interval curves were drawn for each standard rain-gage station in New Mexico and Arizona whose records exceed 15 years, and for certain stations of shorter record, in order to derive values of 24-hr rainfall that may be expected to be equaled or exceeded in a given period of years. These data are useful in the design of engineering structures, especially where it is necessary to design for a rain greater than has been experienced in the past. The data also indicate the recurrence-interval of rainfalls that have occurred in the past.

In this analysis the highest one-day rainfall in each year of record at the station was tabulated, the data arranged in order of magnitude, and the curve platted by the "exceedance interval," or "California," method. From the platted curves, the 24-hr rainfall that probably will be equaled or exceeded in 5, 10, 15, 20, 35, 50, 75, and 100 years, was tabulated and the data are presented in Table 3(*a*) for New Mexico stations and Table 3(*b*) for Arizona stations.

The rainfall data used were recorded by standard nonrecording rain gages maintained by the Weather Bureau. The rainfall depths were taken from the original records on which, in about half the cases, the observer had noted the time of beginning and time of ending of the precipitation. By use of these notations of times it was possible to ascertain the greatest rainfall in a 24-hr period, which was the value used in the frequency array wherever possible. Particularly in the case of summer rain, the precipitation often starts in mid-afternoon and ends during the night, which is a period of less than 24 hr. Many observers read the gage at sunset; so, in the foregoing example, if no rain fell on the day following, the sum of the two sunset readings equaled the amount that fell in a 24-hr period. Rains continuing through two or more days could not be broken down accurately to determine the largest amount in a 24-hr period and, therefore, the largest amount recorded for one day was used in the recurrence-interval array. The method used approximates, closely, the actually greatest fall in a 24-hr period, since a large percentage of the high rains fell in summer and lasted less than 24 hr.

The characteristics of summer and non-summer precipitation were considered sufficiently distinct and important to warrant separation in the recurrence-interval determinations. Arrays were made separately for the highest rainfall recorded each year between June 1 and September 30 (the summer period), and the highest rain recorded in each complete year. Certain stations may be expected to experience the same 24-hr rainfall at a given recurrence-interval in summer as they will experience in the entire year as can be seen in the tabulations of 50, 75, and 100-yr frequencies. This simply indicates that that station characteristically received the largest 24-hr rainfalls in the summer period and, therefore, the recurrence-interval curves for summer and all year would be practically identical.

Winter values of rainfall amounts probably are somewhat less accurate than summer values owing to the effect of snow. One source of error was the failure of a gage to catch the full snowfall, but probably a more important error was introduced by the general policy of assuming that 1 in. of snow equaled 0.10 in. of precipitation in the form of water. Investigations by the Weather Bureau indicate that, in particular instances, much larger amounts of precipitation were assumed by the use of this policy than actually fell.

The compilation of a recurrence-interval array necessarily involves some exercise of judgment. In many cases, particular months were missing from a

[1] Average of the maximum 1-day rain recorded for the

[2] Average of the maximum 1-day rain recorded in each

[3] Some missing months interpolated from surrounding

given year, in which case it was necessary to decide whether to include the year. The decision was made after inspection of the complete record to determine what quantity constituted a high rainfall at that station. Depending on the number and season of the missing months, the year was included in the array if it appeared probable that the available record included the day of highest rainfall for the year.

If the data do not plat as a straight line in the recurrence-interval curve, the relatively few widely-spaced points in the upper limits of the series determine how the curve will be drawn and will control the extrapolation. In this study two curves (summer and all-year) were drawn for each of 283 stations. They represent stations in all kinds of topography in regions of average annual precipitation varying from 8 to 30 in. By far the most important factor affecting the extrapolation of the curves was neither the manner of choosing the series, nor the length of record, but the occurrence of aberrant points in the upper limits of the series. When such an aberrancy occurred the position of the curve was mostly a matter of judgment.

In the Southwestern States there is great variability in both the average annual precipitation and in the magnitude of the highest one-day rainfalls that occur in successive years. One year may include a number of heavy rainfalls and may have a high total precipitation, whereas the following year may be dry, with no high rains. To demonstrate this variability the heaviest rain of record each year was used in the present analysis. The recurrence-interval array, therefore, is comparable to the method used by the late Allen Hazen,[6] M. Am. Soc. C. E., in which he computed from stream-flow records

---

the highest peak discharge each year of record, the average of which he termed "average annual flood." In Table 3, the data on the average of highest rainfall each summer and of highest rainfall each year are comparable to Mr. Hazen's "average annual flood."

ISOPLUVIAL MAPS

The isopluvial maps published by Mr. Yarnell[2] were based on five stations in the Southwestern States. In spite of the fact that the present analysis includes frequency curves for 283 stations in the same region, due to marked variation in frequency curves for closely adjacent stations of comparable records, isopluvial maps are difficult to construct. This difficulty can be attributed to a number of facts. Owing to the great divergence in topographic relief between closely adjacent points, two stations within a very short distance of one another may be in very different topographic settings. One may be in the middle of a broad, flat plain, the other in a deep, narrow mountain canyon. It appears from the present analysis that stations above El. 7500 experience relatively few high rainfalls. This indicates that elevation above sea level has some effect on the frequency characteristics, although ruggedness of relief and position of the station in relation to the source of moisture and the surrounding mountainous areas probably are of more direct importance.

The small areal extent of high rainfalls occurring in summer-type storms is a factor leading to differences between stations since any high-intensity, individual storm rarely is recorded at more than one station.

The 24-hr rainfall quantity expected to be equaled or exceeded once in 50 years at various stations in relation to topography is shown by the relief maps

FIG. 4.—NEW MEXICO: 24-HR RAINFALL EXPECTED TO BE EQUALED OR EXCEEDED ONCE IN 50 YEARS

of Figs. 3 and 4. These maps demonstrate the variability of the recurrence-interval figure between closely adjacent stations, and they indicate the position of the stations relative to the major mountain masses. Stations in deep mountain valleys, for the most part, are shielded from the effect of moisture-bearing air masses moving into the area and tend to have low rainfall expectancy. This is not true in all cases, but the relief apparently offers sufficient explanation for the relative magnitude of the recurrence-interval figure for certain stations. In other cases, two stations in apparently similar topographic positions have quite different expectancies.

In spite of these differences between individual stations, certain general patterns of rainfall expectancies are apparent in New Mexico and Arizona. The area in southeastern New Mexico, particularly along the eastern flanks of the Delaware, Sacramento, and Capitan mountains, is subject to high rainfalls because summer moisture moving in from the south or southwest impinges on these topographic barriers. The same is true for northeastern New Mexico: In the central Pecos watershed no important topographic barrier obstructs the moisture-bearing winds south of the relatively rugged country in the headwaters of the Pecos and Canadian rivers.

The Black Range between Silver City and Hillsboro in southwestern New Mexico forms a barrier to south winds and protects northwestern New Mexico from high rainfalls. Stations in the Rio Grande Valley as far north as Albuquerque, N. Mex., however, are subject to high rains from moisture moving up the valley.

In Arizona, the mountainous area of the central and northwestern portion, particularly along the Mogollon and Yarnell escarpments, is subject to high rainfalls and tends to protect or shadow the northeastern plateau country.

These relationships can be easily visualized by inspection of Figs. 3 and 4. From these generalized relations an isopluvial map for 50-yr frequency has been drawn and is presented in Fig. 5. No attempt was made in the preparation of this map to draw each "isopluve" in the exact position indicated by the computed value for each individual station, but the lines were generalized to indicate broadly the comparative expectancies of various regions.

In the use of the recurrence-interval data presented herewith, engineers are cautioned to compare the topography and position of the point for which a recurrence-interval value is desired with those factors affecting all stations near the particular point. Moreover, it must be remembered that the data presented are for a 24-hr period, but in the summer type of rainfalls, the maximum rainfall in 24 hr probably fell in a much shorter period of time. The value of total storm rainfall for a given recurrence-interval in the summer period may be used in connection with average intensity-time patterns for the purpose of designing engineering structures.

Applicability of Station-Year Analysis

One method of ironing out differences between recurrence-interval curves of adjacent stations and improving the value of short records is a combination of stations by the station-year method. The requirements for use of this method discussed by H. C. S. Thom[7] and Katharine Clarke-Hafstad[8] may be summarized as follows:

(1) Stations grouped must be mutually independent—that is, far enough apart so that no single storm covers more than one of the stations; and

(2) Stations grouped must be included in a meterologically homogeneous region.

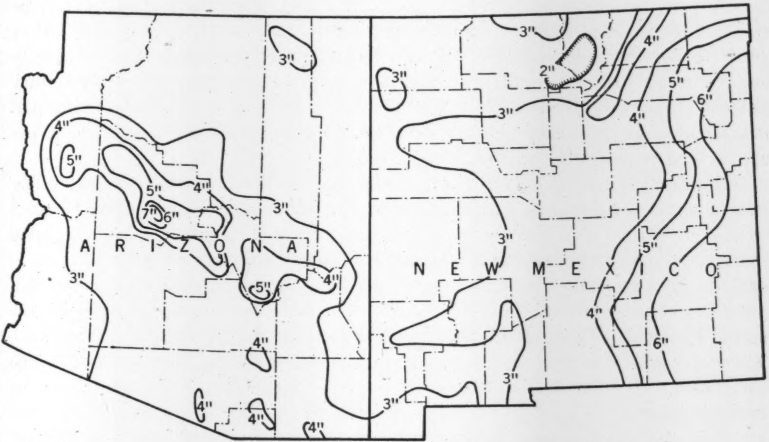

FIG. 5.—ISOPLUVIAL MAP OF ARIZONA AND NEW MEXICO (24-HR RAIN EQUALED OR EXCEEDED ONCE IN 50 YEARS)

Mr. Thom defines a meteorologically homogeneous region as an area each point of which would have identical frequency curves of rainfall. He states that delineation of such a region by this criterion is impractical since "assignable causes," such as topographic differences, operate to produce dissimilarity of rainfall experience at various points within the region; and he suggests, therefore, that homogeneity must be established by meteorological studies. Assignable causes operate in the following way: A storm situation, one favorable for rain, prevailing over a region may be so weak that rainfall occurs only at points that are subject to significant orographic effects, and these stations, over a long period, would therefore experience more rainy days than do stations with assignable causes of lesser magnitude.

Although it is possible, in New Mexico and Arizona, to delineate meteorologically homogeneous areas defined by meteorologic studies, recurrence-interval curves at various stations within such a region may be so different that assignable causes appear to operate in these states to such an extent that there may be more difference between curves of stations within the homogeneous area than between two stations in dissimilar meteorologic regions.

[7] "On the Statistical Analysis of Rainfall Data," by Herbert C. S. Thom, *Transactions*, Am. Geophysical Union, Pt. II, 1940, pp. 490–499.

[8] "Reliability of the Station-Year Rainfall-Frequency Determinations," by Katharine Clarke-Hafstad, *Transactions*, Am. Soc. C. E., Vol. 107 (1942), p. 633.

Examples of station-year groupings were platted in connection with the present study. It did not appear satisfactory to group stations by the station-year method, although the stations were in meteorologically similar regions, inasmuch as the frequency curves were so distinctly different.

Comparison of Magnitude of 1-Day, 2-Day, and 3-Day Rains

In the use of frequency-magnitude data for design, it usually is necessary to apply an intensity pattern to a given rainfall total. In general, it may be stated that in New Mexico and Arizona summer rainfall depths published as 24-hr totals characteristically fall in a period much less than 24 hr—usually less than 10 hr. Since design storms ordinarily are assigned an intensity pattern that would result in relatively high stream discharge, the rainfall magnitudes for summer listed in Table 3 logically may be used with the characteristic intensity patterns presented in Fig. 1(*a*).

The great winter floods in these states are the result of rainfalls extending over a period of days, as was the case in the flood of the upper Gila River in January, 1916. For the determination of the probability of long-duration storms, the recurrence-interval of various total amounts of precipitation in periods greater than 24 hr was derived by tabulating the highest rainfall amounts each year that fell on two or three consecutive days, arranging the terms in order of magnitude, and platting as in the studies of 24-hr rains. These arrays were prepared for a limited number of stations, each of which was chosen to represent a certain area with characteristic topographic relief and elevation.

This analysis showed that the ratio of the total rainfall in a 48-hr period to that falling in a 24-hr period is essentially constant regardless of the recurrence-interval of the rain, and similarly, the ratio of 72-hr total to 24-hr is approximately constant. At any given recurrence-interval the amount of rain in any consecutive 48-hr period is about 10% to 20% greater than the 24-hr amount expected, and the total for any 72 consecutive-hr period is 20% to 30% greater than the amount in 24 hr.

These ratios are only an indication of the relation between 1-day, 2-day, and 3-day rains, since the present analysis did not include sufficiently detailed studies of long-duration rains and winter intensity patterns to form the basis for positive statements on this subject. The rains experienced in the Pecos River watershed of eastern New Mexico in September, 1941, indicate that, at least in that section of the state, summer-type rainfalls of very high amounts may fall on two consecutive days.

Acknowledgments

The writer gratefully acknowledges the assistance of Thomas Maddock, Jr., for suggestions during the progress of the study, B. T. Mitchell in checking original records, and a number of workers of the Work Projects Administration, principally the late E. F. Blanchard, who copied data from the original observers' records and assisted in the frequency tabulations. The cooperation of E. L. Hardy and G. K. Greening, U. S. Weather Bureau, in allowing access to the original records of cooperative observers is appreciated.

DISCUSSION

Lawrence Pratt,[9] Assoc. M. Am. Soc. C. E.—Engineers of the Southwest will find this paper a valuable compilation of 1-day rainfall records, supplementing the previous work of Mr. Yarnell.[2]

It has been observed at Tucson, Ariz., that, for a period of six to eight weeks during July and August, thunderstorms are of almost daily occurrence. A notable feature of these storms is the punctuality of their appearance. About 10:00 a.m. high cumulus "thunderheads" appear in the northwest and mount rapidly to the zenith. The first drops of rain may be expected about 2:00 p.m. but within another 2 hr the storm will have passed and the sun will be shining again. The first raindrops are very large, making splashes on the ground the size of silver dollars, but quickly becoming smaller. Probably the heaviest intensity during the storm occurs within the first 15 min. Each storm is accompanied by a sharp temperature drop of 20° to 30°, and there may or may not be a strong northwest wind.

Another type of storm which may be peculiar to southern Arizona and southern New Mexico is the "duster" which occurs in early and late summer. This is characterized by a persistent wind which at times reaches a high velocity and which carries great quantities of dust. The usual duration of this storm is 3 days. The wind increases in velocity from day to day and the storm culminates in a thundershower which may last no longer than 30 min. It is hoped that the author will explain the meteorological aspects of this type of storm.

From the summit of Bill Williams Mountain, 4 miles south, and 2,500 ft above Williams, Ariz., the writer had an opportunity to observe weather phenomena throughout one summer. On certain days as many as four separate and apparently independent thunderstorms were seen at the same time, moving from west to east over the plateau which reaches north to the Grand Canyon. These storms were of small extent, with sharply defined boundaries, covering from 1 to perhaps 4 or 5 sq miles.

Because of the limited area and short duration of high-intensity summer storms, the problem of deducing runoff from rainfall is complicated. Only the smaller drainage basins have times of concentration sufficiently short to coincide with the times of precipitation of the storms, although local flash floods may be produced occasionally even in streams of considerable drainage area. However, notable floods on the larger rivers, the Colorado, Rio Grande, Pecos, and Gila, are generally associated with winter storms of low intensity, wide extent, and long duration.

The danger of using 24-hr records from nonrecording rain gages should be emphasized. Unless the times of beginning and ending of precipitation are noted carefully at the time of observation, the total rainfall is of little value in any intensity study.

---

[9] Los Angeles, Calif.

L. L. HARROLD,[10] ASSOC. M. AM. SOC. C. E., AND A. J. DICKSON,[11] ESQ. —The data presented by the author will be very useful to engineers engaged in hydraulic designs for the arid Southwest region. The writers have had occasion to make a concentrated tabulation and study of the type of rainfall reported in this paper.

The statement under the heading, "Storm Types," that "Valley areas usually receive the highest monthly precipitation in July, August, and September * * *" is assumed to mean that the precipitation in these months is usually higher than values for other months of the year. The records at the Navajo Experiment Station, Mexican Springs, N. Mex., verify this conclusion. Furthermore, the mountain gages at this research station usually record more monthly rainfall for these three months than for the other months of the year. This is contrary to the author's findings which probably are based on records from areas in Arizona and New Mexico where the winter snowfall is greater than at this research station. It is true, however, that the winter precipitation, December through March, at the higher elevations is significantly greater than that for the valley areas.

The data on areal extent of various quantities of summer rainfall (Table 1) are of great value even though rain gages were spaced rather far apart to delineate the limits of these areas adequately. The areal extent of summer storms over the watersheds of the Navajo Experiment Station (Fig. 6), 25 miles north of Gallup, N. Mex., cannot be well defined at all times although each of 83 rain gages represents an area of only 0.8 sq mile. Fig. 7 shows isohyetal lines for the total rainfall of the storm of August 6, 1941, a typical summer storm. It can be seen that the position of these isohyets would be entirely different if there were fewer gages so that each rain gage represented 10 sq miles. In areas where the gages are spaced 10 to 100 miles or more apart, it is no wonder that so little is known of the occurrence and distribution of summer storms. It is believed that on the Navajo Experiment Station there are more recording rain gages per unit than on any other area of the same size or larger in this region. These gages are operated in connection with runoff stations for the purpose of studying rainfall-runoff relations, land use, and water spreading. A description of some summer storms for 1941 on this experimental area is given elsewhere.[12,13]

The records at this station confirm the author's statement (see heading, "Storm Types") that "The effect of topographic relief is relatively small * * *." They do not, however, tend to confirm his statement under the heading, "Areal Pattern of Summer Storms," that "* * * in any one summer storm the center of greatest precipitation usually is near the base of the mountain slope." On the Navajo Experiment Station area, elevations range from 6,200 to 8,800 ft, and, during 1941, six storms had thirteen different centers of greatest pre-

cipitation (Table 4). Eight of the thirteen centers were at elevations of from 7,000 to 8,000 ft and three were below and two above this range.

The author's conclusion (see heading, "Isopluvial Maps") "* * * that stations above El. 7500 experience relatively few high rainfalls" may be influenced largely by the fact that there were but few gages above this elevation. At this station, six out of thirteen centers of greatest precipitation were above El. 7500 (see Table 4).

FIG. 7.—ISOHYETAL MAP OF TOTAL RAINFALL FOR STORM OF AUGUST 6, 1941, NAVAJO EXPERIMENT STATION, MEXICAN SPRINGS, N. MEX.

The maximum point of rainfall for one day recorded on the experimental watershed during 1941 was 2.40 in. at gage D1 (Fig. 6). This corresponds to a storm of about a 10-yr to 15-yr recurrence according to the Tohatchi record in Table 3. Tohatchi is 7 miles northeast of the experimental watershed. According to the scale of the author's data in Table 3 for Tohatchi, the experimental watershed recorded three storms in 1941 having a 10-yr to 15-yr recurrence and two storms having a 5-yr recurrence. Some day it will be possible to give recurrence intervals for time-area-depth curves. Until such time engineers will have to be content with recurrence intervals for point rainfall records, which are none too satisfactory.

The author's statement that (see heading, "Isopluvial Maps") "* * * any high-intensity, individual storm rarely is recorded at more than one station" is obviously dependent on the spacing of rain gages. At this experiment station, where the gages are spaced about 1 mile apart, the following amounts, in inches, for the storm of July 23, 1941, were recorded at different gages: (2.40), (2.05), (2.02), (1.82), 1.73, 1.50, 1.39, and 1.07, in which values in parentheses belong to the same storm center.

[a] See Fig. 6.

This discussion is presented to emphasize the need for additional information on the behavior of summer storms of high intensity. As these storms are extremely erratic in time and areal distribution, the need can only be met by a rather concentrated network of recording rain gages operated over a long period. In order to give adequate areal coverage for deriving time-area-depth curves, it is estimated that the gages should be spaced 1 or 2 miles apart and the network should extend over roughly 250 sq miles.

JAMES GIRAND,[14] ASSOC. M. AM. SOC. C. E.—The utilization of meteorologic data in the design of engineering projects always has been surrounded with uncertainties. The engineer approaches his problem with the conviction that some definite correlation between the rainfall records and the runoff data does exist. To establish a proof that will satisfy design requirements is another matter. It is apparent that any relations that do exist are highly complex, requiring the greatest perseverance to discover.

The author was fortunate in having available to him a relief project furnishing the large number of man-hours necessary to make a detailed study of a vast amount of rainfall data. This man power is seldom available to the designing engineer. The publication of the results of these studies is doubly valuable in that it opens a vista of the possibilities of further study and also develops definite information as to what continuing data should be collected. As the science of analyzing climatological data progresses, it should be possible to induce the Weather Bureau to collect its records in the most useful form. Eventually a card system might be devised so that these studies could be made with tabulating machines instead of such great expenditures in man-hours.

The interpretation of weather data is essentially a laborious process requiring a great amount of time and energy; but before this process can be set in motion, it is necessary to determine the basis upon which the analysis is to be made, the result to be sought, and the method of assembling and analyzing the recorded data. The author has not given a sufficiently complete exposition of the various assumptions and methods involved for others to apply his methods.

---

[14] Cons. Engr., Phoenix, Ariz.

Weather data are basically erratic and unreliable. The use of short-term or broken weather records is extremely hazardous. However, meteorologic observations can be valuable when carefully analyzed so that the weight of numbers will offset the individual errors. This effect of erratic records is quite apparent in Table 3 under stations 206, 207, and 209, for Granite Reef Dam, Casa Grande, and Florence, respectively. These stations are about 25 miles apart and are similarly situated in regard to topographic features. However, Table 3 indicates that the one-day rainfall that probably will be reached or exceeded once in a hundred years is 2.50, 6.00, and 2.09 in., respectively. Obviously such wide variation could not be expected at three

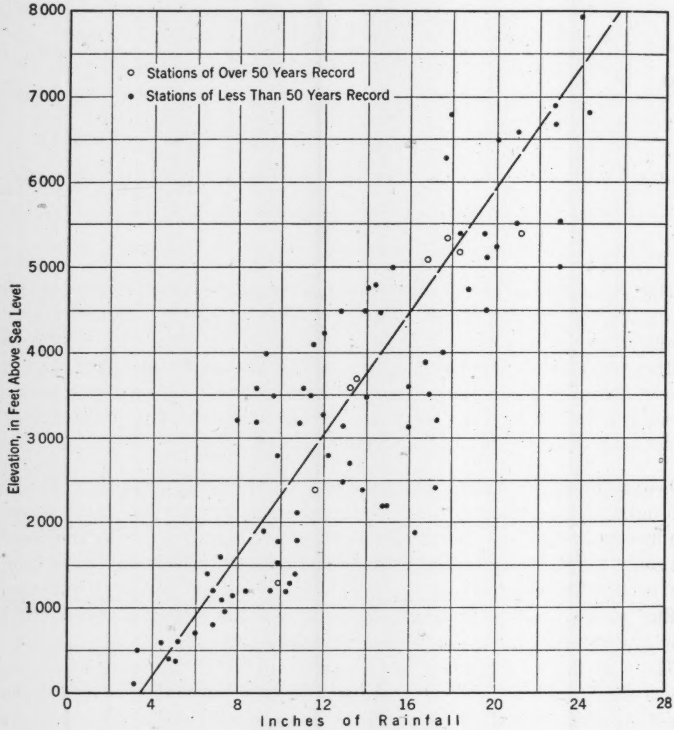

FIG. 8.—RAINFALL IN ARIZONA

similar stations so closely grouped. This divergence is accounted for possibly by erratic records. Further examination shows that the author predicted 5-yr storms for the same stations to be 1.64, 1.63, and 1.72 in., respectively. These latter values appear reasonable.

The effect of elevation on rainfall in the Southwest is a field that deserves further study. The author touches on this by stating "rainfall * * * tends to increase with elevation," but he fails to investigate further. The writer's conclusion, based on numerous studies in Arizona, is that the rainfall is almost exactly proportional to the elevation, as shown in Fig. 8. It is surprising how close a relation is shown, particularly in the long-record stations. These studies seem to indicate that topographic influences are not as important as might be concluded from limited observations. If the relation between elevation and rainfall were introduced into the author's studies, more consistent and satisfactory results might be obtained.

The correlation of observation stations and elimination of erratic data should be the first steps in any rainfall-runoff study. Short-term or broken records should be correlated to that of the longest-term record available. When such a correlation is made, the probability curves of all similar stations will have the same shape and slope. The final results will then be consistent and will represent the nearest approach to an accurate solution.

In many cases it may be desirable to go beyond the terms of available records by some other method, such as the tree-ring technique of A. E. Douglass,[15] as applied by John Girand,[16] Assoc. M. Am. Soc. C. E. By such devices it is possible to ascertain whether the available records represent normal conditions, or periods of excessive drought or flood. Accurate predictions must be based on a complete knowledge of whether the data extrapolated represent normal, wet, or dry years. The tree-ring technique has demonstrated the periodic recurrence of an excessive drought in Arizona at 300-yr intervals. This is highly important to the irrigation or water supply engineer. The presence of long-term periodic floods has not been proved adequately. For flood studies it is possible that existing rainfall records, some of which exceed 70 years, may be adequate as a base from which to predict future floods. The use of any shorter base is certain to lead to erroneous results.

Another valuable field of research would be to amplify the results shown in Table 1. The author's work and results, as set forth in Fig. 5, are for small watersheds. For the design of structures other than the smallest, it is essential that some relationship be found in terms of watershed area. The use of these figures for watersheds of even limited extent would lead to astronomical runoffs.

The author has made a substantial contribution to rainfall studies and it is hoped that he will be able to continue this work after he returns from duty with the armed forces. It is also to be hoped that, in the future, through various governmental agencies, the man power will be made available to the engineering profession for detailed studies such as this.

Clarence S. Jarvis,[17] M. Am. Soc. C. E.—No matter how many hours were required to assemble and analyze those hundreds of station records for the two states, comprising more than 7,000 station-years, full recompense is realized in the third from the last paragraph of the noteworthy paper under discussion. To be able to state with definite assurance that two-day rainfalls for any given recurrence interval may be taken as 10% to 20% greater than for the 24-hr record depth, or 20% to 30% greater for a three-day period, is proof of a notable achievement by the author.

The impressive array of authoritative information shown on both the relief maps and the isopluvial maps of the two states marks additional steps forward toward a firm grasp and understanding of a subject hitherto regarded as too vague and irregular for actual analysis and classification.

The writer recalls his personal observations at the Grand Canyon of the Colorado River one summer afternoon, when six or more distinct showers were in progress, moving like gray curtains against the backgrounds of intervening blue sky or red sandstone formation. Although there was no way of determining the actual intensity of each disturbance, it was noted that some of the curtains were like gauze, whereas others were nearly opaque. Presumably, other than orographic influences determined which storm centers should yield with high intensity; for all of the cloud forms were high above the canyon rims, and still higher above the areas of precipitation, which were almost invariably within the confines of the chasm.

Having been permitted to review the early draft of the paper under discussion, and having noted the distinct improvements accomplished by the author, it is the writer's pleasure to enumerate some of the distinctive modifications:

(1) Reduction of the number of objectives;

(2) Unification of effort toward those tangible, simple objectives;

(3) Elimination of such features as might have afforded something of a diversion without particularly strengthening the main thesis;

(4) Employment of graphical presentation at its best for the immediate purposes;

(5) According as much prominence to the deficiencies in basic hydrologic data as to the wealth of records discussed in the textual paragraphs; and

(6) Securing the most effective teamwork from both those in charge of the precipitation records, and those making the necessary transcriptions and orderly tabulations. This should amount to a guarantee as to the correctness of data used and summarized.

It is the writer's belief that the author will be able to extend the generalizations in his closure to great advantage. More of that kind of scientific contribution and discussion is needed, especially where the field has yielded so readily to a patiently conducted, yet masterly, approach.

Paul V. Hodges,[18] M. Am. Soc. C. E.—The assembly and analysis of rainfall records from the many stations, together with the characteristics of certain heavy storms, add a great amount of valuable data to the somewhat meager information available for this area. In Table 3, the summer rains, as the author states, usually occur in periods of less than 10 hr, and therefore this fact should be considered in the use of the table for flood studies.

---

[17] Hydr. Engr., With Office, Chf. of Engrs., U. S. Army, Washington, D. C.

[18] Care, U. S. Engrs. Office, Omaha, Nebr.

The shorter the period of rainfall, the greater the number of rains, probably, in inverse proportion to the rainfall period; whereas summer rains of one or two days would be relatively infrequent.

An example of a rainfall of long duration is the storm producing the San Pedro River flood of September 28, 1926, which had a momentary peak discharge of 98,000 cu ft per sec and a calendar-day discharge of 28,800 cu ft per sec at Fairbank station. The average precipitation over the basin for a 7-day period (September 24 to 30) was 5.04 in., producing a runoff at the Fairbank station of 110,000 acre-ft or 1.38-in. depth over the area during the same period—that is, 27.4% of the precipitation.

From a study of the record flood flows of the upper Gila Basin, a formula representing the relation of momentary peak discharge in cubic feet per second to drainage area in square miles was derived.

The formula $Q = 2{,}070\,A^{0.44}$ represents the maximum recorded floods of the larger rivers, and about the average of flood estimates of many small tributaries. This formula gives the following peak discharge:

A, in square miles	Discharge, in cubic feet per second	Discharge, in inches per hour
1	2,070	3.20
5	4,200	1.30
10	5,700	0.88
20	7,700	0.60
30	9,250	0.48
50	11,600	0.36
100	15,700	0.24

Summer rains are very erratic in size and location, and records at any one station would include but a small percentage of the total number of storms, and those of the highest intensity would very rarely be recorded or measured at any particular station. For this reason the data, for most of the stations, are considered insufficient for determining the maximum rainfall to be expected over long periods of time.

The isopluvial map of New Mexico as developed in Fig. 5 shows higher 24-hr rain than that indicated for western Texas by the probability chart for 50-yr frequency, shown in "Excessive Rainfall in Texas."[19] This is due, no doubt, to the longer record available to the author.

The writer made a study of the rainfall and runoff of the upper Gila River Basin in Arizona and New Mexico (unpublished report of August 14, 1936), in which he determined the average precipitation for different periods of the year, for the precipitation stations having 19 to 38 years of record. It was determined that the average precipitation for the month of July was more than three times the monthly winter precipitation on an average, and that the average precipitation during July, August, and September was greater than that for any other period, being 48% of the yearly total for all stations during periods of record.

---

[19] *Bulletin No. 25*, State of Texas, Reclamation Dept., November, 1934, p. 110.

The average number of days with a precipitation of 0.01 in. or more was computed for the 15 upper basin stations having a station-year record of 315 years. The distribution and average number of days, for different periods of the year, were found to be:

Period	Average number of days	Percentages
April to June	7.48	13.7
July to September	24.22	44.5
October to March	22.80	41.8
Twelve months	54.50	100.0

From this study it seems that the summer storms have a greater daily precipitation than other storms; that is, the summer storms, representing 44.5% of occurrences, produce 48% of the annual precipitation.

Mr. Leopold has presented much information of great value on intensity and the occurrence of rains at the various stations. Although the data for some of the stations may give reliable indications, the great variation in rainfall between near-by stations would tend to discount the value of many predictions of maximum rainfall in Table 3. With longer records the maximum rainfall would tend, no doubt, to be more uniformly distributed.

Edgar E. Foster,[20] **Assoc. M. Am. Soc. C. E.**—A fundamentally sound analysis of the precipitation in the two southwestern states, New Mexico and Arizona, has been presented in this interesting paper. The author has extended the analysis to the basic causes, such as type and movements of air masses, type of storms, and effect of topography. These and related climatic factors should be the first items considered in an investigation of the hydrology of a given region, since they are the underlying causes of the occurrence and distribution of precipitation.

The region under consideration is somewhat off the usual paths of air masses affecting the United States other than the adjacent areas of the Great Basin and Colorado Plateau, and it is protected furthermore from invasion of outside air by the border of high mountains. It is isolated meteorologically to the extent that H. C. Willett[21] designates it as a source region of tropical continental air masses. Since air must remain quiescent to acquire the characteristic properties of a source region, the applicability of such a designation indicates that there could be relatively little interchange of air with outside areas.

---

[20] Head, Flood Control Section, U. S. Engr. Office, Omaha, Nebr.

[21] "American Air Mass Properties," by H. C. Willett, Papers in Physical Oceanography and Meteorology, Mass. Inst. of Tech. and Woods Hole Oceanographic Inst., Vol. 2, No. 2, 1933.

This meteorological isolation probably promotes the spotted, irregular summer precipitation. This irregularity, added to the effect of the rugged, mountainous topography, would make difficult the construction of isohyetal maps of storms, as the author has indicated by the omission of such maps from his paper. Furthermore, the data of precipitation at one station should be used at other points only after a careful consideration of all pertinent factors that may vitiate the results. For this reason the station-year method of constructing frequency curves would be open to some question because topographical features may cause sufficiently discordant data to offset climatic homogeneity. The author wisely has advised caution in the use of the recurrence-interval data, even through curves were drawn for each of the stations listed.

The writer questions the use of the term "recurrence-interval" when referring to data or curves that show frequency. These are in reality "frequency data" or "frequency curves." It appears desirable to adhere to commonly and widely accepted terms rather than those relatively unknown. The data of 1-day rainfall which probably will be equaled or exceeded once in the specified period of years may be obtained from frequency curves that have been expressed in the integral form as $P = \int_{-\infty}^{+\infty} e^{-u^2} du$. The fact that the data were taken from empirical curves would not alter this principle.

Where rainfall frequencies are important factors in an investigation, the writer suggests that they be computed by methods based on the mathematical theory of statistics or probability. For this purpose the unbounded function proposed by J. J. Slade[22] is recommended. The use of this function involves considerably more work, but it takes into proper consideration the "widely-spaced points in the upper limits" which are the values of rare intense rainfall.

R. W. DAVENPORT,[23] M. AM. SOC. C. E.—The derivation of Fig. 5 showing, for Arizona and New Mexico, the 24-hr rains equaled or exceeded once in 50 years may well be considered in the light of inherent statistical characteristics of the basic data. These data are summarized in Table 3.

Out of the 283 station records that are used, two records have frequency arrays of 50 years or more. The average length of record is approximately 27 years. Substantially, therefore, the records may be considered as offering 283 samples of the highest 24-hr rain in periods of about 27 years. The extrapolation of the frequency arrays to show rains equaled or exceeded once in 50 years produces results that fall short of being equivalent to actual samples of the highest 24-hr rains experienced in periods of 50 years. For purposes of this discussion, however, the data in the "50 years—all year" column of Table 3 will be considered as representing maximum 24-hr rains in 50-yr records at the respective stations.

If long-time frequency relations for 24-hr rainfalls at the respective stations were available, the 50-yr maxima could be assigned frequencies according to their positions on the magnitude-frequency scales. One maximum might be such as the long-time relation showed would be equaled or exceeded once in 40 years, another once in 75 years, another once in 150 years, etc.

---

[22] "An Asymmetric Probability Function," by J. J. Slade, Jr., *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 35.

[23] Chf., Div. of Water Utilization, Dept. of the Interior, U. S. Geological Survey, Washington, D. C.

The probability that the value to be equaled or exceeded once in 50 years would be equaled or exceeded in a given year is $\frac{1}{50}$. The probability that such value would be equaled or fallen short of in a given year is $\frac{49}{50}$ and in a 50-yr period $(\frac{49}{50})^{50}$, or 0.364. This signifies that, in a large group of 50-yr samples, the maxima in 36.4% would equal or fall short of the values to be equaled or exceeded once in 50 years.

TABLE 5.—DISTRIBUTION OF 283 MAXIMA ACCORDING TO PERCENTAGES

Frequency scale[a] (1)	% (2)	Distribution (3)
50 years or less.......	36.4	103
50 to 75 years........	14.7	41
75 to 100 years.......	9.4	27
100 to 500 years.......	30.0	85
500 years and more....	9.5	27

[a] Equaled or exceeded once in the number of years indicated.

Similarly the value to be equaled or exceeded once in 75 years would be equaled or fallen short of $(\frac{74}{75})^{50}$, or 51.1%, of the samples. The corresponding results for values to be equaled or exceeded once in 100 years and once in 500 years are 60.5% and 90.5%, respectively.

The foregoing shows that for a large number of 50-yr samples the maxima would be distributed on the frequency scale according to the percentages shown in the following tabulation. If the distribution of the 283 assumed maxima of Table 3 conformed to these percentages, the classification of the station records according to frequencies would be as shown in Col. 3, Table 5. Of course, it would be possible to have a great variety of other distributions in samples limited in number to 283, but that shown is reasonably typical.

If frequencies were assigned to the values shown in Figs. 3 and 4, they would be distributed somewhat as shown in Col. 3, Table 5. The median frequency would be that equaled or exceeded once in slightly less than 75 years.

It would seem that, in the definition of isopluvial lines by such data, considerable uncertainty would be involved as to the extent to which they represent variations of magnitude incident to topography and other local causes or variations incident to the use of samples of limited size. The latter variations might tend to obscure the former. Moreover, the isopluvials developed might correspond most closely to the median of the frequencies represented; that is, 24-hr rains equaled or exceeded once in 75 years. Viewed in the light of the uncertainties discussed herein, the significance of Fig. 5 is not clear.

The author is to be commended for his extensive compilation of rainfall data and the presentation of the results in compressed form convenient for reference and use.

A. K. SHOWALTER,[24] ESQ.—This paper is a contribution to the hydroclimatic history of New Mexico and Arizona. The results are representative of the available data, but it is doubtful whether point-rainfall frequencies can indicate directly the frequencies of selected average depths over specific drainage areas. The author demonstrates, for example, that rainfall is more frequent at higher altitudes but that, nevertheless, in a single storm the heaviest rainfall usually occurs near the base of the mountain. If data on frequency of average depths of rainfall over a small, steep drainage area were desired, the results would differ radically if in one case the key station were leeward of a high mountain and in another case at a low elevation directly exposed to the prevailing storm wind.

---

[24] Meteorologist in Charge, Hydrometeorological Section, Weather Bureau, U. S. Dept. of Commerce, Washington, D. C.

If Mr. Leopold's data are to be used in design, it is recommended that pilot studies be conducted to determine the typical relationship between the depth of rainfall at the key station and the average depth over the project basin. Such studies would seem to be especially important in regions dominated by pronounced orographic influences.

More complete data are needed on typical depth-area-time relationships in this region, and it is probable that adequate data will never be obtained without the use of very dense networks of electrically synchronized automatic rain gages. Sampling networks should be located in the relatively flat areas and also in regions of marked topographic variation.

The author neglected to mention that tropical Pacific hurricanes sometimes move up the west coast of Mexico or through the Gulf of California bringing with them deep currents of moist air and subsequently heavy widespread rains over parts of Arizona or New Mexico long after surface barometric indications of the tropical cyclone have disappeared.

Another storm type not mentioned is a deep, cold, cyclonic circulation which may move slowly across the region and cause the northward-flowing, moist, tropical, maritime air to the east to curve cyclonically as it advances up slope through Texas and northern Mexico into New Mexico and Arizona. Such a circulation pattern in a surface air mass must necessarily be accompanied by horizontal convergence and vertical stretching which tend to accelerate the release of potential instability and convective overturning. Such patterns are typical of eastern Colorado and New Mexico from late April through early June.

Mr. Leopold's data and conclusion regarding the relationship between rainfall intensity and height seem more consistent with theoretical deductions than much of the previous literature on this subject. The opportunity for rainfall is increased at high-level stations by the increased lift, and therefore there is a higher frequency at the higher elevations if only average rains or rains of low magnitude are considered. However, as the height increases, the depth of available precipitable water in the air above decreases (neglecting localized chimney effects which carry suspended condensation particles), and also the zones of horizontal convergence are not so well defined. The result is lesser frequency of excessive rains of a given magnitude at the higher elevations.

WALTER B. LANGBEIN,[25] ASSOC. M. AM. SOC. C. E.—In general, rainfall regimes for engineering purposes are completely defined only by evaluation of the depth-area-intensity-frequency characteristics—a four-dimensional problem that has nowhere been solved. Merrill Bernard[26] and Gail A. Hathaway,[27]

---

[25] Associate Engr., U. S. Geological Survey, Washington, D. C.

[26] "Primary Rôle of Meteorology in Flood Flow Estimating," by Merrill Bernard, *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 311.

[27] *Ibid.*, p. 370.

Members, Am. Soc. C. E., have described the latest methods of deriving depth-area-intensity relations, frequency being omitted. Mr. Yarnell's useful publication[2] treats the depth-intensity-frequency relations of "point" rainfall at first-order Weather Bureau stations exclusively, omitting area of storm rainfall. In the western part of the United States the sparsity of first-order stations imposes a serious shortcoming. The author contributes much toward filling this need by incorporating information from all stations, although his compilation is limited in turn because of this broader coverage to 24-hr periods. Thus, he reveals an expectancy of 24-hr rainfall of 6 in. or more once in 50 years on the average in Arizona, whereas Mr. Yarnell showed nothing more than 3.5 in. The deviation from Mr. Yarnell's results in New Mexico, although appreciable, is not so marked.

Isopluvial maps such as Fig. 5 are open to many kinds of errors, including errors of measurement, errors of sampling (the next 30 years might produce materially different frequency curves), and also errors arising from necessary generalization. Such errors are inherent in the statistical methods available to the engineer and are not peculiar to Mr. Leopold's expert handling.

Statistical theory is not at all clear even in the matter of fitting a frequency time scale to the annual data. Mr. Leopold has computed his plotting positions by the California method, in which recurrence-intervals are computed by the formula $\frac{y}{m}$ (y being the number of years in the series, and m, the relative rank of an annual rainfall, listed in decreasing order of magnitude). Equally legitimate is the method of listing in the reverse order, in which case the interval in years is $\frac{y}{y - n}$ (n being the relative rank beginning with the lowest as 1). The values obtained by the second formula are generally called exceedance intervals. A graph plotted to conform with the recurrence-interval plotting positions will be higher than the exceedance-interval graph (that is, for a given interval in years the former will give the higher rainfall). There are other methods of plotting;[28, 29] all produce graphs that lie between the recurrence-interval graph and the exceedance-interval graph. A common method is the Hazen compromise, $\frac{y}{m - 0.5}$ or $\frac{y}{y - n + 0.5}$, these two ratios becoming numerically equal. However, it is desirable to emphasize that Mr. Leopold's results, particularly the extrapolated 50-yr and 100-yr rainfalls, are higher than would be obtained by any other method of plotting now in use, applying the same data.

Assuming that the frequency data in Table 3 and Fig. 5 are accepted, this paper presents a wealth of material for study and analysis. For example, a search might profitably be made to find the effects of altitude or other mea-

---

[28] "Statistical Analysis in Hydrology," by L. R. Beard, *Transactions*, Am. Soc. C. E., Vol. 108 (1943), p. 1110.

[29] "On Serial Numbers," by E. J. Gumbel, *Annals of Mathematical Statistics*, Vol. 14, No. 2, June, 1943, pp. 163–178.

surable factors on rainfall intensity. The following statement by G. N. Brancato[30] seems pertinent to such an inquiry:

> "However, contrary to published and popular accounts, the thunderstorms produced the greatest amount of precipitation at the lower elevations and not on the mountain slopes. The most favorable condition for the production of heavy rain is the presence of an air mass with a sufficient amount of available energy and the greatest possible amount of moisture. Orographic lifting is very effective as a mechanism to release the latent energy in an air mass but as the air is lifted over progressively higher terrain the total amount of available precipitable water above any given area becomes progressively smaller. Over the lower level areas therefore there is always more potential rain waiting to be released, but the opportunity for realization occurs less frequently than at the higher elevations which are favored by orographic lifting."

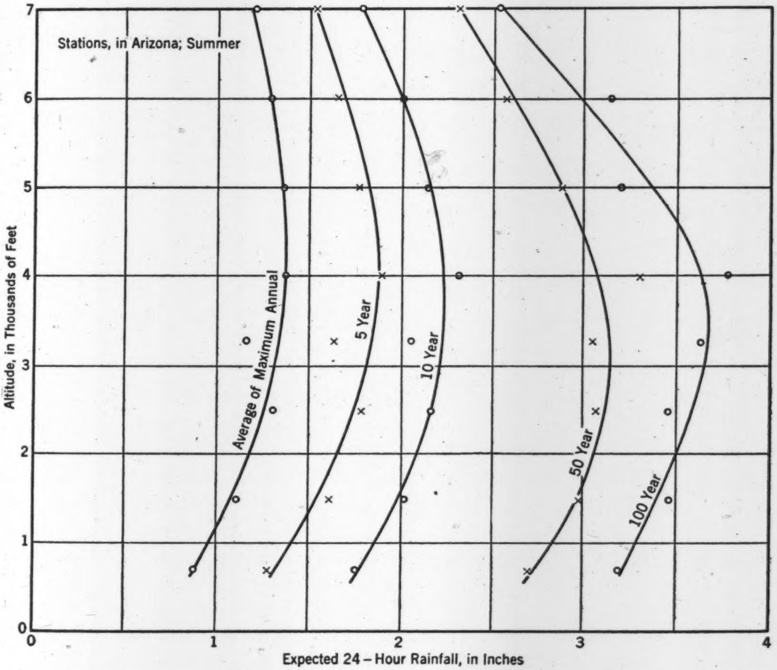

FIG. 9.—STUDY OF RELATION BETWEEN ALTITUDE AND EXPECTED 24-HR RAINFALL OF INDICATED RECURRENCE INTERVALS

Fig. 9 shows results of averaging groups of stations of like altitude for the summer in Arizona. The graphs show that, on the average, rainfall intensities are greatest in the range of altitudes between 3,000 ft and 4,000 ft. The decline in expected intensities at high altitudes is especially noteworthy.

---

[30] "The Meteorological Behavior and Characteristics of Thunderstorms," by G. N. Brancato, Hydrometeorologic Section, U. S. Weather Bureau, April, 1942 (processed).

Furthermore, the spread between the 5-yr and 50-yr recurrence-interval graphs is greater at low altitudes than at high altitudes. Indeed, the indicated 50-yr rainfall is greater on the average at altitudes below 1,000 ft than at the 7,000-ft level. However, 5-yr rainfall is greater at the 7,000-ft level; and 10-yr rainfall is nearly the same at both levels. These relationships probably result from greater thunderstorm frequency at high levels due to instability created by lifting of the air. Seemingly, when, at rare intervals, conditions favor the development of critical storms at low levels, the resulting intensities are apt to be greater because of the greater amount of precipitable moisture in the air column.

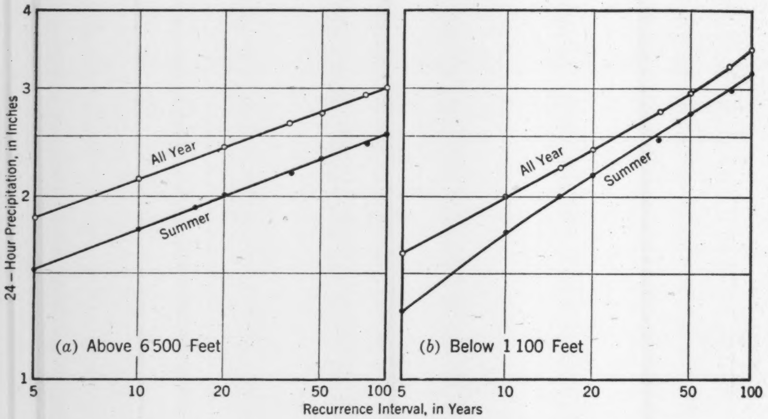

FIG. 10.—COMPARISON OF AVERAGE FREQUENCY CURVES FOR SUMMER AND ALL YEAR, AT ALTITUDES BELOW 1,100 FT AND ABOVE 6,500 FT, IN ARIZONA

These ideas are further explored in Fig. 10. There is a 20% difference between the "summer" and the "all-year" curve at altitudes higher than 6,500 ft (see Fig. 10(*a*)), indicating that non-summer rainfalls are important contributors to storm intensities at high altitudes. At stations below 1,100 ft (Fig. 10(*b*)) the spread is much less, especially at the upper end. At low altitudes in Arizona, the characteristics of rainfall intensities are seemingly dominated by those of summer. The difference in slope of the high-altitude and low-altitude graphs indicates a greater range in expected intensities at low altitudes than at high altitudes, as already has been mentioned.

Mr. Brancato outlines two influences on the intensity of rainfall produced by thunderstorms: (1) Lifting forces, and (2) amount of precipitable moisture. Altitude is a measure of the lifting indigenous to a station. It would seem that, for stations at the same altitude, mean seasonal or annual precipitation might furnish an approximate measure of such meteorologic and local effects as are indicative of precipitable moisture. Furthermore, comparisons of intensities at stations having the same mean seasonal or annual rainfall would provide a basis for study of the effect of altitude separately. These studies are made most simply by means of a multiple-correlation chart.

Table 3 does not list mean summer precipitation, and therefore "all-year" data have been used in this correlation. Altitude and mean annual precipitation have been correlated with "average of maximum 1-day rainfall" for "all year." Separate correlations would need to be made for each recurrence-interval as well. For the longer recurrence-intervals the correlations become less accurate.

Diagrams were prepared on which were plotted altitude as ordinate and "average maximum 24-hr rainfall" as abscissa; and mean annual precipitation was written along each plotted point. On this background of points, contours

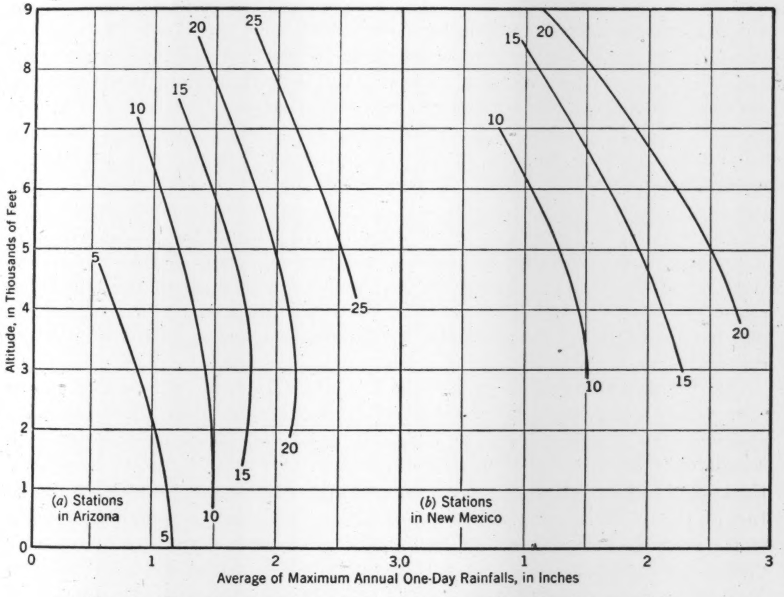

FIG. 11.—RELATION OF ALTITUDE AND AVERAGE OF MAXIMUM ANNUAL 1-DAY RAINFALLS IN TERMS OF MEAN ANNUAL PRECIPITATION

of equal mean annual precipitation were drawn. The resultant contours are shown in Fig. 11 for Arizona and New Mexico, respectively. The mean error of estimate in Fig. 11(*a*) is 0.15 in., and in Fig. 11(*b*), 0.20 in. The decrease in rainfall intensity with altitude, mean annual precipitation constant, is to be noted. Also, for a given altitude there is a marked increase in rainfall intensity with increase in mean annual precipitation. Diagrams similar to Fig. 11 should provide means for estimating rainfall intensity at places in Arizona and New Mexico when the altitude and mean annual precipitation are known.

Mean annual precipitation can be interpolated from isohyetal maps modified if necessary on evidence given by native vegetation.

Any generalization, whether by graph or map, however, would be subject to erratic variation because of the great divergence in relief in the mountainous and intermountainous parts of the West. Measurements of rainfall provide the best and only reliable guide to storm frequency and intensity. As Mr. Leopold states, caution is imperative in transferring the results to locations distant from the place of observation, especially if the topographic setting or orientation with respect to the moisture-carrying winds is markedly different.

Emil P. Schuleen,[31] Assoc. M. Am. Soc. C. E.—In making available to the engineering profession the results of his extensive study, the author is to be commended. A great amount of the detailed work involved in his analyses apparently was done by a number of workers from the Work Projects Administration. The author was fortunate in having had such assistance at his disposal. The writer wonders, however, if (as is sometimes the case when assistance is available in abundance) the work has not been reduced largely to mechanical procedures with efforts directed toward volume rather than reliability. In this respect he has reference particularly to the extensive results summarized in Table 3, which will be discussed further in later paragraphs.

The section on "Seasonal Distribution of High Rainfalls" might well have followed immediately after the section on "Storm Types," for these two sections, together with Fig. 2, provide an excellent treatment of the relation of storm types and topographic relief to the intensity, geographic distribution, and seasonal occurrence of rainfall in the various parts of the area under consideration.

In the last paragraph under the heading, "Aerial Pattern of Summer Storms," it is implied that the depth-area data given in Table 1 are but a few samples, and that other similar data are available, although considered inadequate to indicate depth-area-time patterns for design purposes because of the lack of definite information concerning intensities. Apparently the limitation on the use of the available data for making such analyses applies primarily to the case of small areas where rainfalls of a few hours duration would govern design requirements. Would not the available data, however, permit analyses for larger areas where rainfalls of 1-day or 24-hr duration would be important? Data of that nature, separated in accordance with the summer-type and winter-type storms, would provide a valuable addition to the author's paper in the interest of design storms and floods for larger drainage areas.

In the first paragraph under the heading, "Rainfall Intensity," it is indicated that the mass curves in Fig. 1(*a*) represent the most intense rainfalls on record at recording gage stations in New Mexico and Arizona. In the second paragraph of this section it is indicated that the points in Fig. 1(*b*) were obtained from the records of standard nonrecording rain gages where the times of beginning and ending of rainfall had been noted by the observer. The writer is not familiar with the available data, but suggests that it may have been possible to develop reasonably accurate mass curves for some or many of the 72 storms represented, by comparing the records from the nonrecording stations with those from recording stations in the vicinity and by comparing the times of beginning and ending of rainfall at the respective stations. This analysis would be facilitated further if the regular time of observation differed materially among the several stations, as is frequently the case. If such mass curves were available, presumably their envelope would approximate the envelope curve shown in Fig. 1(*b*). This envelope curve, therefore, would serve as the mass curve for the design storm, if the project were to be designed for the maximum storm possibility.

---

[31] Senior Engr., U. S. Engr. Office, Pittsburgh, Pa.

The author states that the frequency data given in Table 3 are based on records for 15 years or more from standard nonrecording rain gages, and that in a few instances shorter record periods were used. There is reason to question the reliability of frequency determinations for intervals of as many as 100 years when the studies are based on records for as few as 15 years. Most extensive rainfall records indicate tendencies for cyclic variation with alternate periods of heavy and light rainfall. Frequency studies based on short periods of record, therefore, may not reflect truly average conditions. There is also the possibility in the use of short records for one or two abnormal or subnormal values to warp the true tendency of the remaining data. The author has recognized this possibility by his reference (see heading, "Frequency of High Rainfalls") to "aberrant points in the upper limits of the series." It is noted also that in some cases the rainfall values were "24-hr values" based on the observer's notations with respect to the time of beginning and ending of rainfall, which in some instances indicated a total lapsed time of considerably less than 24 hr, whereas in other cases the values were "1-day values" as obtained from consecutive regular daily observations. It is noted further that, where rains continued through two or more days, the largest amount recorded for one day was used. All these variations in the manner of applying the basic data, while difficult to avoid, affect the reliability of the results.

Illustrations of apparent inconsistencies in results may be had from a study of the rainfall values for various frequencies given in Table 3, in conjunction with reference to the relief maps of Figs. 3 and 4. The writer has selected two instances as examples. The first of these involves a comparison of the stations at Tatum and Prairieview, N. Mex. These two stations differ but 125 ft in elevation and are only 10 or 12 miles apart in an area where the topographic relief apparently is uniform and similar, yet the 50-yr value for the first is almost twice that for the second. The second instance involves a comparison of the stations at Palo Verde, Roy, Solano, Hoosier Ranch, and Mosquero, in New Mexico. These stations range from El. 5579 to El. 5884, an over-all difference of 305 ft. All five stations are located within a radius of 6 or 7 miles in an area which, from Fig. 4, appears to be relatively uniform and similar in topographic relief; yet the 50-yr rainfall values range from 3.77 to 6.80, an over-all difference of about 80%. Two of these stations, Palo Verde and Roy, are indicated by Fig. 4 to be only 3 or 4 miles apart and by Table 3 to differ in elevation by only 4 ft, yet the 50-yr rainfall value for the second is more than 30% greater than that for the first. One might expect that rainfall frequencies should be similar at the various stations in these respective areas, unless there are topographic features, not apparent in Fig. 4, that are of sufficient extent to explain the differences in the rainfall frequency values given for those stations in Table 3. If no such explanation can be found, these differences must be attributed to inconsistencies in the basic data or to the method in which the data have been applied to obtain the results.

In commenting on the fact that Table 3 indicates certain stations to have the same 24-hr rainfall expectancy at a given recurrence-interval for summer as for the entire year, the author makes the statement that (see heading, "Frequency of High Rainfalls") "This simply indicates that that station characteristically received the largest 24-hr rainfalls in the summer period and, therefore, the recurrence-interval curves for summer and all year would be practically identical." It is recognized that this might be true in some cases, but in others it is difficult to understand why it should be true with respect to one station and not with respect to another in the immediate vicinity and in the same general topographic setting. Referring again to the stations at Tatum and Prairieview, Table 3 indicates the 50-yr values for the former to be 7.70 and 8.00 for summer and all year, respectively, whereas in the case of the latter both values are given as 4.08. Unless (as mentioned in the first comparison of these two stations) there are topographic features, not apparent in the relief map, that affect one station and not the other, it does not appear reasonable that the greatest rainfalls characteristically should occur in the summer at one station and during the remaining seasons at the other.

Under the heading, "Isopluvial Maps," it is stated that "The small areal extent of high rainfalls occurring in summer-type storms is a factor leading to differences between stations since any high-intensity, individual storm rarely is recorded at more than one station." By this statement the author indicates that the records in some instances are erratic. It is probable also that, in many instances, the greatest rainfall during a high-intensity storm was not recorded at any standard station. Where such spotty rainfall occurs in a region of relatively uniform topographic relief, and heavy rainfall is recorded at one station and not at another near-by station, the location of the point of heaviest rainfall must be attributed to mere chance. Presumably, if both stations had long record periods, the occurrence of high rainfall values would be about the same at each and their frequency curves would approach one another.

The writer's comments, particularly with respect to the variable nature of the results in Table 3, are made with the intent of calling attention to possible sources of inconsistencies in the basic data and in their application leading to the tabulated results. He is not familiar with the topographic details of New Mexico and Arizona and his comments regarding the effects of such details on rainfall intensity and distribution are based solely on the apparent variations in relief indicated by Figs. 3 and 4.

The paper as a whole is very well prepared and presents much valuable information to the engineering profession. It is suggested, however, that the value would be enhanced if the results in Table 3 were classified as "excellent," "good," "fair," etc., in accordance with the author's knowledge of the relative merits of the basic data and his results.

LUNA B. LEOPOLD,[32] JUN. AM. SOC. C. E.—When the writer started the preparation of the tables of frequency-magnitude of precipitation (Table 3) for nonrecording rain gage stations in New Mexico and Arizona, he was confronted with the task of making estimates of design floods for numerous flood control structures on small watersheds scattered throughout the two states. Each time such a design problem arose the rainfall records available for stations near the watershed in question had to be analyzed. The watersheds were scattered through two states where topographic relief, elevation, soils, and rainfall vary tremendously within short horizontal distances, and the flood control structures were often to be located in inaccessible country where rainfall stations were scarce. It was necessary, therefore, not only to analyze rainfall records for stations adjacent to the watershed in question but to attempt to find other watersheds where the factors affecting runoff would be comparable. Thus, tabulations of rainfall records soon were accumulated for rainfall stations located all over the two states. In practically all cases, intensity records were lacking for stations where rain analyses were necessary.

As a result of these circumstances and limitations of time, the writer was not able to make detailed studies of storms of long duration which would be applicable to the design of major structures on large watersheds. However, even the problem of intensities and frequency of storms of small areal extent in the Southwest has always been one of considerable importance owing to the scarcity of rain gages, particularly intensity gages, in such a large area of diverse topography. The writer wishes to emphasize the comments made by Mr. Girand and Mr. Hodges that, as stated in the paper, the frequency data were prepared primarily to study the storm rainfall on small watersheds, and have limited applicability to long duration storms. Mr. Schuleen suggested that analyses of the rainfall for long duration storms would add to the value of the paper. The writer is in entire agreement and regrets that the study could not, at that time, have been so extended.

The data presented under the heading, "Comparison of Magnitude of 1-Day, 2-Day, and 3-Day Rains," and discussed by Mr. Jarvis represent a preliminary approach to the problem of long duration storms, but, as stated in that section of the paper, the results are indicative only. Even since the installation of additional intensity gages by the Weather Bureau in 1940, numerous storms of long duration and considerable magnitude have occurred, the records of which should certainly be considered in any detailed study of extended storms in the area.

The variability of the frequency-magnitude values for closely adjacent stations was noted by Messrs. Girand, Hodges, and Schuleen. At first glance, these variations seem to invalidate the final results, and they lead Mr. Schuleen to conclude that either the basic data are inconsistent or the method of analysis is at fault. The writer called attention to these variations under the heading,

---

[32] 2d Lt., Air Force, U. S. Army, Los Angeles, Calif.

"Isopluvial Maps," and, to give added prominence to the variations, the 50-yr values were plotted on topographic maps in Figs. 3 and 4.

This variation between stations is a reflection of an important characteristic of the summer-type rainfall. Because of the physical nature of the short duration storms, the area of most intense rainfall is small, and one station may receive a large amount of rainfall while adjacent stations receive none. An example is the storm at Las Cruces, N. Mex., on August 29, 1935. At that station 6.49 in. of rain fell in 7 hr while other stations in the vicinity recorded "none" or "trace" up to 1.83 in.[33]

Both from the standpoint of the actual frequency figures computed and from a consideration of the physical character of the short duration storms, the element of chance seems to play an important part in determining the rainfall values actually recorded at a given station. The available records for the Southwest generally cover too short a period to give either a true picture of the frequency of the infrequent storms, or consistent frequency values at any pair of adjacent stations.

W. V. Turnage and T. D. Mallery[34] analyzed one year of rainfall records from sixteen standard rain gages in a 300-m square plot and concluded that, although one rainstorm gave considerable variation of precipitation between gages, at the end of the season, the total rainfall for each gage compared closely with the average seasonal rainfall for all gages. They noted that the variation in total seasonal rainfall between near-by gages was smaller for stations in Arizona near Tucson than for stations near Yuma, and concluded that spatial variation in seasonal precipitation is greater in areas of low rainfall than in areas of high rainfall.

The variation between adjacent stations does tend to iron out as the length of record increases, but, when a station happens to experience an exceptionally great rainfall, a long time might elapse before other rains of that magnitude are recorded again at the station (as, for example, at Las Cruces). In the 48-yr record at Las Cruces the greatest rain recorded in 24 hr was 6.49 in., which actually fell during a 7-hr period. The second largest rain at that station was 2.43 in.

The topographic maps of Figs. 3 and 4 show that the frequency-magnitude values in a given broad area differ considerably from the data for other areas in a different geographic setting, in spite of the tendency for variations between adjacent stations to mask the broad differences. As an example, compare the data for a 50-yr expectancy (summer) for stations in a west-east strip across east central New Mexico. The stations chosen for Table 6 were divided arbitrarily into three groups separating stations into geographic areas more or less centered around Torrance, Guadalupe, and Quay counties. In this strip of territory there are no important mountain ranges, and all stations are approximately at the same elevation. However, the stations in the Estancia Valley area (Torrance County) are more or less protected by the Sangre de Cristo Mountains to the north, the Manzanos on the west, and the Gallina-Capitan ranges on the south. This relative isolation differentiates the Estancia Valley from the high plains along the east edge of the state where the effect of the frontal weather of west central Texas is often felt. No important topographic barriers protect the high plains stations from southerly wind currents.

TABLE 6.—COMPARISON OF 50-YR (SUMMER) FREQUENCY-MAGNITUDE VALUES FOR STATIONS IN EAST CENTRAL NEW MEXICO

WEST			CENTRAL			EAST		
Station	El. (ft)	50-yr frequency (in.)	Station	El. (ft)	50-yr frequency (in.)	Station	El. (ft)	50-yr frequency (in.)
Stanley	6,317	3.09	Palma	7,000	5.40	Logan	3,851	3.80
McIntosh	6,355	3.25	Cuervo	4,849	3.06	Tucumcari	4,100	3.58
Estancia	6,300	2.90	Santa Rosa	4,624	2.35	San Jon	3,982	4.55
Tajique	7,100	3.45	Pastura	5,285	3.00	Montoya	4,335	5.60
Mountainair	6,475	3.11	Vaughn	5,930	3.40	Melrose	4,400	4.25
....	....	....	Lagunita	4,500	4.30	St. Vrain	4,250	3.50
....	....	....	Alamogordo	4,338	3.65	Clovis	4,262	5.01
....	....	....	Ft. Sumner	4,028	3.85	....	....	....

Table 6 indicates an increase in the magnitude of 24-hr summer-type rain of 50-yr frequency from Torrance County on the west to Quay County on the east, although closely adjacent stations vary considerably between themselves.

The manner of grouping stations or records that do so differ is a question on which probably no two persons would agree. One method might be by station-year grouping. The requirements for the use of such a grouping were discussed under the section, "Applicability of Station-Year Analysis." As stated there, frequency curves differ so much that it is difficult to decide whether the rainfall experience at certain stations differs mostly due to chance, or whether assignable causes, such as topography, were operative. The assignable causes may operate in subtle ways which are not immediately apparent. Thus, different persons may not agree on which stations should be grouped together.

In order not to generalize the basic data by grouping stations, the writer presented the frequency data separately for each station, and then generalized in the construction of the isopluvial map. Since the number of rain gages is small per unit area, the short records are included even though their value is less than that of the long records. For comparability the short records were analyzed in the same manner as longer records, and the engineer who uses the data must consider the length of record in weighing its worth. To facilitate this, the writer included in Table 3 the exact years of record used in making the frequency arrays. The writer agrees with Mr. Schuleen that the 100-yr frequency value based on a 15-yr record is of questionable reliability, but the short records should be considered rather than disregarded. Since the grouping of stations appeared to be open to many questions, particularly concerning which stations should be thrown together, the writer considered it justifiable to present the analysis of the short records as well as that of the long records, with the caution that reliability of the computed frequencies varies.

The use of the highest rain on record each year for the construction of frequency curves is comparable to the annual flood method.[35] The recurrence-interval or California Method of plotting[36] has had considerable popularity, but it represents only one of many procedures which might have been employed in this analysis and, as Mr. Langbein stated, gives values somewhat higher than other methods.

Comparison of the results obtained by various methods of plotting indicated that the magnitude of rainfall values for frequencies of 50 to 100 years was determined mostly by the four or five highest rainfall values recorded at the station. If these highest rainfall values fall on a smooth curve, the method of computing the plotting position is of importance. However, for many stations whose records were short, the highest values did not plot in a smooth curve and the fitting of a curve through the points was a matter of individual judgment. Consequently, the writer concluded that the different methods of plotting in such a case give less variation in final values than would the positions of a smooth curve drawn through the plotted points by different workers.

The construction of an isopluvial map such as Fig. 5 is open to many kinds of errors, as Messrs. Langbein and Davenport have explained. It is presented, however, as one way the frequency data may be generalized to give a rough over-all picture of the geographic distribution of the rainfall expectancy. As shown by Mr. Davenport, with a large number of 50-yr samples of maximum 24-hr rainfalls, these maxima would be scattered around their mean in a probability curve, or with random distribution. This would be true if there were no assignable causes such as topography to make the rainfall differ between stations. In such a case, the geographic distribution of maxima would also be random.

However, when the data are plotted on a map, the geographic distribution of values is not random but, as demonstrated by Fig. 5, tends to show a distribution which can logically be explained by topographic differences and relation of the area to sources of moisture. Thus, if an isopluvial map were properly analyzed, it should provide a key to the geographic distribution of causes which tend to vary the record between stations—all causes being integrated into the final map. In practice, however, only general principles can be cited to explain why isopluves are distributed as they are. More detailed studies of macro-climate and micro-climate are necessary before all the obscure effects of assignable causes can be evaluated.

The rainfall frequency for a given small area should be derived from the applicable station frequency-magnitude curves rather than from a general isopluvial map as presented in Fig. 5. As a generalized picture of the distribution of frequency data over a large area, the isopluvial map is a convenient picture but should not be trusted alone to define the frequency-magnitude values for a given spot.

Mr. Langbein points out that the highest 24-hr isopluve for 50 years shown by Mr. Yarnell[2] in Arizona is 3.5 in., whereas the writer placed a 6-in. isopluve over the mountain area surrounding Crown King, Ariz. This difference might be expected inasmuch as the maps constructed by Mr. Yarnell were based on only two intensity records in Arizona—at Phoenix and Flagstaff. In the record analyzed by Mr. Yarnell, the greatest rain at Phoenix was 1.15 in. in a 30-min period, whereas the greatest 24-hr rain (during the summer season) in the writer's analysis for Phoenix was 2.91 in. In a 25-yr record, on the other hand, Crown King experienced three rains in the summer season which exceeded 3 in. in 24 hr, the largest of which was 5.05 in.

---

[35] "Floods in the United States," by C. S. Jarvis and others, *Water-Supply Paper No. 771*, U. S. Geological Survey 1936, p. 54.

[36] *Ibid.*, p. 58.

Thus, the importance of adding to the very valuable material published by Mr. Yarnell is apparent, even if the data available for analysis are subject to the limitation that they are 24-hr totals and not intensity records.

Although the isopluvial values presented by the writer in Fig. 5 are in closer agreement with those of Mr. Yarnell for New Mexico than for Arizona, they are higher for both states. The isopluves of Mr. Yarnell for New Mexico agree very satisfactorily with those derived by Robert L. Lowry, Jr.,[37] M. Am. Soc. C. E., for the western part of Texas. A reconsideration of the position of the isopluves in Fig. 5 for eastern New Mexico would probably be profitable in order that they might be drawn in a more easterly position for better agreement with those of Messrs. Yarnell and Lowry.

Mr. Langbein's valuable discussion presents more detailed studies of the relation of intensity to elevation. The writer indicated that the center of greatest precipitation occurred near the base of the mountain slope. Mr. Langbein's further analysis of the same data showed a decrease of intensity with elevation. The same result was reached by Mr. Brancato[30] whose conclusions were supported by Mr. Showalter at least from theoretical considerations; but Messrs. Harrold and Dickson show that the data from Navajo Experiment Station are not in agreement with this conclusion. As Mr. Harrold stated, there is need for additional information before the details are understood.

In summary, the lack of long records and the scarcity of rain gages make it necessary to utilize records that are really too short to be considered reliable for frequency determinations The physical character of summer-type storms leads to differences between records of adjacent stations. These differences result from a combination of chance and assignable causes, which cannot be satisfactorily separated. Workers agree that most of the high rainfalls which fall in summer, and are recorded as 24-hr totals, actually fall in periods of less than 10 hr, and a study of intensity records and times of beginning and ending of rain shows that many of these rains fall during periods of 2 to 3 hr.

The intensity-time curves presented in Fig. 1 probably represent the intensity patterns for most of the summer-type, 24-hr rains which were analyzed for frequency, but, at best, the combination of an average intensity histogram with a total rainfall amount for a given frequency only provides additional data for depth-intensity-frequency relations of "point" rainfall. The relation of these factors to areal distribution of a single storm still remains to be demonstrated by research such as that being conducted at Navajo Experiment Station and Southwestern Forest and Range Experiment Station.

---

[37] "A Study of Rainfall in Texas," by Robert L. Lowry, *Bulletin No. 18*, State of Texas Reclamation Dept., August, 1929.

Engineers who use the data presented in Table 3 should do so with caution, because in many cases the variation of frequency values between adjacent stations cannot be explained satisfactorily. Only by detailed studies of assignable causes can the effect of chance be properly evaluated. Consideration of the frequency-magnitude curves for individual stations will lead to a better choice of a composite frequency value than will the use of a generalized isopluvial map.

Because of the inherent differences between long duration storms typical of winter and the intense thunderstorm type of summer rainfall, the frequency-magnitude values are applicable primarily to small watersheds, whose maximum flood flows result from the cloudburst type of storm.

The writer wishes to express his appreciation for the contributions made by the discussers. They are pertinent and valuable additions to the paper.

FLOW CHARACTERISTICS AT RECTANGULAR OPEN-CHANNEL JUNCTIONS

By Edward H. Taylor,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. Harold K. Palmer, G. H. Hickox, J. C. Stevens, C. J. Posey, I. B. Hosig, L. Standish Hall, Brooks T. Morris, and Edward H. Taylor.

Synopsis

The research of which this paper is a part comprised a study of the phenomena associated with the combining and dividing flow of water in open and closed conduits. The paper is concerned only with the open-channel problem, in which the variables involved are so numerous that only an empirical solution seems possible. The conformity of actual behavior to theory is discussed, and an empirical solution is included which may be applied to rectangular channels. For other prismatic channels or for natural streams, the flow characteristics at the junction are best determined by models controlled in an hydraulic laboratory.

Notation

The letter symbols introduced in this paper are defined where they first appear and are assembled for convenience of reference in the Appendix.

Combining Flow

The principal problem of combining flow may be stated as follows: When two streams combine in a single channel, the depth just below the junction will be fixed by the backwater characteristics of that channel and the magnitudes of the combined rates of flow. The problem is to predict the depth in each tributary channel just upstream from the junction. One of the factors involved is the ratio in which the incoming flows are divided. In studying the combining streams, this ratio was made one of the independent variables.

Note.—Published in November, 1942, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Naval Ordnance Laboratory, Washington, D.C.; formerly Instr., Mech. Eng., Univ. of California, Berkeley, Calif.

It is immediately apparent that an unlimited number of different types of stream intersections could be devised. The angles of intersection, the breadths of the channels, the directions of flow, etc., could be combined in such a multiplicity of ways as to make a completely exhaustive investigation a matter of many years' work. The studies have indicated that generalization of the results presented is not possible, or even desirable, so that no attempt has been made to present a mathematical statement applicable to every type of stream intersection. Rather, the attempt has been to investigate the importance of the problem, to point out limitations in the theory, and to demonstrate how the results may be applied in practice.

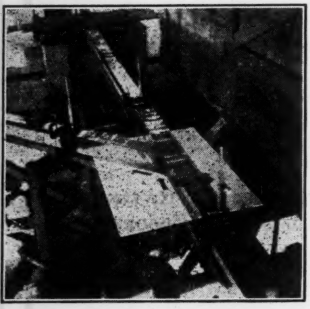

FIG. 1

Experimental Equipment.—The tests were conducted in small, horizontal, rectangular channels, all 4 in. wide and with a maximum depth of 4 in. The intersections were constructed of a transparent plastic, and the remainder of the channels were built of galvanized sheet metal. Fig. 1 gives a general view of the experimental setup. Water-surface elevations were measured with point gages, and rates of flow by calibrated diaphragm orifices in the supply pipe. The elevations of the water surfaces in both channels could be varied by means of adjustable gates at the lower ends.

Theory and Assumptions.—The scope of discussion will be limited to the case shown in Fig. 2. The restrictions are: (*a*) The channels are of equal width, (*b*) the bottom slopes are all zero, (*c*) the flow is from channels 1 and 2 into channel 3, and (*d*) channels 1 and 3 lie in a straight line. The assumptions are: (1) The flow is parallel to the channel walls immediately above and below the junction, (2) ordinary wall friction is negligible in comparison with other forces involved, and (3) the depths in channels 1 and 2 are equal immediately above the junction.

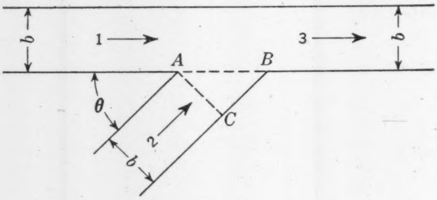

FIG. 2

From the principle that the net force acting upon a fluid system is equal to the rate at which the momentum of the system is changed, the following equations are obtained:

The net force, F, acting in the direction 1 to 3 is—

$$F_{1-3} = \frac{\gamma\, b\, (y_a)^2}{2} + \frac{\gamma\, b\, (y_a)^2}{2} \cos\theta - \frac{\gamma\, b\, (y_b)^2}{2} + U \ldots\ldots\ldots (1)$$

in which: γ = specific weight of water; b = width of a rectangular channel section; y_a = depth of flow above the junction; y_b = depth of flow below the junction; θ = angle between the diverging channels; and U = an unknown reaction. The rate, ΔM_{1-3}, at which momentum is changed in the direction 1 to 3 is—

$$\Delta M_{1-3} = \frac{Q_3 \gamma V_3}{g} - \frac{Q_1 \gamma V_1}{g} - \frac{Q_2 \gamma V_2}{g} \cos\theta \ldots\ldots\ldots\ldots (2)$$

in which: Q = rate of flow, the subscript referring to the appropriate channel; V = average velocity in the channel denoted by an appropriate subscript; and g = acceleration of gravity.

Upon examining Eq. 1 more closely, it is apparent that U must be the component of the pressure force upon the part of the wall marked BC in Fig. 2. If a further simplification is made so that the depth in the triangle ABC is everywhere equal to y_a, then U evidently must be equal and opposite to the term $\frac{\gamma\, b\, (y_a)^2}{2} \cos\theta$. Eq. 1 is now simply:

$$F_{1-3} = \frac{\gamma\, b\, (y_a)^2}{2} - \frac{\gamma\, b\, (y_b)^2}{2} \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Equating Eqs. 1 and 2:

$$\frac{Q_1 \gamma}{g} V_1 + \frac{\gamma\, b\, (y_a)^2}{2} + \frac{Q_2 \gamma}{g} V_2 \cos\theta = \frac{Q_3 \gamma}{g} V_3 + \frac{\gamma\, b\, (y_b)^2}{2} \ldots\ldots (4)$$

Eq. 4 may be put in dimensionless form by the introduction of the factors n_q, n_y, and k_3. The final form is:

$$(n_q)^2 (1 + \cos\theta) - 2\, n_q + 1 = \left[\frac{1 - (n_y)^2}{4\, k_3} + 1 \right] n_y \ldots\ldots\ldots (5)$$

Experimental Results.—The factor k_3 in Eq. 5 varies inversely as the cube of the depth y_b. As this depth was difficult to measure, owing to the rough water surface below the junction, the numerical value of the factor k_3 as obtained experimentally was of doubtful accuracy. Therefore, Eq. 5 was modified so that the value of k_2, or the ratio of the velocity head to the depth in the branch channel, was made the independent variable. The resulting equation is:

$$k_2 = \frac{(n_q)^2 \left[(n_y)^2 - 1\right]}{4\, (n_y)^2 \left[2\, n_q - (n_q)^2 (1 + \cos\theta) + n_y - 1\right]} \ldots\ldots\ldots (6)$$

Eq. 6 is shown graphically in Fig. 3 for intersection angles of 45° and 135°, and for values of n_q equal to 0.4, 0.6, and 0.8. Plotted thereon are a few of the points obtained in the laboratory. The agreement with the theory is seen to be quite good for $\theta = 45°$ (Fig. 3(*a*)) and rather poor for $\theta = 135°$ (Fig. 3(*b*)).

Summary; Combining Flow.—(1) The agreement between theory and experiment for the 45° junction supports the conclusion that all the aforementioned assumptions are justified in this case of combining flow;

(2) Since the boundary friction was the same in both cases, it may be considered as a negligible influence in comparison with the other forces;

(3) The experimental data clearly showed that the depths in the two channels upstream from the junction had nearly the same value, regardless of the angle of intersection; and

(4) The lack of agreement between theory and experiment for the 135° intersection is due to the distortion of the velocity distribution below the junction and to the fact that the flow does not remain parallel to the channel walls. Item (4) is apparent from a comparison of Figs. 4(*a*) and 4(*b*) with Figs. 4(*c*) and 4(*d*). It is worthy of note that the injection of dye in the junction does not clearly define the line of demarcation between the two streams after they have joined. Notice that the line of separation is different in Figs. 4(*a*) and 4(*b*), whereas the photographs are of identical conditions, except as to the dye. The differences between the two lines must represent the region in which diffusion and turbulent mixing are taking place.

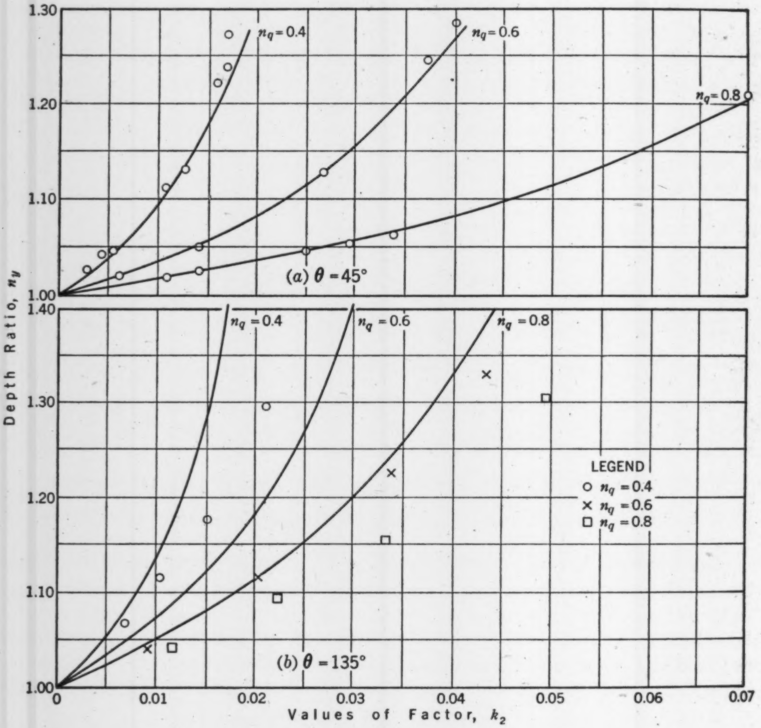

FIG. 3.—INTERSECTION CHARACTERISTICS, COMBINING FLOW

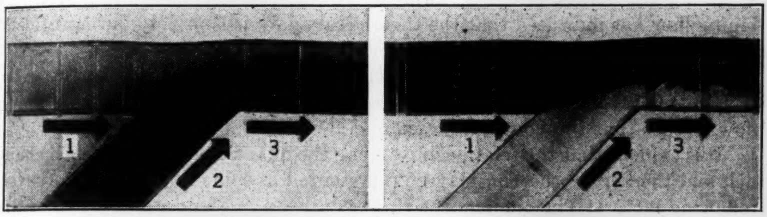
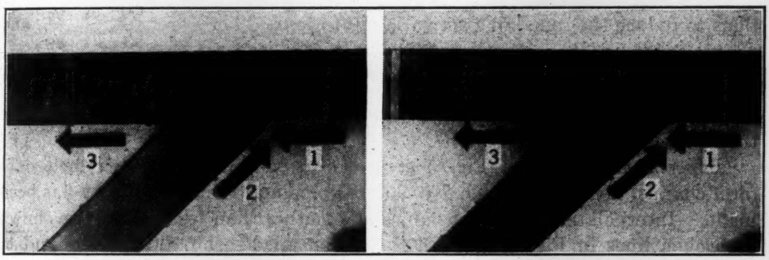
Application of the Results.—These results are not directly applicable to natural streams because of the restrictions placed upon the experimental procedure. A little reflection will show, however, that the problem is of minor importance if deep, slow-moving rivers are considered. The ratio of the velocity head to the depth is such a small number that the resulting ratio of depth above (y_a) to depth below (y_b) the junction will be close to unity. For example, consider a stream entering another at 45° and carrying 60% of the total flow. Suppose this tributary is 20 ft deep and is moving at 3 ft per sec.



(a) θ = 45°; Dye in Channel 2 (b) θ = 45°; Dye in Channel 1



(c) θ = 135°; Dye in Channel 1 (d) θ = 135°; Dye in Channel 2

FIG. 4.—FLOW PATTERNS, COMBINING FLOW

According to Fig. 3(a), the difference in depth between two points above and below the junction would be approximately 2%, or 0.40 ft.

The results show clearly that, owing to the negligible effect of friction, model studies of special stream intersections (if the problem were sufficiently important) would be successful. This procedure is recommended since, as stated, theoretical and experimental investigation of every conceivable type of intersection is impracticable.

DIVIDING FLOW

In dividing flow the problem is somewhat different from the case of combining flow. A logical statement of this problem would be: A given stream branches into two separate channels. What will be the division of the flow? This will depend upon the backwater characteristics of the two branch channels and the dynamic conditions existing at the junction.

Analysis of the problem of dividing flow is considerably more difficult than that of combining flow, for the following reason: In the former case, it was possible to assume that the depths in the tributary channels were equal immediately above the junction. No analogous assumption is permissible in the case of the dividing flow. The momentum equations are then complicated to the extent of containing an additional unknown term. In view of this fact, no attempt at rational analysis in terms of momentum was made, because assuming a relation among the three depths would be almost tantamount to assuming the solution to the problem. Furthermore, experience with combining flow has indicated that the theoretical analysis is in only fair agreement with the observed facts.

This part of the paper will be limited to the case in which the flow of water in Fig. 2 is reversed. The restrictions will be the same as for the combining flow, except that the flow is from channel 3 into channels 1 and 2.

It is evident that the relationship among the quantities flowing in each channel, and the depths therein, may be represented as some function of the seven following factors: The angle θ; the three depths, y_1, y_2, and y_3; any two of the three quantities, say Q_3 and Q_2; and the velocity with which the stream enters the junction. For any given angle θ, it is possible by dimensional considerations to reduce the remaining six variables to four. They are: $\frac{Q_2}{Q_3}$, $\frac{y_3}{y_2}$, $\frac{y_1}{y_2}$, and $\frac{(V_3)^2}{2\,g\,y_3}$ $(= k_3)$. It is proposed to present the experimental data for one type of intersection and then demonstrate how these data may be applied to a case that may occur in practice.

Experimental Results.—Fig. 5 gives the experimentally determined data for a channel division in which $\theta = 90°$. No comparison with theory has been made. Interpolated curves for values of k_3, other than test values, are shown as broken lines in Fig. 5. Fig. 6 shows the relationship that was found to exist among the three depths within the range of the values of k_3 considered. Figs. 7(*a*) and 7(*b*), which are of identical flow conditions, except as to the dye, show qualitatively the manner in which the flow divides.

Application of Results.—It has been stated previously that a practical use of a study in stream division would be to predict the division of flow when a given stream branches into two separate channels. It is assumed, of course, that the inflows to the branches are not controlled by gates but merely by the characteristics of the junction and the branches themselves. The following hypothetical case will be assumed to exist: A rectangular canal, 10 ft wide, divides at a 90° branch. The branch channels are also 10 ft wide and rectangular. They are of such slopes and roughness that their rating curves for sections just below the division point are as shown in Fig. 8. The problem is to predict how much water will be naturally diverted to each branch channel if 500 cu ft per sec are admitted to the main canal.

Determination of the division of flow involves the following steps:

(1) Assume a certain division, say $Q_2 = 250$ cu ft per sec and $Q_1 = 250$ cu ft per sec $\left(\frac{Q_2}{Q_3} = 0.5\right)$. This fixes the depths y_1 and y_2. The ratio of y_3 to y_2

may then be determined by means of Fig. 6. It is possible, by choosing various values of Q_2, to obtain a curve between $\frac{Q_2}{Q_3}$ and $\frac{y_3}{y_2}$. For the conditions assumed herein, this curve appears in Fig. 5 and is marked A.

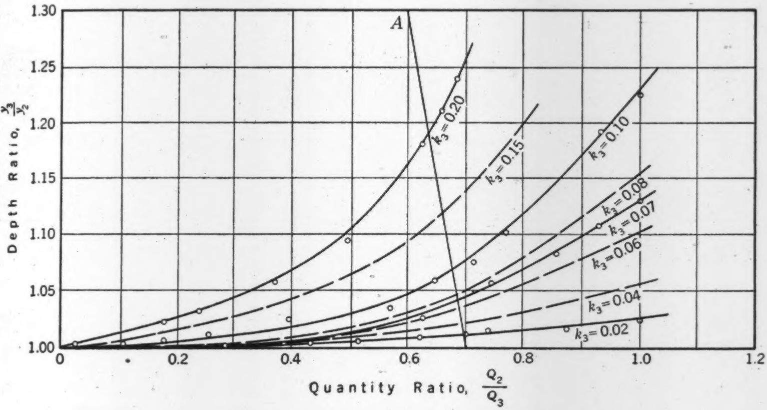


FIG. 5.—CHARACTERISTICS OF STREAM DIVISION IN WHICH $\theta = 90°$

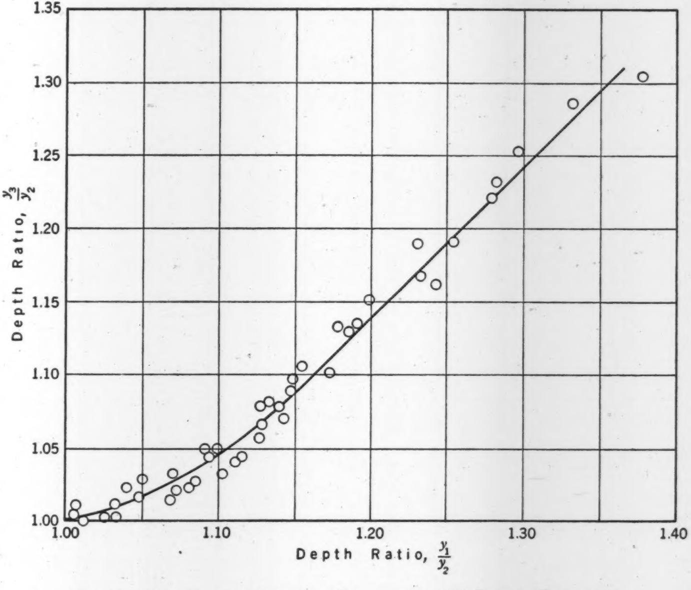

FIG. 6.—RELATIONSHIP BETWEEN DEPTHS IN A 90° STREAM DIVISION

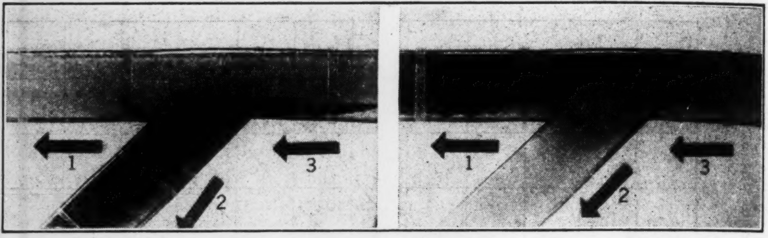
(2) The locus of the points of intersection of curve A and the k_3-curves (Fig. 5) now gives all possible combinations of the variables. Still undetermined is the value of k_3 with which the flow of 500 cu ft per sec enters the junction. It is necessary to replot curve A in terms of the numerical values of the depth y_3 and the factor k_3. This is done as follows: Take the intersection of curve A and $k_3 = 0.10$; $\frac{y_3}{y_2} = 1.067$ and $\frac{Q_2}{Q_3} = 0.677$. Then $Q_2 = 338$ cu ft per sec and, from Fig. 8, $y_2 = 6.0$ ft and $y_3 = 1.067 \times 6 = 6.4$ ft. The point ($k_3 = 0.10$ and $y_3 = 6.4$) is plotted in Fig. 9. Other points are plotted in the same manner. The resulting curve is marked B in Fig. 9.



(a) Dye Entering Channel 1 (b) Dye Entering Channel 2

FIG. 7.—FLOW PATTERNS, DIVIDING FLOW; $\theta = 45°$

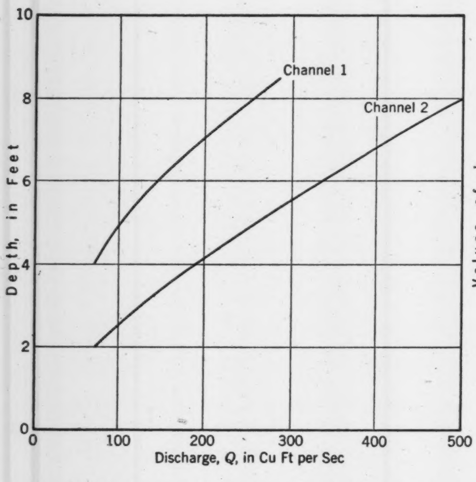


FIG. 8.—RATING CURVES FOR BRANCH CHANNELS

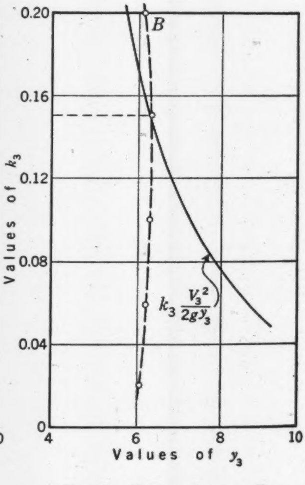

FIG. 9.—FACTOR k_3 AS A FUNCTION OF y_3

(3) The proper value of k_3 must satisfy not only curve B, but also the relationship $k_3 = \frac{(V_3)^2}{2\,g\,y_3}$. This is easily found by plotting $k_3 = \frac{(V_3)^2}{2\,g\,y_3}$ in Fig. 9 and obtaining the intersection with curve B. For these hypothetical conditions, k_3 is found to be 0.15 and $y_3 = 6.4$ ft.

(4) Entering Fig. 5 with $k_3 = 0.15$ at its intersection with curve A, the value of $\frac{Q_2}{Q_3}$ is seen to be 0.66. Then $Q_2 = 330$ cu ft per sec and $Q_1 = 500 - 330 = 170$ cu ft per sec.

Conclusion

The example given is admittedly a very special case, as such an ideal set of conditions could hardly be expected to occur in practice. It has only been included to indicate the data that would be necessary in order to solve a general problem of this type, as it is felt that rational analysis is not practical.

The research described in the foregoing may be considered by some to be incomplete in that no attempt was made to study the details of the mixing process in quantitative terms. Studies have since been undertaken, and are still continuing, at the University of California under somewhat simpler conditions; namely, the mixing of parallel streams, in which velocity and pressure gradients have been measured in the region of mixing.

Acknowledgment

The Committee of the Hydraulic Division on Hydraulic Research has had for one of its projects "The Phenomenon of Intersecting Streams." With funds allotted by The Engineering Foundation, the University of California conducted the investigation, with Morrough P. O'Brien, M. Am. Soc. C. E., as the cooperating member of the Committee.

The quantitative data from which this paper was prepared were taken from two sources: "Combining of Streams in Open Rectangular Channels,"[2] by F. C. Horowitz and John R. Morgan, Juniors, Am Soc. C. E., and "The Characteristics of Dividing Streams in Open Rectangular Channels,"[3] by Lt. Ivan C. Rumsey. The photographs were obtained from a thesis entitled "A Qualitative Study of the Intersections of Converging and Dividing Streams,"[2] by R. M. Bickerstaff, Jun. Am. Soc. C. E. R. L. Stoker was immediate supervisor of these studies.

APPENDIX

Notation

The following letter symbols, used in this paper, conform essentially to American Standard Letter Symbols for Hydraulics,[4] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942 (numeral subscripts refer to appropriate channel numbers, channel 3 being the main stream and channel 2 the channel entering or leaving the straight axis of flow):

[3] Thesis submitted to the University of California in partial fulfilment of the requirements for the degree of Master of Science in Engineering.

[4] ASA-Z10.2—1942.

b = width of rectangular channel section;
F = net force acting on a fluid system: F_{1-3} = net force acting in the direction 1 to 3;
g = acceleration of gravity;
k = a factor $= \frac{V^2}{2\,g\,y}$;
M = momentum of a system: ΔM_{1-3} = the rate at which momentum is changed in the direction 1 to 3;
n = ratio symbol: $n_q = \frac{Q_2}{Q_3}$ and $n_y = \frac{y_a}{y_b}$;
Q = rate of flow: Q_2 is the flow from or to the side tributary or branch channel; and $Q_3 = Q_1 + Q_2$ (see Fig. 2);
U = an unknown reaction in Eq. 1;
V = average velocity across a given cross section;
y = depth of flow: y_a = depth above the junction and y_b = depth below the junction;
γ = force per unit weight; specific weight of water; and
θ = angle between merging or diverging channels.

DISCUSSION

HAROLD K. PALMER,[5] M. AM. SOC. C. E.—Some interesting experiments are offered in this paper in an attempt to find a solution of some important hydraulic problems; but unfortunately some of the author's hypotheses are not confirmed by the experiments, which leads to the suggestion that the plan of attack may require some modification.

An examination of the photographs in Fig. 4 shows clearly that there are three zones at the junction: A zone of slight deflection, and the narrowing of stream 1 along the straight side; a bending and narrowing of stream 2 around the angle; and a zone of turbulence between the two outer zones, where the mixing of the two streams takes place. The deflection of a stream will cause a small loss of energy and in the zone of turbulence there will be a much larger loss, but the two are of such different natures, and affect such different parts of the same stream, that they should be considered as two terms with different coefficients. The shape of the junction would have a marked effect on the loss due to bending stream 2 and might affect somewhat the loss due to turbulence. It appears to the writer, therefore, that the problem should be approached from the standpoint of loss of energy rather than from change of momentum.

To solve the problem by this method it would be necessary to assume y_3 and v_3 below the junction of the converging streams, thus establishing the relation:

$$E_3 = y_3 + H\,v_3 \qquad \text{(7a)}$$

in which E represents the total energy in the part of the stream indicated by the subscript.

Stream 1 would lose some energy in the zone of turbulence and in being confined to a narrow strip, and it would require some experiments to evaluate this combination of losses. Once this loss is found, the energy in this stream would be expressed by the relation

$$E_1 = E_3 + \Delta E_1 \qquad \text{(7b)}$$

In the same way,

$$E_2 = E_3 + \Delta E_2 \qquad \text{(7c)}$$

In the latter case, the loss due to deflection would be much greater than in stream 1, but still would be much less than the turbulence losses.

To find the constants to be used in this method, it would be well to conduct experiments on the deflection of a single stream, avoiding the turbulence losses. The only way to segregate the deflection and turbulence losses is first to find the magnitude of one and then subtract that from the total to find the other. Such a study may determine the importance of rounding corners on the concave side of the entering stream to avoid excessive loss, and it would also show the effect of the width of the side channel.

---

[5] Office Engr., Los Angeles County Sanitation Dists., Los Angeles, Calif.

The same methods could be applied to the case of dividing flows. In this case, the deflection loss is very important, as the momentum of the water tends to make it continue down the straight channel. The width of the side channel is even more important in this case and, if the side channel can be so designed that the stream is always in contact with the convex bank, there will be no backwater, and losses will be minimized.

This proposed method of attack may not be the solution, but the writer believes it accounts more nearly for the forces acting on the streams, and that therefore some constants may be found that would give an approximate idea of what happens in either combining or dividing streams.

If such studies should prove successful, it would not be necessary to construct a model for every case, as suggested by the author. It is to be hoped that the continuing studies at the University of California, which the author mentions in his "Conclusion," may help to solve this general problem by furnishing the necessary constants.

G. H. Hickox,[6] M. Am. Soc. C. E.—By attacking a problem which has received comparatively little attention Mr. Taylor has made a distinct contribution to engineering literature. His attempt at a solution points the way to a better understanding of the general subject of branching flow. A similar problem exists in pipe flow where several attempts have been made to predict the discharge through the orifices of irrigation sprinkler systems. Some of these attempts have been made on the basis of the momentum principle, relating the change in pressure in the feeder pipe to the rate of change of momentum. As far as the writer is aware, however, the pressure differences on the walls of the lateral outlets, parallel to the flow in the feeder pipes, have not been taken into account. The author's method of attack, considering the effect on the momentum equation of the wall pressures in the branch channel, is suggestive of similar treatment of the problem in pipe flow.

With respect to the application of the momentum principle to the problem of combining flow, Eqs. 1 and 2 state the sums of pressures and rates of momentum change correctly. The derivation of Eq. 3 from Eq. 1, however, is of somewhat doubtful validity. It assumes that the depths in the main channel and the branch channel at their junction are the same and are uniform across the channel. Also, it assumes that the pressure on the wall of the branch channel is equal to the hydrostatic pressure of still water at the same depth. This would be the case if the flow in the branch channel was everywhere parallel to the walls. At the junction, however, and particularly in the vicinity of the wall BC, the flow is not parallel to the wall but is curved. This curvature of flow will modify both assumptions. The water surface across the channel no longer will be level, and it is possible that the variation of pressure with depth may not be quite hydrostatic. Also, there may be some modification of pressure on the walls of the branch channel above section AC. From a further application of the momentum principle, the elevation of the water in the branch channel should be lower than that at the junction since there is a component of velocity normal to the main channel which is reduced to zero.

---

[6] Senior Hydr. Engr., TVA, Hydraulic Laboratory, Norris, Tenn.

It would have been interesting if the author had developed his equations without the simplification introduced in Eq. 3 and had evaluated the term U from the experimental data. The results then might have been expressed in terms of a coefficient relating the experimental value of U to the calculated value.

Also it might have been enlightening if the pressures on the walls of the branch channel had been measured by means of piezometers. There seems to be no reason why the momentum principle should not give excellent results if it is applied correctly. Its proper application depends upon a complete knowledge of all the pressures having components in the direction of flow. The assumptions made in this case regarding pressure might well have been verified experimentally.

J. C. STEVENS,[7] M. AM. SOC. C. E.—It would be worth while for the reader of this excellent paper to look back 17 years and review the writer's short article[8] on similar flow characteristics at pipe intersections and particularly the discussions that followed, by Harold A. Thomas[9] and Julian Hinds,[10] Members, Am. Soc. C. E. In that article it was assumed that the pressure in each intersecting conduit would merge into a common value at the intersection. Momentum and energy relations were based on mean velocities. There followed from those assumptions a formula purporting to give the theoretical energy losses when n pipes of varying sizes join at a common junction at varying angles from which the water flowed away in a main.

Another formula gave expression to the theoretical losses resulting from n pipes of varying sizes discharging at right angles into a header of constant diameter. It made no difference in which direction the water was flowing—for example, the water flow could divide from the main to the several pipes and the same theoretical energy losses would result.

Those formulas will give approximate results. The errors are on the side of safety in that the losses indicated are on the excessive side. However, the formulas do illustrate the danger of simplifying assumptions if accuracy is important. Mr. Taylor was able to simplify his theoretical analysis by assuming that the depth in the branch remained constant to the wall of the main and that it was also equal to the depth in the main above the junction. Both of these assumptions are somewhat similar to the writer's assumption of uniform pressure at pipe intersections, and both are incorrect; yet approximate results may be obtained from the use of the author's formula and diagrams.

The sources of error in these analyses are obvious. The water never has a uniform velocity distribution. After the junction a greatly distorted velocity distribution results. Both momentum and energy relationships based on a $\frac{Q}{A}$-mean are therefore considerably in error.

[10] *Ibid.*, pp. 883–884.

The force due to pressure on certain parts of the peripheries of the conduits at their junction, even in the case of uniform size conduits intersecting at right angles, cannot be expressed in known terms. In the paper cited,[8] this force was simply ignored as the easiest solution. Mr. Taylor assumes it to be equal and opposite to the pressure force in the branch, which, although preferable to ignoring it completely, still leaves much to be desired.

The Society's Committee on Hydraulic Research assigned the research project "Phenomenon of Intersecting Streams" to Professor M. P. O'Brien in 1936. Mr. Taylor's paper is the final paper on the open-channel phase of this subject. Research on intersecting pipes is being continued, although temporarily postponed in favor of more urgent war activities.

Flow in open-channel intersections was found to involve too many unknowns. Flow in intersecting pipes also contains too many complexities until more can be learned about how two streams mingle. As stated by the author, that phase is under study—first in its simplest form of mixing parallel streams. The next step will be to study the mixing of two nonparallel streams. Upon completion of these investigations, it is anticipated that studies on the flow characteristics of intersecting pipes can be resumed.

Almost any kind of research progresses slowly. The first steps open new vistas that must be explored before tangible results can be achieved on the original objective. Those engaged in teaching, of course, must make that their first duty, and research in such cases must be satisfied with what can be accomplished as extracurricular activities.

C. J. Posey,[11] Assoc. M. Am. Soc. C. E.—It should be emphasized that the data and conclusions of this paper are for flow deeper than the critical throughout—that is, with a ratio of velocity head to depth of less than one half in both branches of the stream. Although no statement to this effect appears in the paper, it is obviously true from the results, and is implicit in the author's statement that the elevations of the water surface in both channels could be varied by means of adjustable gates at the lower ends.

The data presented by the author justify the assumption customarily made in dealing with problems in combining or dividing flow at greater than critical depth—namely, that depths in the intersecting channels are substantially the same, with the division, in case of dividing flow, depending chiefly upon the backwater characteristics of the two branch channels. If greater refinement were needed, in some particular case, a model study patterned after the experiments reported in this paper should yield the desired information.

I. B. Hosig,[12] Esq.—To the writer this paper is of interest principally because it presents an additional case in which the application of the principles of analysis by forces yields results in an hydrodynamic problem. It is gratifying to find this method of analysis being used by the young men entering hydraulic work and, although, to date, its practical applications have been few, it has elucidated with brilliancy the problem of the hydraulic jump—for instance, where work with the principles of analysis by energy content had enveloped that problem in a fog of empiricism.

---

[11] Associate Prof., Hydraulics and Structural Eng., State Univ. of Iowa; and Research Engr., Iowa Inst. of Hydr. Research, Iowa City, Iowa.

[12] Engr., Bureau of Reclamation, Denver, Colo.

The author modestly disclaims a solution of great practical value because the theory is adequately bolstered only by experiments in which the angle between the two intersecting streams is 45°. However, it is probable that in cases in nature the angle will be found to be that or less, and thus the work is practical.

In the irrigation and drainage work with which the writer is familiar, the case of division of water is entirely ruled out of the class of problem herein discussed because division is under control by means of structures. Division is a major work in the control of irrigation water.

The joining of streams in irrigation work consists principally of taking storm water or return flow into supply canals. The water surface of the principal stream is usually much lower than that of the incoming stream and the volume is also much greater. Hence the question of the elevation of the joined waters is of no interest; but the problem of the force of the incoming water is of paramount importance.

In the case of drainage channels the resultant water surface at the junction may be of considerable importance. In the writer's practice the method of treating the problem has been to make the channel below the junction of such size that it will handle the anticipated flow with the water surface at the junction at the same elevation as that of the incoming channels, assuming flow in each branch to follow Chézy's formula where the anticipated flows are of consequence. Otherwise, the bottom grades are all brought to one elevation. In the writer's practice observation of the behavior of drains at junctions has not been very illuminating as discharges are difficult to predict and are highly variable; hence flows observed are usually not those assumed when making the layout but the observations are clear in one respect—that the forces involved govern resultant channel conditions. It is sometimes necessary either to direct the combined channel as a resultant of the two branches or to contemplate additional work in the nature of bank protection which is in effect the introduction of additional force. This leads to the idea that more fruitful results will be obtained if the problem is presented in such a way as to recognize all forces of such magnitude as can appreciably affect the motions of the body involved.

In the case in the paper where two streams meet at an angle of 45°, the transverse (with respect to the straight channel) component of the $\frac{Q\,v}{g}$ force of the stream coming in at an angle was not included in the mathematical treatment. The author recognized the omission but the photographs show that the force does have an effect on flow conditions. The writer believes that it is this force which limits the use of the mathematical treatment presented to angles of an order of 45° or less for the case considered. This is not a criticism which is intended to imply that analysis by forces in this case is a weak approach to the problem. In fact it appears to be the only analytical approach and the proper course is a more comprehensive setup. Model study probably would solve a particular problem, but model study without analysis is a barren plant in the field of engineering science.

L. STANDISH HALL,[13] M. AM. SOC. C. E.—Little research has been done on the phase of hydraulics described in this paper. Many variables are involved in the solution of the problem, one of which has been eliminated in the paper by making the bed horizontal. The flat grade produces low velocities and, consequently, small values of kineticity.

In many of the design problems involving converging channels, the writer has found that the velocities have been great enough to require paving or a lined channel. The velocities often are greater than the critical and the kineticity greater than 2. With kineticity of this magnitude, the depth of flow above the junction is not affected by backwater from the combined flow; hence, the depth of flow in the two converging channels is not necessarily the same. When the depths are different, cross waves will develop that are transmitted downstream, sometimes with undesirable results.

Even with the velocities below critical it would be difficult to project the curves to include higher kineticity on the basis of the data presented in the paper.

For the data plotted in Fig. 3, it should be noted that, for small values of n_q, n_y would be independent of the value of k_2. For this reason, the intersection characteristics should be plotted against k_3.

If the flow from the side channel becomes zero, the ratio $n_q = 0$. Then, from Eq. 5,

$$(n_y - 1)[(n_y)^2 + n_y - 4\,k_3] = 0 \qquad (8)$$

With $n_q = 0$, assuming that wall friction can be neglected, the depth ratio, $n_y = \frac{y_a}{y_b} = 1$ can only occur when $k_3 = \frac{1}{2}$; or, expressed in words, under the condition of no flow in the side channel, the velocity head is always one half of the depth. This may be true, but it is difficult to believe. If Eq. 8 is solved for n_y, then

$$n_y = \frac{-1 \pm \sqrt{1 + 16\,k_3}}{2} \qquad (9)$$

From Eq. 9, it is seen that one root is positive and one negative; and with kineticity less than $\frac{1}{2}$, such as was observed in the author's experiments, the value of n_y should be less than unity. In other words, a jump should occur at very low velocities. This is contrary to accepted hydraulic theory, as a jump can only occur when k_3 is greater than $\frac{1}{2}$.[14] The solution to this dilemma lies in the fact that in Eq. 5, when $n_y = 1$ and $n_q = 0$, the term containing k_3 drops from the equation. Hence, for this special case the kineticity is immaterial, and Eq. 9 can apply only when $n_y \neq 1$.

[14] "The Hydraulic Jump in Terms of Dynamic Similarity," by Boris A. Bakhmeteff and Arthur E. Matzke, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 630.

For the other extreme, if all of the flow originates from the side channel, $n_q = 1$. Then, from Eq. 5, if $\theta = 90°$, the relation

$$n_y = \sqrt{1 + 4\,k_3} \qquad (10a)$$

is obtained and, from Eq. 6,

$$k_2 = \frac{k_3}{(1 + 4\,k_3)^{1.5}} \qquad (10b)$$

These relations indicate that depths in channels 1 and 2 (Fig. 2) would be greater than in channel 3, and k_2 would be less than k_3. The lack of agreement between theory and experiment shown in Fig. 3 makes the application of Eqs. 10 questionable. The results of experiments covering this condition would be interesting if available.

For converging channels, the lack of agreement of the results with the momentum equation when $\theta = 135°$ would suggest that a comparison of the energy losses might yield a more satisfactory solution. In Fig. 3, when $n_q = 0.4$, the relation between $\frac{y_a}{y_b}\left(\text{or } \frac{y_1}{y_2}\right)$ and k_2 is identical for both $\theta = 45°$ and $\theta = 135°$. With $n_q = 0.6$ there is very little difference in the relation with either angle. Only when $n_q = 0.8$—that is, with 80% of the flow entering from the side channel—is definite difference in the relation apparent between supplementary angles of convergence. The results would indicate that the momentum of translation is converted into a momentum of rotation, and, hence, with small flows in the side channel, the angle of entrance is immaterial.

An example of dividing flow is given by a side spillway for regulating the diversion into a canal system. The conditions are not parallel with those given by the author since the bottom of the side channel is at a higher elevation than the bottom of the main canal. The momentum principle can be used in solving this problem. In the case of the change of momentum affecting the water surface profile in such a canal, it has been assumed that momentum is lost with the overflowing water.[15]

On the other hand, in a side-channel spillway from a reservoir (an example of combining flow), it has been assumed that the momentum of the water discharging over the spillway lip is entirely lost upon impact with the water in the spillway channel. This assumption has been made since the flow moves over the crest of the weir in a direction approximately at right angles to the axis of the spillway channel.[16] This would correspond with the assumption made by the author in Eq. 2.

The variables affecting combining and dividing flow are so numerous that no general relation applicable to all conditions can be found. In most cases, when a prior knowledge of the flow characteristics at an intersection is important, a model should be constructed as suggested by the author. General relations applicable to specific cases may be obtained where it is possible to control a sufficient number of the variables. The results presented in this paper are a step in the right direction.

BROOKS T. MORRIS,[17] JUN. AM. SOC. C. E.—Experiments on so general a problem as channel junction performance cannot be expected to cover more than a fraction of the field. Within the limits of his apparatus and of the time given to its operation, Mr. Taylor has developed good data. The quantities employed in both combining and dividing streams cover the range of tranquil flow nearly to the limit of critical velocity in the most heavily loaded conduit.

The analyses attempted by Mr. Taylor make the data of considerable use in revealing the weaknesses of certain assumptions which are customarily employed in hydraulic computations but which are inappropriate to problems of combining and dividing flow. The first of these is the assumption of uniform velocity distribution over the channel cross sections. Theoretical analysis and long experience each have shown that this assumption is adequate in ordinary pipe and channel calculations where similar, although not strictly uniform, velocity distributions exist at the various sections for which force-balance equations are written. On the other hand, within individual cross sections, manifold pipes and branched channels contain extreme variations of velocity distribution. Such conditions, like the 135° intersection, contain stream filaments moving in opposite directions in the same cross section. To describe such conditions, formulas like Eq. 2 should contain distribution coefficients corresponding to the ratio of the integrated mean momentum to that calculated from the mean velocity of flow. As long as those coefficients approach unity, as in the 45° junction, the analysis as presented by the author is successful.

The second familiar assumption is the dual one of hydrostatic pressure distribution and of horizontal surface at each cross section. This assumption leaves the author short one equation in studying the dividing flow problem and makes necessary his assumption (3) regarding the depths in combining flow. Except for this, the fact of a gradient of depth, or pressure, gradient across the 1–3 channel might be recognized and the second equation of momentum might be written. The writer recognizes the difficulties inherent in writing this equation, but he believes that it is a necessary step in the rational description of combining or dividing flow. Also, the determination of momentum distribution coefficients suited to varying junction geometry is not easy. The continuing studies on the mixing of parallel streams should be informative in this regard. Excellent investigations of certain types of such mixing have been made already by W. Tollmien and A. M. Kuethe.[18]

The writer felt handicapped by the coefficient k until he recognized it as merely another form of the Froude number or kineticity of flow such that

$$k = \frac{V^2}{2\,g\,y} = \frac{\mathbf{F}^2}{2} = \frac{\lambda}{2} = \frac{1}{2}\left(\frac{y_c}{y}\right)^3 \dots\dots\dots\dots\dots (11)$$

Mr. Bickerstaff's photographs are very helpful in picturing the conditions in the author's experiments. However, the writer is concerned over the effects that departure of the dye interface from the vertical might have on the interpretation of the illustrations. Was the dyed stream only a shallow layer or did it occupy the full depth of the section? If the latter was the case, did the interface remain vertical?

[18] "Modern Developments in Fluid Dynamics," by S. Goldstein, Oxford, 1938, p. 592.

The verity of Mr. Taylor's data is undeniable, and his conclusions have been drawn with care. Still, the writer would be sorry to see either used to discourage further attempts at theoretical analysis of the problem. It is for that reason that he has sought to show the weaknesses of the underlying assumptions.

EDWARD H. TAYLOR,[19] JUN. AM. SOC. C. E.—The interest shown in this rather specialized problem has been an agreeable surprise to the writer. The discussers have uniformly realized that the purpose of the research was to investigate the degree to which elementary physical laws can be applied to the situations devised, rather than to discuss the problem of turbulent mixing in detail. The mixing problem is essentially complicated, and thus should be approached from a consideration of pressure and momentum. If it is possible to write down correct expressions for the pressures and momenta at the boundaries of the process in question, the intermediate details can be disregarded.

Mr. Palmer suggests that the problem should be studied from the standpoint of energy loss rather than from that of change of momentum. This would require knowledge of the mechanism of energy loss, which was not contemplated in the original studies. Thus, in the absence of theoretical considerations relating to these losses, such an approach would seem to require greater recourse to empiricism than had been intended.

In raising the question of evaluation of the pressure force on the walls of the branch channel, both Mr. Hickox and Mr. Stevens have accurately stated the chief source of disparity between the experimental results and the equations. The measurements substantiated the assumption of equal depths above the junction; but this, of course, disregards wall pressures arising due to curvature of flow in the branch between the junction and the point of measurement of depth. The writer now recognizes that failure to measure the static pressures in the region constitutes an important omission.

Mr. Stevens brings up the same question in connection with pipe intersections. In the article he cites,[8] the pressures are assumed uniform over the pipe cross sections immediately upstream from the junction. In measurements[20] made at the University of California on a 90° pipe intersection, this factor was investigated. It was found that an appreciable lateral pressure gradient existed in the branch for some distance upstream. This is due to the fact that the flow in the branch does not change abruptly on reaching the junction, but starts to curve while it is yet in the straight part of the branch. This section of the flow system is included in writing the equations, since at its upstream end the direction of the velocity is known to be parallel to the walls. However, its inclusion introduces a component of pressure force in the direction of summation which cannot be accounted for by elementary methods.

[20] "Energy Loss in Mixing Streams in Closed Circular Conduits," by William Reeves Shuler, thesis presented to the Univ. of California in Berkeley in May, 1940, in partial fulfilment of the requirements for the degree of Master of Science (unpublished).

Professor Posey correctly states that no consideration has been given to cases involving flow at less than critical depth. The same fundamental principles would apply to such cases, although the problem of maintaining supercritical velocities throughout the junction might prove troublesome. It is also likely that the factors causing disagreement would be amplified by the higher velocities.

The comments of Mr. Hosig regarding the practical aspects of this research are very welcome, since such considerations were quite beyond the scope of the original studies. It is gratifying to have Mr. Hosig's testimony that these results are not entirely academic.

In his examination of the momentum equation, Mr. Hall has reached certain conclusions which are not correct, and at the risk of appearing pedantic, the writer wishes to point out the errors involved. Mr. Hall finds that "under the condition of no flow in the side channel, the velocity head is always one half of the depth." The algebraic steps leading to this result involved division by zero, which, of course, invalidates any subsequent conclusion.

In Eq. 9, Mr. Hall has derived the hydraulic jump relationship, but appears concerned because of the possibility that the jump might occur in the reverse direction, which he notes, is "contrary to accepted hydraulic theory." Mr. Hall has overlooked the fact that, in so far as momentum changes alone are concerned, the jump is quite a reversible process. A reverse jump would require an increase in total energy in the direction of flow, which presumably accounts for the rarity of its occurrence in nature.

Both Mr. Morris and Mr. Stevens note that the momentum terms are based on average velocities, and, to be strictly correct, such terms should contain a velocity distribution coefficient. Although this is undeniably true, it seems to be of secondary importance in comparison with inability to express all pressure forces correctly. This is particularly true of the experiments described in this paper, in which tranquil flows were maintained in all cases. Mr. Morris draws attention to Mr. Bickerstaff's photographs, which are isolated examples taken from a large collection of very good pictures. In each case the dye had been injected so that, by the time it had reached the junction, it occupied the full depth of the section. If the writer's memory serves correctly, the interface remained essentially vertical in the vicinity of the intersection.

Messrs. Hickox, Stevens, and Morris are in substantial agreement on the uncertainties in the analysis as presented. In the event that a problem similar to this one should be investigated in the future, the experimenter would be well advised to heed their comments.

SIMPLIFIED ANALYSIS OF SKEWED REINFORCED CONCRETE FRAMES AND ARCHES

By Richard M. Hodges,[1] M. Am. Soc. C. E.

With Discussion by Messrs. C. D. Geisler, Arthur G. Hayden, Bernard L. Weiner, Alfred L. Parmé, J. Charles Rathbun, Maurice Barron, Phillips H. Lovering, Jaroslav Polivka, A. A. Eremin, and Richard M. Hodges.

Synopsis

The principal purpose of this paper is to present a simplified general method of analysis for solid-barreled skewed reinforced concrete rigid frames and arches which can be understood readily by capable designers who know something about the theory of elasticity, without necessarily having made a special study of the subject of skewed arches. All unnecessarily complicated terms and expressions have been avoided, particularly those resulting from the solution in general terms of simple simultaneous equations which can be handled more easily by the direct substitution of numerical quantities.

The method presented is based on the assumption ordinarily made in the analysis of rigid frame bridges on earth foundations—that virtual hinges exist along the z-axes at the bottoms of the footings, due to the compressibility of the soil. Methods previously presented also have been based on the additional assumption that complete fixity against rotation exists about the other two axes. In view of the evident inconsistency of these two assumptions, the probability of slight rotations about the x-axes and the y-axes has been taken into account also. It will be found that the necessary adjustments can be made with very little difficulty on account of the simplification effected in the general analytical process.

A practical application is made to the design of a grade separation access structure of small span but heavy skew, constructed by the Westchester (N. Y.) Cross County Parkway Authority in 1942, which is typical of the kind of structure with which this paper is mainly concerned. Suggestions are given

which, it is hoped, will be helpful in the matter of procedure to those not familiar with the subject.

In the Appendix, the original four simultaneous equations for determining the redundant reaction components of a skewed arch according to the method of analysis first published[2] in 1931 by Arthur G. Hayden, M. Am. Soc. C. E., are given, and certain deductions are made as an additional confirmation of the fundamental relationship on which this paper is based. It will be found unnecessary to make further reference, in this connection, to Mr. Hayden's equations—the simplified method, as here presented, is complete in itself.

The term "frame," or "rigid frame," as used in this paper, is defined to include structures of the full-centered arch type, such as are sometimes used in the form of elliptical arches for grade crossing eliminations.

INTRODUCTION

Following the general adoption of rigid frame bridges along the parkways of Westchester County and Long Island, New York, there has been a rapid increase in the construction of this type of bridge, due, in a large measure, to the particular suitability of solid-barreled frames for grade separations. In general, grade separations are seldom at right angles. It is probably an understatement to say that at least 25% of the frames used for grade separation work either are, or should be, skewed to an extent sufficient to affect the design. Such bridges are normally small and inexpensive. It should be made possible for any ordinary highway bridge design force, or small design organization, to handle them correctly, confidently, and with a reasonable amount of speed and economy. It should never be necessary, under any conditions, to resort to a bridge of less suitable type, or to juggle the alinement in order to dodge the problem.

It is unfortunate, therefore, that so little has been done to simplify the available methods of analysis, and to make them accessible, in effect, to the average designer. During the six or seven years immediately following the presentation, in 1924, by J. Charles Rathbun, M. Am. Soc. C. E., of a paper[3] giving, for the first time, a rational basis for the design of skewed arches and frames, several variations and modifications were proposed, all leading by more or less devious channels to identical results (except the distribution of the internal stresses), and all being open, in a greater or less degree, to the same objection. They are all tedious and complicated, and difficult to apply without an unreasonable amount of time and labor.

The method published by Mr. Hayden is perhaps the easiest, or rather the least difficult, for the average designer. In the method referred to, Professor Rathbun's theory, as applied to the determination of the external forces, was adapted by the writer, under Mr. Hayden's direction, to the design methods used for rectangular two-hinged rigid frame bridges in the Design Department, Westchester County Park Commission, the internal stress distribution being handled (in the later edition) in very much the same way as was proposed originally by Professor Rathbun. The process has been simplified in this paper to such extent that more than one half of the work formerly involved in a complete analysis and design has been eliminated.

DERIVATION OF METHOD FOR DETERMINING REACTIONS

General Basis of Derivation.—The redundant reaction components H acting at the supports of a two-hinged rectangular rigid frame are so nearly identical with the corresponding redundant reaction components R_x acting at the supports of a two-hinged skewed rigid frame of the same right span that, for purposes of practical design, the difference is negligible. This fact has been attested by comparative analyses, regardless of skew, span, or deck curvature. It was verified by comparative analyses of flat-topped and elliptical frames, made under the writer's supervision in 1932, for skews up to 60°, and has been further confirmed as one of the results of a study,[4] by Ernest J. Clark (Supervising Designer for W. Earle Andrews, Consulting Engineer, New York, N. Y.), of a skewed frame of comparatively long span, using entirely different methods.

The identity referred to has been applied for years as an approximate method of analysis,[5] under variously defined limitations, but its implications have not been thoroughly understood. It can be derived mathematically for flat-topped frames, and can be demonstrated as applicable to any type of frame by making an assumption (see Appendix), the practical validity of which, for cases of unrestricted deck curvature, it has been necessary to establish by trial. No comparative analyses have been made, to the writer's knowledge, of arches of the segmental type, and it is not certain, in the absence of such supporting evidence, that the simplified method is valid in such cases. Skewed segmental arches, however, are rather too scarce, in general, to be of much importance in this connection, since, when used, they are usually sufficiently large and expensive to justify more extended methods of analysis.

The general applicability of the foregoing relationship to all kinds of frames is of fundamental importance in any real simplification of skewed frame analysis. The reaction components H and their static equilibrants ϵH (see Fig. 1) which thus have been found to be independent of the torsional elastic deformations in the structure, are of much more importance to the design than any of the remaining redundant quantities, and the advantages to be gained by considering them independently are obvious.

It will be noted that the equilibrants ϵH are the principal parts of the total reaction components R_z. The remaining parts of R_z, which have been designated as R'_z, together with the reaction components M_x and M_y, constitute an independent group, all of which are functions of the torsional elastic deformations, and no one of which is of much more (or less) importance in its effect on the design than either of the others. The reaction component M_{yL} at the left support is equal to the reaction component M_{yR} at the right support for all cases of symmetrical loading, and both can be obtained by statics as soon as

R'_s has been found. Therefore, the determination of the remaining redundant reaction components requires the solution of only two simultaneous equations, with simple corrections for unsymmetrical loading. Separate solutions for the two independent groups of redundant quantities acting on a skewed frame not only shorten the calculations but also (which is more important) reduce the probability of serious error. It may be added that the extreme precision required for the solution of four simultaneous equations, each involving quantities belonging to two separate elastic systems, is no longer necessary.

Fig. 2.—Balanced Earth-Pressure Forces and Reactions Acting on the Base Structure

Although this paper is not primarily concerned with the problem of internal stress distribution, the design method originally proposed by Professor Rathbun has been adopted, in the form presented by Mr. Hayden, and has been simplified further. The method presented by Bernard L. Weiner,[6] M. Am. Soc. C. E., was a valuable contribution to the theory of the subject, but the writer, as well as other designers, has used the very much simpler Rathbun method for many years with satisfactory results.

Details of Derivation.—All of the forces acting on the structure, as well as all of the internal stress components which need to be considered in any ordinary practical problem, are shown in Figs. 1 and 2. Unbalanced earth pressure is so seldom used in practical design that it has not been included.

The redundant reaction components to be determined directly are those acting at the point of origin at the right support. The complete solution for any loading condition is made in two steps:

1. The first step requires very little explanation. It consists of the determination of the horizontal reactions H for an ordinary two-hinged rectangular rigid frame (designated as the "corresponding rectangular frame"), which is outlined in longitudinal section by projecting the skewed frame under consideration on a vertical plane perpendicular to the abutments, or parallel to the xy-plane. The same reactions apply to the skewed frame, without any change except that the H for temperature change must be multiplied by $(1 + \epsilon^2)$.
2. The second step consists of setting up and solving the equations for the redundant reaction components R'_z, M_x, and M_{yR}, using, as the base structure, the skewed frame in equilibrium with the reaction components H and ϵH included. Except for the number of redundants involved, the type of base structure used, and the fact that only one elastic system is used instead of two, the method is very similar to that originally used in deriving the equations given in the Appendix.

In setting up the equations, the internal stresses acting at any point P (Fig. 1) are represented as a system of external moment and force components exerted by the portion of the structure to the left of P on the part of the structure to the right. The applied loading and the reaction components acting on the base structure are shown in Figs. 1 and 2 as applied, of course, in their known directions. The unknown redundant reaction components, and also the components representing the unknown internal stresses, are shown applied in their assumed positive directions. The convention used for indicating moment directions is indicated in Fig. 1, the subscript representing, in each case, the axis about which rotation tends to occur.

The equations state the customary assumption that each of the redundant reaction components will prevent displacement or rotation in its particular direction. Since this assumption is open to question under ordinary soil conditions (see Fig. 6, under "Application of the Method to a Practical Example"), additional equations are set up and solved to find the effect on the design if free rotation is allowed about the x-axes, or about both the x-axes and the y-axes. The structure can be reinforced, at very small extra expense, to meet all of these assumed conditions of rotation or fixity.

---

[6] "Design of a Reinforced Concrete Skew Arch," by Bernard L. Weiner, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1212.

Geometrical Relations and Definitions.—The geometrical relations involved are indicated in Fig. 1. The coordinate axes, applied loads, reaction components, and the components representing the internal stresses at any point P are all applied in directions parallel with, or perpendicular to, a vertical plane perpendicular to the abutments. The profiles shown in Figs. 1 and 2 are projections of the skewed frame on such a vertical plane. The point P is taken on the neutral axis at the center of any subdivision s, the coordinates of which are x, y, and z. The components representing the internal stresses at P are assumed to act along the directions of the u, v, and z-axes passing through point P. These directions (except the direction of z) are variable. The angle ϕ is the angle of slope of the neutral axis (or of the v-axis) at P; it can be represented conveniently as shown. The quantity u is shown to be the component parallel to the u-axis of the distance between point P and the origin. It cannot be emphasized too strongly that a complete understanding of the basic relations shown in Fig. 1 will remove the principal source of difficulty in skewed arch or frame analysis.

The following definitions are supplementary to the information shown in Figs. 1 and 2:

c = coefficient of linear expansion for concrete and reinforcing steel;

$t°$ = temperature rise or fall, in degrees Fahrenheit;

w = equivalent fluid pressure of earth, in pounds per square foot per foot of depth;

M_o = simple span moment on the corresponding rectangular frame, for vertical loading;

$$K = \frac{\text{Modulus of elasticity for concrete under axial stress}}{\text{Modulus of elasticity for concrete in shear}} = \frac{E}{G};$$

F = factor of torsion (a quantity corresponding to the moment of inertia I where ordinary flexure is concerned) $= \dfrac{b\,t^3}{3.58}$.

Basic Equations.—The basic equations are developed under the assumption that no rotation can occur at the footings, except about the z-axes, and that no movement of translation can occur in any direction. There are five reaction components at each footing, therefore; at the right-hand footing they are R_x, R_{yR}, R_z, M_x, and M_{yR}. The components R_x and R_{yR} are known, as well as ϵR_x, which is a part of the total component R_z. The redundant reaction components to be considered are therefore R'_z, M_x, and M_{yR}. The deflections at the right support along the lines of action of the redundants, due to all of the forces acting, are assumed, in each case, to be equal to zero. The usual assumption is made that the effects of all thrusts and shears can be neglected in considering deflections. It is only necessary, therefore, to consider the deflections due to the torsional moments about the v-axis, at point P.

Let:

M_v = moment at P about the v-axis, due to all the forces acting;

$m_{v(z)}$ = moment at P about the v-axis, due to unit force acting along and in the direction of R'_z;

$m_{v(ox)}$ = moment at P about the v-axis, due to unit couple acting along and in the direction of M_x; and

$m_{v(oy)}$ = moment at P about the v-axis, due to unit couple acting along and in the direction of M_y.

Summing up for all points P, the three deflection equations are:

$$\frac{s}{G}\sum\frac{M_v\,m_{v(z)}}{F} = 0\ (1a),\quad \frac{s}{G}\sum\frac{M_v\,m_{v(ox)}}{F} = 0\ (1b),\ \text{and}\ \frac{s}{G}\sum\frac{M_v\,m_{v(oy)}}{F} = 0\ (1c)$$

The fundamental expression for M_v (for vertical loading), in terms of all of the external forces acting on the structure, can be written from a careful inspection of Fig. 1, as follows:

$$\begin{aligned} M_v &= R_x\,\epsilon\,x\sin\phi - R_z\,u + M_x\cos\phi - M_{yR}\sin\phi \\ &\quad + R_{yR}\,\epsilon\,x\cos\phi - W\,\epsilon\,(x - x')\cos\phi \\ &= R_x\,\epsilon\,x\sin\phi - R_z\,u + M_x\cos\phi - M_{yR}\sin\phi + M_o\,\epsilon\cos\phi \quad\ldots\ldots(2) \end{aligned}$$

Also, by inspection:

$$m_{v(z)} = -\,u \quad\ldots\ldots(3a)$$

$$m_{v(ox)} = \cos\phi \quad\ldots\ldots(3b)$$

and

$$m_{v(oy)} = -\sin\phi \quad\ldots\ldots(3c)$$

Substituting Eqs. 2 and 3 in Eqs. 1, making $R_x = H$, and noting that the summation terms $\sum\frac{\sin\phi\cos\phi}{F}$ and $\sum\frac{y\sin\phi\cos\phi}{F}$ are each equal to zero, by symmetry, Eqs. 1 for vertical loading can be written, in preliminary form, as follows:

$$\begin{aligned} R'_z\sum\frac{u^2}{F} - M_x\sum\frac{u\cos\phi}{F} + M_{yR}\sum\frac{x\sin^2\phi}{F} \\ = \epsilon\left(\sum\frac{M_o\,u\cos\phi}{F} - H\sum\frac{u\,y\cos\phi}{F}\right) \quad\ldots\ldots(4a) \end{aligned}$$

$$R'_z\sum\frac{u\cos\phi}{F} - M_x\sum\frac{\cos^2\phi}{F} = \epsilon\left(\sum\frac{M_o\cos^2\phi}{F} - H\sum\frac{y\cos^2\phi}{F}\right) \ldots(4b)$$

and

$$R'_z\sum\frac{x\sin^2\phi}{F} + M_{yR}\sum\frac{\sin^2\phi}{F} = \epsilon\sum\frac{M_o\sin\phi\cos\phi}{F} \quad\ldots\ldots(4c)$$

The expression for M_v in Eq. 2 and the resulting Eqs. 4 can be adjusted to include balanced earth pressure and temperature loading, as follows:

It should be noted that the simple span moment, or M_o, as used in the equations for vertical loading, has no direct component in the direction of M_v. It is simply a convenient abbreviation of the terms $R_{yR}\,x - W\,(x - x')$, which happen to enter into the expression for M_v as $[R_{yR}\,x - W\,(x - x')]\,\epsilon\cos\phi$. No such expedient is possible in the cases of earth pressure and temperature loading. For balanced earth-pressure loading, the corresponding terms may be written: $\left(\frac{w\,h^2}{2}\right)\left(y - \frac{h}{3}\right) - H\,y$, which equals $\left(\frac{w\,h^2}{2} - H\right)y - \frac{w\,h^3}{6}$.

As far as its effect on M_v is concerned, $\frac{w\,h^3}{6}$ can be omitted (see Fig. 2), and the moment $\left(\frac{w\,h^2}{2} - H\right) y$, like the moment M_o, has no direct M_v component. The force $\left(\frac{w\,h^2}{2} - H\right)$, however, cannot be neglected. For balanced earth pressure, therefore, the M_o-terms are to be omitted both from the expression for M_v and from the equations, and H is to be replaced throughout by $\left(\frac{w\,h^2}{2} - H\right)$.

For temperature rise, replace H throughout by $H\,(1 + \epsilon^2)$, which corresponds to R_x in this case (see the Appendix). Omit the M_o-terms in the expression for M_v and in Eqs. 4*b* and 4*c*, and replace the M_o-term in Eq. 4*a* by the quantity $\frac{E\,c\,t^\circ\,L}{K\,s}$. The latter substitution simply represents the substitution of the direct temperature displacement in the direction of R'_x in place of the elastic displacement due to the applied loading. There is no corresponding direct temperature displacement in the direction of M_x or of M_{yR}.

The preliminary equations can be simplified also in the following manner: In Eqs. 4*a* and 4*c*, $\sum \frac{x \sin^2 \phi}{F} = \frac{L}{2} \sum \frac{\sin^2 \phi}{F}$, since the values of x entering the first summation can be taken in pairs, each pair being equal to $\frac{L}{2}$. For any kind of symmetrical loading, the M_o-term in Eq. 4*c* is equal to zero. Eq. 4*c* reduces to the simple expression $M_{yR} = M_{yL} = -\frac{L}{2} R'_x$, and there are only two simultaneous equations left to be solved for R'_x and M_x. For symmetrical loading, R'_x and M_x at the right support are respectively equal to R'_x and M_x at the left support. Similarly, $M_{yR} = M_{yL}$ for symmetrical loading. For unsymmetrical vertical loading (Eq. 4*c*), $M_{yR} = -R'_x \frac{L}{2} + C$, in which C represents the quantity $\sum \frac{M_o \sin \phi \cos \phi}{F} \div \sum \frac{\sin^2 \phi}{F}$. By statics, $M_{yR} + M_{yL} = -R'_x\,L$, and therefore $M_{yL} = -R'_x \frac{L}{2} - C$.

Now assume the unsymmetrical loading balanced by adding equal loading placed symmetrically with respect to the original unsymmetrical loading. Evidently M_{yR} (or M_{yL}) for the balanced loading is equal to $-R'_x \frac{L}{2}$ for the unsymmetrical loading, which leads directly to Eqs. 5*d*. The redundants R'_x and M_x for unsymmetrical loading are each equal to one half, respectively, of the corresponding quantities for balanced loading. It is possible, therefore, to make the two simultaneous equations apply, not only to symmetrical loading, but also to unsymmetrical loading, by balancing, solving, and making the corrections noted.

Performing the substitutions and simplifications indicated, Eqs. 4 reduce to the following final equations for R'_x and M_x and formulas for M_{yR} and M_{yL}:

For vertical loads,

$$R'_z\left(\sum\frac{u^2}{F}-\frac{L^2}{4}\sum\frac{\sin^2\phi}{F}\right)-M_x\sum\frac{u\cos\phi}{F}$$

$$=\epsilon\left(\sum\frac{M_o\,u\cos\phi}{F}-H\sum\frac{u\,y\cos\phi}{F}\right)\ldots\ldots\ldots\ldots$$

for balanced earth pressure,

$$=-\epsilon\left(\frac{w\,h^2}{2}-H\right)\sum\frac{u\,y\cos\phi}{F}\ldots\ldots\ldots\ldots \tag{5a}$$

and, for temperature,

$$=\epsilon\left(\frac{E\,c\,t^\circ\,L}{K\,s}-H\,(1+\epsilon^2)\sum\frac{u\,y\cos\phi}{F}\right)\ldots\ldots\ldots\ldots$$

Also, for vertical loads,

$$R'_z\sum\frac{u\cos\phi}{F}-M_x\sum\frac{\cos^2\phi}{F}=\epsilon\left(\sum\frac{M_o\cos^2\phi}{F}-H\sum\frac{y\cos^2\phi}{F}\right)$$

for balanced earth pressure,

$$=-\epsilon\left(\frac{w\,h^2}{2}-H\right)\sum\frac{y\cos^2\phi}{F}\ldots\ldots\ldots\ldots \tag{5b}$$

and, for temperature,

$$=-\epsilon\,H\,(1+\epsilon^2)\sum\frac{y\cos^2\phi}{F}\ldots\ldots\ldots\ldots$$

For symmetrical loading,

$$M_{yR}=M_{yL}=-R'_z\frac{L}{2}\ldots\ldots\ldots\ldots \tag{5c}$$

and, for unsymmetrical vertical loading,

$$M_{yR}=+\frac{M_y}{2}+C,\qquad\text{and}\qquad M_{yL}=+\frac{M_y}{2}-C\ldots\ldots \tag{5d}$$

in which M_y is equal to either M_{yR} or M_{yL} for balanced vertical loading, and

$$C=\sum\frac{M_o\sin\phi\cos\phi}{F}\div\sum\frac{\sin^2\phi}{F}\ldots\ldots\ldots\ldots \tag{5e}$$

using the values of M_o for unsymmetrical vertical loading. Also R'_z and M_x for unsymmetrical loading are equal to one half, respectively, of R'_z and M_x, as previously noted, for balanced vertical loading.

The solution of Eqs. 5 completes the analysis of the external forces acting on the frame for the basic assumption of complete fixity at the footings, except about the z-axes. (A correction, which is considered subsequently, will be necessary in analyzing the effect on the footings of the component M_x for earth pressure loading.)

The corresponding general expression for M_v, expressed by Eq. 2, must be adjusted similarly for the various loading conditions, as follows: For vertical loading, $R_x = H$; for balanced earth pressure, $R_x = \frac{w\,h^2}{2} - H$; and, for temperature rise, $R_x = (1 + \epsilon^2)\,H$. The simple span moment M_o is to be omitted for all loading conditions except vertical loading.

Equations for Rotations at Footings.—The customary assumption that the footings are fixed rigidly at the footings against rotations about the x-axes and y-axes (especially the x-axes) seems to be unwarranted under ordinary soil conditions and for bridges of the type here considered. The degree of rotation necessary to overcome a condition of complete fixity in any direction is so small that even elaborate and expensive provisions for insuring fixity cannot be relied upon with any degree of certainty. The soil pressure distribution about the x-axes (see Fig. 6 under "Application of the Method to a Practical Example") is such that variable settlement and resulting rotation are to be expected. Theoretically, uniform pressure can be obtained by splaying the footings; but, aside from the fact that temperature effects (which are very important for heavy skews) are reversible, this is objectionable from a practical standpoint. On the other hand, any assumption of unrestricted rotation is also questionable unless special measures are taken to separate the frame and approach wall footings. Since the analysis can be made easily for both of these assumptions, there can be no reason for basing the design exclusively on either one of them. Therefore, in addition to the equations previously derived for the basic assumption, hereinafter called Assumption 1, equations will be derived for Assumption 2—free rotation about the x-axes; and for Assumption 3—free rotation about both the x-axes and y-axes.

Assumption 2.—Assuming free rotation about the x-axes, Eq. 5*b* is omitted and the M_x-term in Eq. 5*a* becomes zero, for obvious reasons. The right-hand terms of Eq. 5*a* remain as before, except that, for balanced earth-pressure loading, there is an additional term $\frac{w\,h^3}{12} \sum \frac{u \cos \phi}{F}$ · (An explanation of this is given subsequently under "Earth-Pressure Loading Considerations.") The M_y formulas and corrections remain unchanged.

In the expression for M_v (Eq. 2) omit the M_x-term for all loading conditions, and, for balanced earth-pressure loading, add the term $\frac{w\,h^3}{12} \cos \phi$ (see "Earth-Pressure Loading Considerations").

Assumption 3.—Assuming free rotation about both the x-axes and the y-axes, it is only necessary to solve Eq. 5*a*, which is exactly the same as for the previous assumption of rotation about the x-axes, except that the coefficient for R'_x becomes simply $\sum \frac{u^2}{F}$ · In the expression for M_v (Eq. 2), omit both the M_x-term and the M_{yR}-term, and make the same addition as before for balanced earth-pressure loading.

Earth-Pressure Loading Considerations.—The effect of earth-pressure loading on the torsional and transverse shearing forces is much greater, in general, than that of dead loading or any of the other loadings to which a skewed frame is subjected. It is more difficult, in many ways, to analyze, and is based on questionable assumptions. It deserves more attention, therefore, than it usually gets.

Fig. 2 represents the forces acting, and the transformations used in analysis. It should be noted that the figure shows only the external forces acting on the base structure; the redundant reaction components and the stress components at P are applied as shown in Fig. 1.

The reactions $\frac{w\,h^2}{4}$ shown acting at the elevation of the resultant total earth pressures are the most that can be taken above the footings, assuming a coefficient of friction of earth on concrete (or mortar waterproofing protection) of 0.5. The remainder, or $\epsilon\left(\frac{w\,h^2}{2}\right) - \frac{w\,h^2}{4}$, is assumed to be applied, in each case, directly against the footing. The customary assumption in practice has been that the entire equilibrating reaction is applied at the elevation of the bases of footings. On the contrary, the writer believes that the tendency is for the abutments to transmit, directly, as much of it as the coefficient of friction will permit. Admitting the many uncertainties affecting the action of earth pressures in general, and especially in this particular case, it is believed that the distribution here proposed is more reasonable.

The transformation of lateral reactions, as shown on the end elevation in Fig. 2, fails to take into account the effects of the forces on the vertical legs of the frame, but, since these effects are negligible, it makes no difference. The couples $\frac{w\,h^3}{12}$ are either directly counterbalanced at each footing, if the footings are assumed fixed against rotation in the direction of M_x, or counteracted across the frame, if the footings are assumed free to rotate. In the first case, these couples can be disregarded, except in so far as they reduce the reaction components M_x; in the second case, they must be taken into account in the equations and in the expressions for M_v. It will be seen that the moment $\frac{w\,h^3}{12}$, at the right end, is in the same direction as M_o for vertical loading, and therefore its M_v component can be obtained by substitution. The necessary corrections have been made accordingly in the equations and expressions for M_v as noted previously in the last two paragraphs under the heading "Equations for Rotations at Footings."

The couples $\frac{w\,h^3}{6}$, as shown on the profile, Fig. 2, are taken into account, in effect, in the analysis of the corresponding rectangular frame, but (since they have no M_v components) can be disregarded here.

DESIGN

Preliminary.—Having determined all of the redundant reaction components acting on the structure for the assumed conditions at the footings, the remaining problem, of course, is the determination of the effect of all forces acting on the structure, and the proportioning of the structure to withstand them with safety and economy. The stress at any section (point P) of the frame is represented by the moment and force components M_x, T_v, M_v, and T_x, as

indicated in Fig. 1. The moment and thrust M_z and T_v are obtained from the analysis of the corresponding rectangular frame, which needs no explanation; M_v has already been considered (see Eq. 2) and T_z is equal to R_z in every case.

Transformation of Forces.—The moment and force components referred to under the heading "Design: Preliminary" represent components of the internal stresses at the point P, acting in directions parallel with and perpendicular to the abutments. The next step will be to resolve or transform them into components acting in the directions most convenient for practical design; that is, parallel to the skewed direction of the bridge and parallel to its abutments. These transformations, the formulas for which are given in Fig. 3, result in a direct moment M_L and an axial thrust T_L acting in the longitudinal direction, and in a torsional moment M_T and a shear T_T acting in the transverse direction.

Design for Longitudinal Forces.—The design for the longitudinal moments and thrusts controls the proportioning of the structure, as well as the longitudinal reinforcement, but, since it consists of the same methods as are used generally for rectangular frames, it will not be considered here, except to note the necessary skew corrections, as indicated in Fig. 4. The procedure to be followed in applying the corrections is thoroughly explained and illustrated under the heading "Application of the Method to a Practical Example."

Design for Transverse Forces.—The design for the transverse torsional moments and shears determines the transverse reinforcement required in the structure as previously proportioned from the design for the longitudinal forces. As previously stated, the method used is fundamentally the same as that originally proposed by Professor Rathbun. The writer could do no better than to restate briefly, for the reader's convenience, a detailed outline of the process as presented by Mr. Hayden, with certain modifications.

The direct transverse shear T_T is assumed to be distributed parabolically across the width of the frame, in the same way as vertical shear is distributed along the depth of an ordinary beam. The maximum intensity at any section is constant throughout the depth, and, at the center line of the frame, amounts to three halves of the average unit shear.

The maximum intensity of the torsional shear at any section is given by Merriman's formula for elongated rectangular shafts (see Formula I, Table 11, presented subsequently). This maximum unit stress, which also exists at the center line of the frame, is exerted in opposite directions at the extrados and at the intrados, with a constant variation throughout the depth of the section and zero stress at the center, as shown in Table 11.

The shearing capacity of concrete (assumed in the example as 60 lb per sq. in.) can be deducted from the combination of the total net shears acting across the center line of the frame at the point considered, and the transverse reinforcing steel is designed to take care of the remainder by a method analogous to that followed in the design of vertical stirrups for a concrete beam whose depth is equal to the skew width of the bridge, and whose width is the depth of the section.

Fig. 1 indicates the positive directions of M_v and T_z at any point P. Whenever M_v and T_z are found to be of the same sign, they work together to cause shearing stress at the extrados and against each other to cause shearing stress at the intrados; and conversely, when they are found to be of different sign, they combine to cause shearing stress at the intrados and work against each other to cause shearing stress at the extrados. Since M_T and T_T are positive in the same directions as M_v and T_z, respectively, the same effects hold true for the transformed moments and forces M_T and T_T. This leads to the following rules for combining the unit torsional shears v_t and unit direct shears v_s for maximum effects:

(1) When v_t and v_s are of the same sign, add to obtain the resultant shear at the extrados and subtract to obtain the resultant shear at the intrados.

(2) When v_t and v_s are of different sign, add (regardless of sign) to obtain the resultant shear at the intrados and subtract (regardless of sign) to obtain the resultant shear at the extrados.

Since the differences between the resulting shears at the intrados and at the extrados are proportionately small, except where the amount of transverse reinforcement is negligible, it is only necessary, in practice, to design for an equal amount of steel in both locations, based, in both cases, on the arithmetical sum of v_t and v_s. The areas of transverse steel reinforcement required at the various subdivision points are calculated by a semigraphical process which can be understood readily by referring to Table 11 (under the heading "Application of the Method to a Practical Example"). The calculations have been shortened by representing v_s in a diagonal instead of in a vertical position, and by deducting, for the shearing resistance of concrete, an amount varying uniformly from zero at the neutral axis of the section to the full allowable value at the top and bottom.

APPLICATION OF THE METHOD TO A PRACTICAL EXAMPLE (SEE FIG. 5)

Part 1. Analysis of Corresponding Rectangular Frame.—The complete analysis of the corresponding rectangular frame, to the point of determining the reactions and the maximum moments and thrusts for the loading conditions considered, constitutes Part 1 of the procedure. There are various well-known methods of procedure which, of course, need not be mentioned. The solution appears in Table 1.

[a] Subdivision $5R$ (Fig. 5) has been omitted since the moments and thrusts at this point are negligible.

[b] See alternate locations of concentrated live loads in Fig. 5.

Part 2. Design of Skewed Frame for Longitudinal Forces.—Part 2 consists, in general, of the complete design of the skewed frame for the longitudinal moments and thrusts found from Part 1, after transforming and correcting them in accordance with the following procedure:

The transformation of forces and the resulting formulas are shown in Fig. 3. The formulas for M_L and T_L applying to Part 2 are:

$$M_L = M_z \sec V \qquad \text{(6a)}$$

and

$$T_L = T_v \sec V \qquad \text{(6b)}$$

The thing to be particularly noted here is that the formulas happen to work out in such a way that M_L and T_L are entirely independent of M_v and T_z, which appear in the corresponding formulas for Part 3. This means that Part 2 of the design, which controls the proportioning of the structure, can be completed without any reference to Part 3; and this is a very decided advantage. With reference to Fig. 3, it should be noted that the moments and forces shown in plan are all acting in the *vz*-plane (tangent to the neutral axis at point *P*). The angle *V* is the projection on the *vz*-plane of the skew angle θ (see calculations in Table 2). In Fig. 3, it is shown projected back on a horizontal plane.

FIG. 5.—DIMENSIONS, LOADINGS, AND PROPERTIES OF CORRESPONDING RECTANGULAR FRAME

The first correction considered is due directly to the fact that *H* for temperature loading, as found for the corresponding rectangular frame, must be multiplied by $(1 + \epsilon^2)$, or $\sec^2 \theta$, in order to make it applicable to a skewed frame (see Fig. 4). The additional skew corrections, which are illustrated in

Fig. 4, consist of multiplying M_L and T_L by sec θ for all conditions of loading, and also multiplying M_L and T_L again, for live loading, by cos θ. Although the two factors evidently cancel for live loading, it is found convenient in tabulation to perform both multiplications. The resulting procedure, as adopted for the present example, is as shown in Table 3.

TABLE 2.—VALUES OF FUNCTIONS OF THE ANGLE V (SEE FIG. 3)

($\theta = 54°$; $\epsilon = 1.376$; and $\epsilon^2 = 1.893$)

Function	Point 0	Point 1R	Point 2R	Point 3R	4R	5R	6R
Cos ϕ	1.00	0.99	0.98	0.95[a]	0	0	0
Tan $V = \epsilon \cos \phi$	1.376	1.362	1.348	1.307	0	0	0
V	54° 00′	53° 45′	53° 25′	53° 35′	0	0	0
Sec V	1.701	1.69	1.68	1.64	1.0	1.0	1.0
Sec θ sec V	2.90	2.88	2.86	2.79	1.7	1.7	1.7

[a] The angle ϕ at point 3R is in a state of transition. The value of cos ϕ, as used for Part 2, is based on a point in the deck portion just to the left of point 3R—which represents the most severe assumption. For Part 3, where it makes very little difference one way or the other, an angle of 45° is assumed (see Table 4).

The remainder of Part 2 consists simply of designing and proportioning the structure from the corrected moments and thrusts in exactly the same manner as for a rectangular rigid frame. The calculated depth at any section is to be measured in a vertical plane perpendicular to the abutments, which is the same as the depth for the corresponding rectangular frame. The calculated steel areas will be the areas required per foot of square width of the structure—that is, perpendicular to the faces of the bridge.

TABLE 3.—QUANTITIES IN TABLE 1 CORRECTED FOR SKEW

Loads	Step[a]	POINT 0		POINT 1R		POINT 2R		POINT 3R		POINT 4R		POINT 6R

Maximum	3	+18.0	7.5	+11.4 −13.2	7.3 7.9	− 37.4	7.9	− 82.8	14.9	−38.4	18.2	+11.7	23.8
Corrected	3	+52.2	21.6	+32.8 −37.9	21.1 22.8	−106.9	22.7	−231.0	41.5	−65.3	30.9	+19.9	40.5

[a] Note that Steps 1 and 2, following, apply also to Part 3:
Step 1.—Live load quantities multiplied by cos θ (0.588).
Step 2.—Temperature quantities multiplied by $\sec^2 \theta$ (2.90).
Step 3.—Maximum moments and thrusts summed up and multiplied by sec θ sec V (Table 2).

[b] See alternate locations of concentrated live loads in Fig. 5.

These matters have been described at some length because frequently they are sources of confusion and error. In the tables, the calculations have been extended only to the point of tabulating the maximum moments and thrusts at the various points, including the necessary skew corrections. It would serve no useful purpose to include in the example details of reinforced concrete design for bending and direct stress. It is worthy of note, however, that in the actual design of the structure used here as an example (Fig. 5), it was necessary to make several preliminary trials before the final dimensions were established, and it was found necessary, in the final design, to reduce the depth of concrete at and adjacent to the crown (the critical section), to a depth considerably smaller than that assumed in the beginning. This is typical of severe skews, where the temperature moments increase very rapidly in proportion to the other moments acting. The preponderant effect of temperature in such cases leads to the anomalous condition that the better the quality of concrete assumed in the design, the weaker the structure tends to become theoretically, until finally a point is reached where it becomes impossible, for any assumed crown thickness, to find room for the amount of tensile and compressive reinforcing steel required.

Part 3. Analysis and Design of Skewed Frame for Transverse Forces.—Part 3 includes (1) the analysis of the frame for the torsional and shearing forces acting in the transverse direction, and (2) the design of the transverse reinforcement needed in the structure as previously proportioned under Part 2.

It is unfortunate that, although Part 3 is of comparatively minor importance, it requires a comparatively larger amount of work. In many cases of moderate skew, the transverse steel will amount to little, if any, more than the spacer bars that would be used in any case, and therefore Part 3 could be omitted entirely. However, it is difficult, if not impossible, to be sure about this in any particular case (unless the skew amounts to less than about 25°) without working it out first.

Σ	....	....	....	....	....	....	2,168.0	0.588	2.97	71.91	1,701.00	70.25

The example includes, for purposes of illustration, the most extensive analysis necessary under any circumstances. In most cases the work can be shortened. For instance, it will be noted that Assumption 3 (free rotation about both the x-axes and the y-axes) controls the design throughout, as might be expected, except that Assumption 2 (free rotation about the x-axes) controls at points along the vertical legs. It will also be seen that live loading could be omitted entirely without materially affecting the results.

[a] See alternate locations of concentrated live loads in Fig. 5.

The procedure for Part 3 is illustrated fully by Tables 4 to 11, and no further explanation is necessary. Experience shows, however, that mistakes occur most frequently in assembling and calculating the proper numerical quantities for substitution in the Eqs. 5. The following two paragraphs, in connection with Table 6, show a systematic arrangement of these quantities.

Quantities for Direct Substitution in Equations, Assumption 1.—The following values of H are obtained from Part 1:

Dead load	Balanced earth pressure	Temperature rise	Live load, Point 0	Live load, Point 1R
3.28	6.3	0.126	1.05	0.85

Substitutions for the left-hand sides of the equations are:

Eq.	Expression	Solution	Substitution
5*a*	$\sum \frac{u^2}{F} - \frac{L^2}{4} \sum \frac{\sin^2 \phi}{F}$	$2{,}168 - 19.2^2 \times 0.588$	1,951
5*a* and 5*b*	$\sum \frac{u \cos \phi}{F}$	....	71.9
5*b*	$\sum \frac{\cos^2 \phi}{F}$	....	2.97

The corresponding substitutions for the right-hand sides of the equations are listed in Table 6.

Quantities for Direct Substitution in Equations, Assumptions 2 and 3.—The balanced earth-pressure substitutions, in the right-hand sides of Eqs. 5*a* and 5*b*, for Assumptions 2 and 3, are as follows: $- \epsilon \left(\frac{w\, h^2}{2} - H \right) \sum \frac{u\, y \cos \phi}{F}$

$+ \frac{w\,h^3}{12} \sum \frac{u \cos \phi}{F} = -\,8{,}890 + 43.4 \times 71.9 = -\,5{,}770$. The substitution for the left-hand side (Assumption 3) is $\sum \frac{u^2}{F} = 2{,}168$. The M_v-correction for Assumption 2 is the same as shown in Table 6 for Assumption 1. With the aforementioned exceptions, all substitutions in the right-hand sides of Eqs. 5*a* for Assumptions 2 and 3 are the same as the corresponding substitutions in Eqs. 5*a*, for Assumption 1, as shown in Table 6.

TABLE 6.—SUBSTITUTIONS FOR THE RIGHT-HAND SIDE OF EQUATIONS ASSUMPTION 1

Loading	Expression	Computation	Substitution
(*a*) Eqs. 5*a*			
Dead load.......	$\epsilon \left(\sum \frac{M_s\, u \cos \phi}{F} - H \sum \frac{u\,y \cos \phi}{F}\right)$	1.376 (5,754 − 3.28 × 1,701)	240
Balanced earth pressure	$-\,\epsilon \left(\frac{w\,h^2}{2} - H\right) \sum \frac{u\,y \cos \phi}{F}$	− 1.376 (10.1 − 6.3) × 1,701	−8,890
Temperature rise	$\epsilon \left[\frac{E\,c\,t^\circ L}{K\,s} - (1 + \epsilon^2)\, H \sum \frac{u\,y \cos \phi}{F}\right]$	(see next line)	
		$1.376\, \frac{288{,}000 \times 0.0000065 \times 50 \times 38.4}{2.67 \times 6.4} - (1 + 1.376^2)\, 0.126 \times 1{,}700$ $= 1.376\,(210 - 620)$	−564
Live Load:			
0............	(Dead-load expression × cos θ)	1.376 (1,883 − 1.05 × 1,701) × 0.588	78.4
1R (balanced).	(Dead-load expression × cos θ)	1.376 (2,973 − 1.7 × 1,701) × 0.588	62.4
(*b*) Eqs. 5*b*			
Dead load......	$\epsilon \left(\sum \frac{M_s \cos^2 \phi}{F} - H \sum \frac{y \cos^2 \phi}{F}\right)$	1.376 (239.4 − 3.28 × 70.25)	12.38
Balanced earth pressure	$-\,\epsilon \left(\frac{w\,h^2}{2} - H\right) \sum \frac{y \cos^2 \phi}{F}$	− 1.376 × 3.8 × 70.25	−367
Temperature rise	$-\,\epsilon(1 + \epsilon^2)\, H \sum \frac{y \cos^2 \phi}{F}$	− (1.376 + 1.376³) 0.126 × 70.25	−35.2
Live Load:			
0............	(Dead-load expression × cos θ)	1.376 (783 − 1.05 × 70.25) × 0.588	3.67
1R (balanced).	(Dead-load expression × cos θ)	1.376 (123.6 − 1.7 × 70.25) × 0.588	3.38
M_v-correction C (Eq. 5*e*)	$\epsilon \sum \frac{M_s \sin \phi \cos \phi}{F} \div \sum \frac{\sin^2 \phi}{F}$	$\frac{1.376 \times (-\,0.94)}{0.588}$	−2.20

Note that the values assumed for the various constants *w*, *c*, *t*°, etc. are plainly indicated in the above substitutions.

The individual reactions, as given in Table 8, are to be used in calculating the values of M_v in Table 9; the summations will apply to the determination of soil pressures at the footings (see Fig. 6), with the following corrections: Deduct $\frac{w\,h^2}{2}$ (or 10.1) from the total for R_x, and $\epsilon \frac{w\,h^2}{2}$ (or 13.9) from the total for R_z,

[a] Alternate locations of concentrated live loads in Fig. 5. Note that the live loadings (Items 4, 5, and 6) are not included in the summations (Items 8 and 9) since live loading has been neglected in the investigation of soil pressures (see Fig. 6).

Note: Values of R_x for dead load, earth pressure, live load, and temperature rise are, respectively: H, $0.5\, w\, h^2 - H$, $H \cos \theta$, and $(1 + e^2)\, H$. The values of H are obtained from Part 1.

for each of the three assumptions; and deduct $\frac{w\,h^3}{12}$ (or 43.8) from the total for M_x, under Assumption 1.

The resulting foundation conditions are indicated graphically in Fig. 6, as plotted from information given in Table 8. It is evident from inspection that

complete fixity against rotation about the x-axis should not be depended on under ordinary conditions.

Attention is called to a departure from general practice in basing the calculations, in the example, on a 1-ft longitudinal design strip instead of the total

TABLE 9.—COMPUTATIONS FOR M_v

Formulas for M_v, under Assumptions 1 and 3, are given in this table. For Assumption 2, the formula is the same as for Assumption 3 except that the quantity $-M_y \sin\phi$ is added. For earth pressure loading, M_{yR} is relatively quite large (see Table 8), but since $\sin\phi$ is very small from point 0 to point 2R, and also since point 3R (because of the increased depth at this point) is not a critical design section, Assumption 2 is confined to points 4R to 6R, inclusive. Values of M_o are given in Table 5, and of R_z, R_s, M_z, and M_{yR}, in Table 8. $\epsilon = 1.376$ (see Table 2).

Load	ϵM_o	ASSUMPTION 1						ASSUMPTION 3				
		$R_z \epsilon x \sin\phi$	− $R_z u$	+ $M_z \cos\phi$	− $M_{yR} \sin\phi$	+ $M_o \epsilon \cos\phi$	= M_v	$R_z \epsilon x \sin\phi$	− $R_s u$	+ $\frac{1}{12} w h^3 \cos\phi$	+ $M_o \epsilon \cos\phi$	= M_v

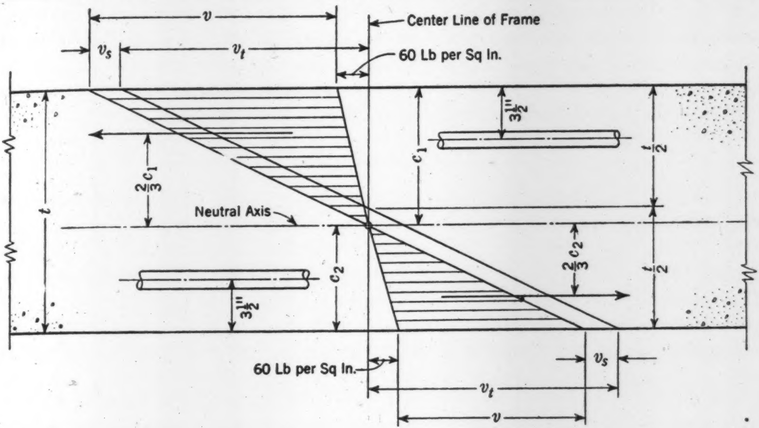
[a] M_T and T_T (see Fig. 3) are equal, respectively, to: M_s tan $V - M_v$; and, T_v tan $V - T_s$. Values of M_s and T_v are given in Table 3, M_v in Table 9, and $T_s = R_s$ in Table 8.

TABLE 11.—RESULTANT UNIT SHEARS AND TRANSVERSE REINFORCEMENT



Referring to the diagram—

$$v_t = \frac{4.5\, M_T}{12\, t^2} \quad \text{I}$$

$$v_s = \frac{1.5\, T_T}{12\, t} \quad \text{II}$$

and

$$v = (v_t \pm v_s) - 60 \quad \text{III}$$

Furthermore—

$$c_1 = \frac{v_t + v_s}{2\, v_t} t \quad \text{IV}$$

$$A_s = \frac{v\, c^2_1}{4{,}500\,(c_1 - 3.5)} \quad \text{V}$$

and

$$A_s = \frac{v\, c_1}{3{,}000} \quad \text{VI}$$

The factor b, which should appear in the denominators of Formulas I and II, is not shown since it is equal to unity. c_1 (see Formula IV) locates the neutral axis, and is the greater of the two c distances, whether measured from the intrados or from the extrados. Formula V equates $A_s f_s$ to the total shear, as represented by the larger shear triangle in the diagram. Formula VI equates the moment $A_s f_s$ about the neutral axis to the moment of the larger shear triangle about the neutral axis. Formulas V and VI are based on $f_s = 18{,}000$ lb per sq in.; and the transverse steel is designed from the greater of the two values of A_s.

Point	Torsional Shear					Direct Shear		Total		Steel Reinforcement

width of the bridge. It should be understood, of course, that the bridge is considered as a whole in this part of the analysis and design. It is possible to use a 1-ft strip only because it just happens that the total width "b" enters into the expression for the factor of torsion, F (under the heading "Geometrical Relations and Definitions"), and into the torsion and shear formulas (Table 11), as a linear quantity. In such case, it is a practical waste of time to introduce "b" into the calculations, since it automatically cancels itself.

CONCLUSIONS

(1) There is no justification for avoiding the use of solid-barreled skewed rigid frame bridges on the basis of difficulties, delays, or uncertainties in design. Parts 1 and 2 of this paper (including the analysis and design for the transformed longitudinal forces), taken together, represent very little more work than that necessary for the design of any ordinary rectangular rigid frame. Part 3 (the analysis and design for the transformed transverse forces) has been developed at some length in the example to illustrate the comparative effects of various loading conditions and various foundation assumptions, but the amount of work involved (a large proportion of which, it will be found, can be omitted in practice) is still considerably less than that formerly required and a great deal easier to follow.

In Part 3, it will be noted that Assumption 1 (footings fixed against rotation about the x-axes and y-axes) leads to transverse torsional moments amounting, in the example, to less than two thirds, at any point, of the torsional moments obtained by either one of the other two assumptions. Although there is reason to believe that this will be true for any skewed frame, it is impossible, at present, to make any such general inference. With accumulating experience, however, it should be possible to eliminate Assumption 1, in at least the majority of cases, which will mean a substantial further reduction in the amount of work required. The example also illustrates the practically negligible effects of live loading. In practice, it ordinarily can be omitted safely, except as a small plus-or-minus percentage (say ± 10%) of the combined dead load and earth pressure. This still further reduces the work necessary for Part 3.

Admitting that various uncertainties exist in skewed arch or frame design (notably the uncertainty as to the correctness of any of the various versions of the basic torsion formula underlying all methods of internal stress distribution), it should be remembered that they apply, for the most part, to Part 3, which is after all a minor part of the design. Attention is called again to the fact that Parts 1 and 2, which control the proportioning of the structure, are independent of Part 3, and of any assumption that has been made therein.

The method of design described for Part 3 is based on the practical method of internal stress distribution originally proposed by Professor Rathbun. It is believed to be well within the limits of justifiable precision. Since Part 3 is of secondary importance and the transverse reinforcement amounts to relatively little in any case, and in view of the uncertainties previously referred to, any greater degree of precision would seem to be both useless and misleading for all practical purposes.

(2) The customary assumption that the footings will be fully restrained against rotation about the x-axes and y-axes is unaccompanied usually by any attempt to make certain, either in the design of the structure or in the details of the footings, that such restraint can be accomplished. It is evident from Fig. 6 that rotation about the x-axes (in the case of the bridge in the example) would be difficult to prevent, in any case. The proposed practice of designing skewed frames to meet either or both of the extreme conditions of complete restraint and free rotation about the x-axes and y-axes meets any condition, and furnishes security against any degree of rotation or restraint that can possibly result. The cost of the small amount of additional transverse reinforcement necessary for this purpose is a small price to pay for the added security obtained.

The practice of designing skewed frames on an assumption of free rotation about the z-axes is based on the well-established practice of designing rectangular frames on a similar assumption. There seems to be no reason why the assumption should not be as applicable in one case as in the other.

(3) The maximum degree of skew for which a frame can be designed successfully by the method here adopted is controlled, in any particular case, by the effects of temperature drop on the crown section under Part 2 (longitudinal forces). The temperature effects increase in the ratio of the fourth power of the secant of the skew angle. They also increase with the strength and stiffness of the concrete used in construction.

(4) It should be noted that the width of the structure, b, does not enter into the analysis or design, except indirectly as a factor in the intensity of live loading to be considered. The width-span ratio, therefore, has little effect on the results, and, according to the method of design here employed, has no more effect on the strength and stability of a skewed frame than it has in the case of an ordinary rectangular frame. Consequently (contrary to the popular belief), it makes no difference whether or not any part of one abutment can be projected, perpendicular to itself, upon the other.

(5) Such tests as have been made in connection with skewed arches and frames have dealt mostly with the effects of live loading in various positions. As previously noted, the effects of live loading are subordinate to temperature effects in Part 2, and are almost negligible in comparison with the effects of earth pressure in Part 3. Therefore, it would be more to the point (at least as far as the ordinary type of skewed frame is concerned) to test the effects of temperature fall and the distribution and intensity of earth pressure forces, as well as the amounts of rotation, in the various directions, that can be expected at the footings under ordinary soil conditions.

ACKNOWLEDGMENTS

The writer gratefully acknowledges the encouragement and assistance of Mr. Hayden in making this paper possible, and the helpful suggestions of Phillips H. Lovering, Assoc. M. Am. Soc. C. E., who checked parts of the manuscript. Permission was granted by Gilmore D. Clarke, M. Am. Soc. C. E., to make use of the design calculations for a grade separation access structure constructed by the Westchester Cross County Parkway Authority. The

skewed arch equations given in the Appendix, together with certain excerpts noted in the body of the paper, have been included by permission of Mr. Hayden and of John Wiley and Sons, Inc. Valuable improvements were pointed out by Norman D. Richardson, M. Am. Soc. C. E.

APPENDIX

DEDUCTIONS FROM SKEWED ARCH EQUATIONS AS PUBLISHED BY ARTHUR G. HAYDEN[3]

The equations presented by Mr. Hayden[3] are:

$$R_x\left(\epsilon^2 K \sum \frac{x^2 \sin^2 \phi}{F} + \sum \frac{y^2}{I}\right) - R_z\, \epsilon K \sum \frac{u\, x \sin \phi}{F}$$

$$+ M_x\, \epsilon K \sum \frac{x \sin \phi \cos \phi}{F} - M_y\, \epsilon K \sum \frac{x \sin^2 \phi}{F}$$

$$= -\epsilon^2 K \sum \frac{M_o \sin \phi \cos \phi\, x}{F} + \sum \frac{M_o\, y}{I} \ldots\ldots\ldots\ldots (7a)$$

$$R_x\, \epsilon \sum \frac{u\, x \sin \phi}{F} - R_z \sum \frac{u^2}{F} + M_x \sum \frac{u \cos \phi}{F}$$

$$- M_y \sum \frac{u \sin \phi}{F} = -\epsilon \sum \frac{M_o\, u \cos \phi}{F} \ldots\ldots\ldots\ldots (7b)$$

$$R_x\, \epsilon \sum \frac{x \sin \phi \cos \phi}{F} - R_z \sum \frac{u \cos \phi}{F} + M_x \sum \frac{\cos^2 \phi}{F}$$

$$- M_y \sum \frac{\sin \phi \cos \phi}{F} = -\epsilon \sum \frac{M_o \cos^2 \phi}{F} \ldots\ldots\ldots\ldots (7c)$$

and

$$R_x\, \epsilon \sum \frac{x \sin^2 \phi}{F} - R_z \sum \frac{u \sin \phi}{F} + M_x \sum \frac{\sin \phi \cos \phi}{F}$$

$$- M_y \sum \frac{\sin^2 \phi}{F} = -\epsilon \sum \frac{M_o \sin \phi \cos \phi}{F} \ldots\ldots\ldots\ldots (7d)$$

To use these equations for temperature reactions substitute the following quantities for the right-hand members of Eqs. 7: Eq. 7*a*, $+\frac{E\, c\, t^\circ L}{s}$; Eq. 7*b*, $-\frac{E\, \epsilon\, c\, t^\circ L}{K\, s}$; Eq. 7*c*, 0; and Eq. 7*d*, 0. For the sake of simplicity, the substitutions for horizontal earth-pressure loading have not been included.

Substituting, in Eqs. 7, the value

$$u = x \sin \phi + y \cos \phi \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

the following results are obtained:

$$R_x\left(\epsilon^2 K \sum \frac{x^2 \sin^2 \phi}{F} + \sum \frac{y^2}{I}\right) - R_z\, \epsilon\, K \left(\sum \frac{x^2 \sin^2 \phi}{F}\right.$$

$$\left. + \sum \frac{x\, y \sin \phi \cos \phi}{F}\right) + M_x\, \epsilon\, K \sum \frac{x \sin \phi \cos \phi}{F}$$

$$- M_y\, \epsilon\, K \sum \frac{x \sin^2 \phi}{F} = - \epsilon^2 K \sum \frac{M_o \sin \phi \cos \phi\, x}{F} + \sum \frac{M_o\, y}{I} \ldots (9a)$$

$$R_x\, \epsilon \left(\sum \frac{x^2 \sin^2 \phi}{F} + \sum \frac{x\, y \sin \phi \cos \phi}{F}\right)$$

$$- R_z \left(\sum \frac{x^2 \sin^2 \phi}{F} + \sum \frac{y^2 \cos^2 \phi}{F} + 2 \sum \frac{x\, y \sin \phi \cos \phi}{F}\right)$$

$$+ M_x \left(\sum \frac{x \sin \phi \cos \phi}{F} + \sum \frac{y \cos^2 \phi}{F}\right) - M_y \left(\sum \frac{x \sin^2 \phi}{F}\right)$$

$$= - \epsilon \left(\sum \frac{M_o\, x \sin \phi \cos \phi}{F} + \sum \frac{M_o\, y \cos^2 \phi}{F}\right) \ldots\ldots\ldots (9b)$$

$$R_x\, \epsilon \sum \frac{x \sin \phi \cos \phi}{F} - R_z \left(\sum \frac{x \sin \phi \cos \phi}{F} + \sum \frac{y \cos^2 \phi}{F}\right)$$

$$+ M_x \sum \frac{\cos^2 \phi}{F} = - \epsilon \sum \frac{M_o \cos^2 \phi}{F} \ldots\ldots\ldots\ldots\ldots (9c)$$

and

$$R_x\, \epsilon \sum \frac{x \sin^2 \phi}{F} - R_z \sum \frac{x \sin^2 \phi}{F} - M_y \sum \frac{\sin^2 \phi}{F} = - \epsilon \sum \frac{M_o \sin \phi \cos \phi}{F} . (9d)$$

(The right-hand sides of Eqs. 9 for temperature are the same as in Eqs. 7. The summations $\sum \frac{\sin \phi \cos \phi}{F}$ and $\sum \frac{y \sin \phi \cos \phi}{F}$ are each equal to zero and have been omitted.)

Multiply each term of Eq. 9*c* by y, making the assumption that an average value of y can be introduced as a constant quantity under the summation signs, and subtract Eq. 9*c*, as thus modified, from Eq. 9*b*. Then multiply the resulting equation by $\epsilon\, K$ and subtract from Eq. 9*a*. The formulas for R_x are obtained directly, as follows: For applied loading—

$$R_x = \sum \frac{M_o\, y}{I} \div \sum \frac{y^2}{I} \ldots\ldots\ldots\ldots\ldots\ldots (10a)$$

and, for temperature—

$$R_x = (1 + \epsilon^2) \frac{E\, c\, t^\circ\, L}{I} \div \sum \frac{y^2}{I} \ldots\ldots\ldots\ldots\ldots (10b)$$

Therefore, $R_x = H$ and $(1 + \epsilon^2)\, H$, respectively, for the corresponding rectangular frame.

DISCUSSION

C. D. Geisler,[7] Esq.—The subject of this paper long has been more or less of a nightmare to structural engineers. When confronted with the task of designing a skewed frame or arch, the designer has been obliged to wrestle with intricate mathematical equations.

The writer favors Mr. Hodges' simple method of procedure, in which first the frame is analyzed as a rectangular structure in computing the horizontal reaction H, and then corrections are made for the varying effects of the skew at the different points along the arch axis. It is surprising, however, that the torsional moments, which determine the amount of transverse reinforcement, have no effect in concentrating the dead load reactions and the live load reactions at the outer edges of the frame, thus increasing the main stresses at the obtuse corner.

Mr. Hodges' analysis of the main stresses would appear to agree with the theory advanced by Rankine and other early authorities who assumed that the stresses in a skewed arch were similar to those in a symmetrical right arch of span equal to the span on the skew.

The presence of certain concentrated stresses at the corners of a skewed barrel structure long has appeared evident from various model tests, and also from the results of tests conducted from 1922 to 1925 by the Bureau of Public Roads[8] on model concrete arches, with skews from 15° to 60°. Investigations of actual failures of concrete arches likewise have led to this conclusion. However, many concrete rigid frames of considerable skew have been constructed during the fifteen years since about 1928, apparently without added allowance for concentration of stress at the obtuse corners, and no reports have come to the writer's attention of any indication of distress in the skewed barrel frames at or near these corners.

It is somewhat doubtful if extreme concentrations of reactions occur to the same degree in the rigid frame type of bridge as they apparently do in arches, since structures of the frame type generally are not founded on rock and any slight yielding of the soil under the loaded corners would cause the resultant of the reactions to shift toward the center of the abutment with a reduction rather than an increase in the critical stresses. On the other hand, a lateral movement of the abutments due to side thrust would tend again to increase the concentration of horizontal reactions at the obtuse corner.

Reports of failures in skewed barrel structures appear to be confined generally to true arches, which have a greater horizontal thrust, and depend for their stability on an unyielding foundation. A relatively thin section for the arch barrel above the springing lines will satisfy design requirements due to the absence of the high bending stresses which exist in a flat-top frame.

[7] Senior Highway Bridge Engr., Public Roads Administration, Federal Works Agency, Washington, D. C.

[8] "Progress Report on Skew Arch Tests," by G. W. Davis, *Public Roads*, Bureau of Public Roads, U.S.D.A., Vol. 6, No. 9, November, 1925, p. 185.

Since 1933 some twenty skewed concrete frames and arches (most of which have been constructed on National Park projects) have been designed under the writer's direction. These structures comprise a variety of barrel-type arches ranging from flat-top frames to circular and elliptical arches, with spans up to 114 ft and skews up to 45°. In these designs the final stresses were determined after calculating the eccentricity of reactions, based on the relative stiffness of elements radiating from the superimposed load to the abutments and involving the angle of skew, span length, and width. The frame or arch barrels were divided into longitudinal sections or strips usually from about 10 ft to 12 ft in skew width, and these extended without transverse construction joints from abutment to abutment. A 10-ft width was found to be about the minimum for practical construction operations. In the computations, the individual section was designed as an independent arch rib, and the stress analysis of the structure was based on the investigation of this rib section. The analysis involved the assumption that each section would deflect independently of the adjacent sections and that no load would be transferred across the longitudinal joints. Inasmuch as the concentration of reactions at the obtuse corners depends on the effective width of the structure, if the barrel is constructed in independent longitudinal sections, each section must transmit its own load to the abutments in much the same way as a timber roadway plank laid diagonally carries its load to the stringers. However, in order to provide lateral distribution for heavy concentrated live loads and to prevent deflections which might break up the roadway pavement in cases where a thin roadway surfacing lay directly on the frame, the sections were keyed together for a length of a few feet at the crown of the arch. Furthermore, to tie the structure transversely, particularly in structures retaining a spandrel fill, transverse reinforcement extended over the full width of a structure, crossing the joints between successive sections. To what extent the keys at the crown and the transverse reinforcement might act to upset the assumption of independent deflection of each strip is questionable, of course, but it is doubtful that the small keying action so furnished would be sufficient to cause deflections in the successive concrete sections which could produce serious overstressing in the outer edges.

The usual computations for reactions in a statically indeterminate reinforced concrete structure are based on relative deflections in which the concrete is assumed to be a homogeneous material in both tension and compression. This would be more nearly correct in an arch than in a frame, since, in a true arch, the line of resultant thrust departs but little from the middle third when only small tension stresses occur. In the computations for deflection of a reinforced concrete barrel frame in a diagonal direction, or along an element not parallel with the reinforcement on which the tension steel can act only directly, considerable error may be involved. An element crossing the reinforcing steel diagonally would likely develop tension cracks under flexural stress, resulting in a reduction in its effective moment of inertia. Its capacity as a beam for transmitting any considerable amount of load to the obtuse corners then would be decreased.

It is quite conceivable that in many existing skewed barrel structures local concentration of forces, if this occurs, could produce overstresses of as much as 50% without giving any indication of distress, particularly in a structure that otherwise is designed conservatively for moments and side thrusts.

Tentative conclusions drawn in 1925 at the completion of the foregoing tests made on models of true arches by the Bureau of Public Roads were as follows:

1. The vertical reactions varied uniformly from a maximum at the obtuse angle of the arch to a minimum at the acute angle.
2. The increase of the vertical reaction at the obtuse angle of the arch varies directly as the angle of skew.
3. The resultant pressures of both the horizontal and vertical components move toward the obtuse angle of the arch with an increase in the skew.
4. The direction of the side thrust is toward the face of the arch at the acute angle and the intensity increases with the degree of skew.

The foregoing conclusions could be interpreted to indicate that the reactions from a superimposed load on a span have a tendency to follow the shortest distance to the abutments. In a beam and girder bridge, the reactions are determined readily by the relative stiffness of the supporting members. In a slab or barrel arch structure, however, a close determination of the reaction distribution is more involved. Fortunately, in the latter structures a concentration of load is seldom serious.

ARTHUR G. HAYDEN,[9] M. AM. SOC. C. E.—The development of analysis for skewed arches and rigid frame bridges has been a subject of intimate interest to the writer from the beginning. Therefore, he can appreciate the value of Mr. Hodges' contribution to the literature on the subject.

Historical Perspective.—In 1920 the writer was assigned the duty of revising plans for an arch bridge on a very heavy skew (more than 50°) and sensed that something was wrong with the design. Undoubtedly, if the bridge had been built according to the original plans, the ends of the arch ring proper would have slipped along the very smooth skewbacks of the abutments which had already been built, and a collapse would have followed. There was comparatively little steel reinforcement projecting from the abutments for anchoring the arch ring thereto. A thorough search was made in technical literature, and it was discovered that several attempts had been made by engineer-mathematicians to solve the problem of the skew arch; but all of the analyses discovered were fallacious. All that the writer could do was to saw-tooth the skewbacks of the abutments already built to prevent slippage of the arch ring when built thereon. An accurate analysis of the stresses throughout such a structure seemed impossible, and the design of several skewed bridges on the parkways of Westchester County was in prospect. Happily, a paper by Professor Rathbun appeared in the February, 1924, *Proceedings* of the Society, giving a solution of the fixed skew arch problem.[3] This paper has proved to be epoch-making in the field of structural analysis. Unfortunately, the validity of Professor Rathbun's theory was questioned at first, and a practical test of the theory was authorized by the Society and assigned to a Special Committee on Concrete and Reinforced Concrete Arches.[10] The late George E. Beggs, M. Am. Soc. C. E., of Princeton University in Princeton, N. J., was engaged to make a deformeter analysis on models of skewed arches and Professor Rathbun, then of the South Dakota School of Mines, in Rapid City, was engaged to make mathematical analyses for structures of the same proportions. Professors Beggs and Rathbun were not in communication with each other during the progress of the work, but, when both parties had completed their assignments, results were compared and were found to be in very close agreement. This was accepted as a verification of Professor Rathbun's theory.

---

[9] Cons. Civ. Engr., New York, N. Y.; formerly Designing Engr., Westchester County Park Comm.

In 1925 Professor Rathbun was engaged to extend his theory of the skewed fixed arch to skewed rigid frame bridges, because the Bronx Parkway Commission and its successor, the Westchester County Park Commission, was faced with the design of a number of bridges of this type for grade separations on Westchester County parkways. Professor Rathbun's work was accepted, but, in order to make it more useful in the designing room, an adaptation was made.[11] Apparently even this "simplification," involving as it does the derivation and solution of four simultaneous equations, was not suitable for use by the average designer, and, because of this, many bridges have been built on poor alinement, or unsatisfactory types of structure have been used in order to circumvent the analysis of a skewed arch or frame bridge.

Early in 1942 Mr. Hodges and the writer were engaged on the analysis of a heavily skewed rigid frame bridge for the highway network near the new War Department Building at Washington, D. C. The writer saw that Mr. Hodges was near the goal of a genuine simplification, and urged him to prepare the paper now under discussion. The value of the work can be appreciated when one considers that the solution of four simultaneous equations is now reduced to the solution of two. Moreover, the author makes the subject much more lucid.

Observations and Suggestions.—Mr. Hodges assumes, to begin with, a "residual" or "transformed" system in which all redundant reactions have been removed except the horizontal thrust as calculated perpendicular to the abutments. He then analyzes the structure on the square span and derives the remaining redundant reactions. It appears that he could as well have taken a residual system in which all redundant reactions have been removed except the horizontal thrust as calculated parallel with the skew. Stresses would be analyzed on the skew span and the remaining redundants derived. Subsequent transformation of stresses in the square direction to stresses in the skew direction would be avoided. Although the same fundamental principles would be involved, the redundants would be derived differently. The final total reactions, however, would be the same. It has been shown that, in general, any one of a number of "transformed" or "residual" systems may be selected as a basis for deriving redundant reactions, the number of possible residual systems depending upon the number of redundants to be calculated.[12] Some of these systems involve much less mathematical work in solution than others. So, in the case of the skewed frame bridge, one of the residual systems may involve less work in solving for the redundant reactions due to the effect of skew than the other system. Such a comparison might yield valuable results.

[10] "Concrete and Reinforced Concrete Arches," Final Rept. of the Special Committee, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), pp. 1551–1573.

[11] "The Rigid-Frame Bridge," by A. G. Hayden, John Wiley & Sons, Inc., 1940, 2d Ed., Chapter X.

A common misconception in regard to skewed arches or frame bridges is that the effect of skew on the stresses can be reduced by the use of T-beam construction. Unless the floor slab is distinctly separated from the ribs so that the two elements do not act as T-beams, skew stresses will exist in the structure to full extent and should be accounted for in design. As a matter of fact, Professor Rathbun has warned[13] that the problem is made even more complicated by the use of T-beam construction. If all the ribs did act independently, the eccentric loading from earth pressure at the ends of the bridge would become troublesome.

BERNARD L. WEINER,[14] M. AM. SOC. C. E.—The design of any structure, including that of a skew arch, is normally divided into two parts: (1) The computation of the reactions, and (2) the design of the sections to resist the internal stresses. Although this is the usual procedure, the two steps are not as separate and distinct as they are generally assumed to be. The major part of the paper is devoted to the first step, but the second step is covered sufficiently to indicate the general method of attack. Each step will be discussed separately and in the order given.

Step I. Reactions.—The purpose of this part of the paper is to show that permissible approximations may be made in the frame constants with the result that the equations developed on the basis of the accepted theory (proved by tests) are simplified. In addition, the equations break up into groups, each of course containing fewer unknowns. That permissible approximations usually result in simplifications is, of course, obvious; nevertheless, the results are approximate and the paper has been misnamed. Neither proof nor data are given for the degree of approximation.

The author states that certain reactions are affected but slightly by the skew and can be computed from a right arch of the same square span and with the same arch constants. Once this assumption is made, the so-called "skew stresses or reactions" can be computed independently. The author states further that, for a flat-topped bridge, these properties can be proved mathematically. This has been known for some fifteen years. In fact, all that is necessary is that the members have straight center lines which are either vertical or horizontal; the individual members may have variable moments of inertia and the strict mathematical proof is still valid. The shape of such a structure is not a practical one, but, for the purpose of studying the permissible approximations, this fact is of no importance.

---

[12] "The Rigid-Frame Bridge," by A. G. Hayden, John Wiley & Sons, Inc., 1940, 2d Ed., Chapter IX.

[13] *Transactions*, Am. Soc. C. E., Vol. 107 (1942), p. 1471.

[14] Designer, Parsons, Brinckerhoff, Hogan & Macdonald, New York, N. Y.

Many years ago the writer found that for a symmetrical structure the approximations were permissible and result in the simplifications stated. In 1931 the writer gave a complete mathematical derivation of the simplified approximate equations applying to the symmetrical rigid frame with straight center lines and with variable moments of inertia.[6] For practical structures, the approximations were shown to be negligible; influence lines obtained by the use of the approximate equations were plotted on the same chart with the corresponding curves from the more accurate analysis.[15] Two sets of curves were given—one for a 32° skew and another for a 50° skew. The square spans were 56 ft and 41 ft, respectively.

The question still remained, at that time, whether the approximate analysis was valid for unsymmetrical rigid frames and for single-span structures with sharply curved soffits. There was also no information available whether the approximations were valid for multiple-span bridges. From his own experience in the design of numerous bridges of various shapes and skews, and of one, two, and three spans, the writer has found that good approximations may be made with great reduction in the amount of numerical work involved. An experienced designer will soon find that he can make his own approximations very easily for any specific case provided he has a good basis from which to begin.

A word of caution is necessary, however. Since bridge design should be regarded as a science, an experienced and conscientious structural engineer should get a thorough understanding of the action of skew structures by completing at least one accurate analysis. He will then get the "feel" of the values involved, and will be able to find permissible approximations of his own which he can use with confidence. The design of skew bridges is not as difficult as seems to be assumed—the real difficulty, if any, is the solid geometry involved rather than the structural theory.

There is still much useful work to be done on a real and complete simplification of the skew structure. It is the writer's opinion that the governing stresses—those that exist in modified form in a right arch—may be computed in all cases by simplified equations regardless of shape and of the number of spans. The skew stresses, however, may not only be computed from approximate equations, but, since they are of lesser importance, it is the writer's belief that curves can be developed from which they could be estimated with sufficient accuracy for design purposes. The reason why this possibility suggests itself will be discussed more fully under Step II, "Stress Distribution."

The complete simplification of the skew structure is an urgent necessity, for modern highway speeds make good alinements obligatory. However, there is no excuse for distorting the alinement of a highway in order to avoid a skew bridge because the cost of even the most tedious "exact" design is less than the cost in human lives lost on sharp highway curves. As a matter of fact, the difficulties which the author and others deplore are largely exaggerated. With an orderly arrangement of the equations and with a simple system of signs, the work involved is only a small part of the total man-hours necessary to prepare a complete set of plans. More time has been spent attempting to avoid work, very often, then the work itself would require. Since short cuts seem so desirable, however, they may be had practically for the asking.

---

[15] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1286.

Much confusion indeed has been caused by the constant search for new "methods." The writer takes issue with the author's contention that his "method" is more simple than other "methods," whether approximate or exact. All the different methods are really not different at all; it is a misuse of the English language to refer to "different methods." The differences consist of such matters as the choice of the origin of coordinates, the "basic structure" chosen for the analysis, and in some numerical short cuts which are usually present in all numerical work.

Obviously, one should choose an origin of coordinates and a basic structure which will reduce the resulting equations to the simplest form. The writer has given complete equations[6] for both the symmetrical and unsymmetrical skew arch (single span) with the origin and basic structure chosen with this idea in mind. There should be no more question about this than there is, normally, about writing $x^2 + y^2 = r^2$ rather than $(x + a)^2 + (y + b)^2 = r^2$ for the equation of the circle. Most of the variations in the different methods consist of differences as profound as that in the two equations of the circle. Furthermore, experienced designers will soon find that, when they are doing the numerical computations themselves, they can apply such arithmetic short cuts as elastic loads to the skew arch as well as to the right arch.

The writer has found from long experience in the drafting room that it is more efficient to use a formal set of equations so that the computers need do nothing more than substitute in formulas. Even the experienced designer will find that, unless a formal setup is used, he will constantly be "thinking it out," which is not only time consuming but is also a constant source of error. When deadlines have to be met and with only juniors available to do the computing, one experience will convince a supervising designer that the proper and formal setup will save him both time and grief.

Furthermore, having well setup equations, it becomes a simple matter to make the angle $\phi = 0°$ and $90°$ and thus derive approximations of his own without going through a complete derivation each time. At the same time he has the more accurate equations available for checking the results of his approximations. Although this is true (using a formal set of equations) for the single span, it is an absolute necessity for multiple spans.

The question of signs is important in all structural analysis, but it is doubly important in skew-arch work. The author does not give a formal statement as to the directions of the positive moments and thrusts. A "picture" is not sufficient, for again experience shows that there is too much room for misinterpretation. In right arches of single span, the moments and thrusts scarcely need a sign system, but even in this case there is confusion about the shears. In a multiple-span and multiple-story analysis, a sign system stated in words is mandatory if error and confusion are to be avoided. It is equally mandatory in skew-arch work.

The writer has found that a system of signs based on the structure rather than a "space system" is very much easier to remember and to apply. In fact, it was partly because the original skew-arch theory was written on the basis of a space system that it had to be revised for efficient use in the drafting room, and this revision constitutes Part I of the writer's paper[16]—and is so stated therein. This system of signs (based on the structure) has been used by the writer for years in his subsequent work and the test in the drafting room has given the verdict. For example, in a space system, if the transverse shear, T_z or R_z, is defined as positive on the left section going away from the observer, it will reverse itself and be of opposite sense on a right section, and reverse again for a right-hand skew if the original definition is for a left-hand skew. As it happens, this shear almost always points toward the obtuse angle and, if it is defined as positive in this direction, the sign sense will not reverse either with the change in section or with the skew for the change from right to left. Such a system based on the structure is as much simpler than a space system as the ordinary convention of positive and negative moment in a horizontal beam is more simple than the clockwise and counterclockwise convention. The signs of the other forces and of the moments also are simplified similarly if the signs are based on the structure. It is a detail, but one of great importance both as a timesaver and as a way of avoiding errors. Perhaps the lack of a simple and easily applied sign system accounts for some of the confusion and difficulty which the author mentions.

The question of the assumption as to the degree of fixity of the footings is not unique with the skew arch. Actually, the footings are assumed neither fixed nor hinged; they are really designed for both conditions—for complete fixity and for free rotation about the z-axis. The theory is that, if the design is adequate for the two limits, it will also be sufficient for the actual condition of partial fixity. It was found, however, that either condition gives practically the same results except at the bottom of the "leg" or post, and even here there is sufficient dowel steel available, as a matter of practical detailing, to resist the moment produced by even full fixity. Hence, since it is simpler to design for the hinged condition and it is also slightly on the safe side for the critical crown section, the analysis is generally made on the basis of this assumption. The assumption of a virtual hinge for rotation about the z-axis is not so inconsistent therefore with fixity about the x-axis as would appear; in any case, rotation about this axis also can be taken care of easily, as the author shows. Rotation about the y-axis is hardly likely as friction and the restraint furnished by the wing walls will prevent it.

In recent years, this question of footing condition has been taken into account directly, especially where the correction is not so simple and obvious as in the single-span frame. The factor "k" or soil modulus has been introduced and thus the condition of the footing is taken into account directly in the analysis.

The writer cannot agree that unbalanced earth pressure is rarely used in practical design. Many designers have come to agree with the late William

---

[16] "Design of a Reinforced Concrete Skew Arch," by Bernard L. Weiner, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1214.

Cain, M. Am. Soc. C. E., that a structure should not be designed so as to depend for its safety on the presence of the active earth pressure. The procedure has therefore been adopted of using the balanced earth pressure only when it is of the same sign as the dead and live load moments and to omit it when of opposite sign. Unbalanced earth pressure is also used but, for this condition, the basic unit stresses are increased by 10% or 15%. This condition often governs the design of the reinforcement.

The author states that such tests as have been made were for the effect of live load in various positions and that, since the effects of these loads are small, the implication seems to be that they are of little value. The writer fails to see the point of this reasoning. The tests still prove that the computed reactions check closely with the measured reactions for loads—any loads, not necessarily live loads—applied in various ways. That more tests would be of value is no doubt true, but that still does not explain why those already made do not prove what they were intended to prove.

The writer also fails to understand the reasoning on the earth-pressure distribution. Once equivalent fluid pressure is assumed, it acts normal to the surface of the wall and that is all that there seems to be to it. It is true, of course, that the equivalent fluid pressure theory leaves much to be desired in the way of a rational theory, but this rather unfortunate situation is not unique with the skew arch; it is true of all structures subjected to earth pressure.

Step II. Stress Distribution.—Even though in practice Step I comes first, it is really, from the analytical point of view, "putting the cart before the horse." Loads acting on a structure are resisted by internal stresses and not by moments, thrusts, and shearing forces. The internal stresses are tensions (or compressions which are merely of opposite sign to tensions) and shears. The so-called bending moments, torsion moments, thrusts, etc., are merely names for the summations or resultants of the primary internal stresses. As a matter of fact, in the rigorous derivation of the beam theory by the mathematical theory of elasticity, the internal stresses are obtained first—and it is then shown that the resultants can be summarized as "bending moments," "thrusts," etc. Since, in the general case, there are stresses in all directions, the total or resultant stresses in any direction will depend on the plane of reference.

It is only in the simple beam and in certain cases of symmetry that the moments, etc., can be found directly from the loads and the geometry of the structure. Even then, the moments and forces found tell something only about the applied loads and nothing at all about the internal stresses except that they can be equated to the resultants of the unit stresses which must be found independently by more complex methods. Since the simple beam was the first and the most common structure analyzed, the fact that it is the internal stresses which are the primary factors has been overlooked, with the result that there has been much confusion of thought about the so-called stress distribution.

Since the moments and the total thrusts and shearing forces are the resultants of the internal stresses, the reference plane chosen determines the values to be obtained. Since by the ellipse of stress, tensions on one plane correspond to shears and smaller tensions on another plane, and vice versa, the same analysis will result in different combinations of "torsion moments" and "bending moments" depending on the plane of reference. The same thing is true of the total forces.

The late George E. Beggs, M. Am. Soc. C. E., was fully aware of the confusion of thought and told the writer that he was very much in favor of discarding the use of the terms, bending moment, etc., even for the simple beam, and to refer only to couples and forces. He was encouraging his students to think along these lines.

The author gives as his reason for not using the procedure for the design of the sections, developed in the writer's paper,[6] the claim that it is too complicated. Simplification with no loss other than mere academic accuracy is not only justified, of course, but is and should be the goal of good engineering practice. It is not a question, however, of mere accuracy. The reason the writer discarded the method of design used by the author, which Mr. Hodges credits to Professor Rathbun, is that it is not correct. Two other design procedures were proposed at that time and not only did all three give results that differed radically in their numerical values, but they even differed in sign. It was for this reason that the writer undertook the study to find the principles involved.

The writer believes that the procedure developed in his paper, with the proofs given and with the qualifying considerations clearly stated, constitutes a logical design. Hindsight being better than foresight, experience has shown that some of the stress combinations derived cannot occur in a practical structure, which simply means that a few of the tabulated procedures are not used. The combinations that do occur happen also to be the most simple to compute as a study of the numerical examples will show. The writer has used the procedure for many years in the drafting room and the men have had no difficulty in following the reasoning, once they made the little effort necessary to a clear understanding.

In Step II as in Step I, much has been written and done in an apparent effort to "simplify," and the result has been confusion. Considering the fact that the design takes about only 10% of the total time necessary for the production of a complete set of plans and specifications, the writer fails to see the necessity for this constant search. Naturally, the design of a skew arch requires a little more effort for a thorough understanding than does a simple beam but the same is true of all present-day design. However that may be, there need be no mystery about the skew structures, and the work involved is nothing to worry about.

As far as the writer knows, the only tests that have been made for the purpose of studying the internal stresses were those by E. F. Gifford and were of qualitative rather than of quantitative nature. With the permission of Mr. Gifford, the writer published photographs of the models tested to destruction in his discussion of a paper by Professor Rathbun.[17] In a general way, the cracks in the models seemed to confirm the writer's stress distribution. Until less crude and more complete tests are made, however, designers still will have to depend on logical reasoning for their designs.

---

[17] "An Analysis of Multiple-Skew Arches on Elastic Piers," by J. Charles Rathbun, *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 46, Figs. 16–25.

For the sake of convenience, the reference plane, on which the total moments and thrusts of a skew arch are computed, is a radial plane parallel to the abutments. The plane chosen for the design of the sections is not the one that is most "practical" but the one on which the particular moments and forces under consideration are maximum. In other words, such recognized criteria as are furnished by the ellipse of stress must still be satisfied—regardless of the type of structure analyzed. In addition, the laws of equilibrium require that the boundary conditions be satisfied without stress on external surfaces. Neither of these conditions, among others, is fulfilled by the procedure given by the author.

To find the maximum moments producing the maximum tensions (or shears, for that matter), transformations similar to those which lead to the ellipse of stress must be made. Before this can be done, however, the moments and thrusts must be reduced to stresses (total over the thickness) per unit width. Although the author states that the width, b, does not enter into the analysis, it is only partly and approximately true; the truth is that everything is divided by b—but the structure, as the author states, is considered as a whole. Thus m/b and t/b result from the analysis, but whether or not these are stresses per unit width depends on whether the distribution is uniform or not. After the total stresses are reduced to stresses per unit width, they must be resolved to find the maximum bending moments and shearing moments ("torsion")—a procedure exactly similar to that of finding principal planes. This the author has failed to do and, however "practical" the omission may be, it is incorrect.

The author quotes Professor Rathbun incorrectly when he states that the transverse shearing force is distributed parabolically—like the shear in a rectangular beam. Professor Rathbun states quite correctly that the portion of the shear equal to the thrust multiplied by the tangent of the modified skew angle is distributed uniformly and the remainder is distributed parabolically. This procedure results from the fact that the boundary conditions must be satisfied; there would otherwise be a shear on the external face of the bridge —an impossibility, of course.

The author makes a similar statement about the shear produced by the torsion moment. In this statement, he quotes Professor Rathbun correctly, and both are in error. The reason is the same; in order to satisfy the boundary conditions for the tensions (and compressions) produced by moment, there must be shears equal to the unit tensions multiplied by the tangent of the modified skew angle. Since the resultant of the tensions is a couple, the resultant of the shears which are proportional to them must also be a couple. Therefore the terms "bending moment" and "torsion moment" are not sufficient; that is, they do not tell the whole story as far as distribution is concerned. At the boundary, the tension must be parallel to the face and the shear can be zero only on a section perpendicular to the external surface. Incidentally, the fact that this must always be true will enable the designer to eliminate some computation as soon as he gets the "feel" of the values involved.

This fact may also prove to be a valuable starting point for a simplified procedure for the design of the sections. Since the design of the sections is the ultimate goal, a simplification of Step II should also simplify Step I.

St. Venant's theory of torsion and such tests that are available show that Merriman's formula is very much in error for long and narrow rectangles. Although the more exact theory of St. Venant is supposed to be quite complicated for rectangles that are nearly squares, the hyperbolic functions reach their limit very rapidly for ratios of sides greater than 3 : 1. In a bridge, the ratio is at least 10 : 1 and there is no arithmetic hardship in the use of the results derived from St. Venant's theory, as a glance at the tabulated formulas for the reduction of total stresses to stresses per unit width presented by the writer[18] will show. In any case, it is time engineers realized that their profession is a science and that, on occasion, science requires something a little more advanced that the addition of 2 + 2.

In general, whether the designer is dealing with skew arches or with any other structure, it is well for him to check the results of an analysis to see that the fundamental laws of equilibrium are satisfied; that the boundary conditions are logical; and that such accepted criteria as the ellipse of stress are also satisfied. Much grief may be avoided by this precaution.

General Remarks.—In spite of the misleading statements that have been made time and time again, the skew arch must be analyzed as a complete unit and the division by b is merely a minor arithmetic convenience which has no structural significance. The various suggestions for using longitudinal strips parallel to the face of bridge, etc., all can be shown to be in error—as often as not, on the side of danger. The "trick" of using strips and then keying and tying the laminations together results in a structure that is usually "solid" in spite of the tricks. There is no need for these subterfuges.

If a systematic set of equations based on a simple system of signs is used (with the origin of coordinates at the point of symmetry), even the "accurate" analysis for the reactions is not a hardship; or at least it should not be in these days when engineers are really beginning to do designing. Least difficult of all is the solution of the four simultaneous equations; for those who are worried, it can be stated that the solution can be done on one sheet of paper. However, simplifications are possible, as the writer showed many years ago, and this fact is now confirmed by the author.

As for the stress distribution, a logical design which satisfies the laws of equilibrium, and, in addition, is also consistent with such accepted criteria as the procedure by which the "ellipse of stress" leads to the conception of "principal planes" is just as simple as other "methods" and also more correct. In this phase of the problem, as in other phases, the work must be well organized —it may be said that organization is the key to true simplicity. The difficulties involved in the design of skew bridges have been largely exaggerated. Such at least has been the experience of the writer over a period of years on the design of numerous skew bridges of various shapes and of single and multiple spans.

---

[18] "Design of a Reinforced Concrete Skew Arch," by Bernard L. Weiner, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1297.

Any designer who makes the moderate effort necessary to grasp the subject need have no difficulty.

ALFRED L. PARMÉ,[19] JUN. AM. SOC. C. E.—A problem that is of vital interest to the engineering profession is treated in this paper. Unfortunately, Mr. Hodges has accepted present-day theory as adequate and has based his simplification on the existing formulas. The validity of these basic equations has not yet been completely substantiated. The writer is aware of only two quantitative experiments that have been conducted on skewed arches—one by the Bureau of Public Roads[8] and the other sponsored by the Committee on Concrete and Reinforced Concrete Arches in 1935.[10] In the former, the results obtained from tests made on concrete arches differ considerably from the values obtained by a mathematical investigation based on the method of Prof. J. Charles Rathbun,[10] M. Am. Soc. C. E. The latter series of tests, directed by the late Prof. George E. Beggs, M. Am. Soc. C. E., involved the technique of reciprocal deflections on rubber models. An apparently favorable agreement between experimental and theoretical values was obtained. However, this satisfactory trend was confined to loads at some distance from the center line of the arches. Marked deviations were noted for loads on the center line (and hence for loads symmetrical about the center line). The inconsistencies revealed by these investigations led to the careful examination (presented in this discussion) of the basic elastic equations advanced by Professor Rathbun. It will be shown that the latter contain highly questionable assumptions which militate against their usefulness.

It is not the simplification introduced by Mr. Hodges that is being questioned but the basic equations contained in the "Appendix." One difficulty with that presentation is that the equations are couched in terms not easily manipulated and having remote referents. This difficulty may be overcome by viewing the equations as extensions of the formulas derived for the analysis of curved beams. Incidentally, an excellent and lucid treatment of curved beams was presented[20] originally by A. V. Pippard and F. L. Barrow in 1926. On the basis of this mode of approach, it naturally follows that the prime difference between a two-dimensional and a three-dimensional analysis lies in the fact that displacements due to torsion are included in the latter. Thus, for the ordinary analysis of a right rigid frame:

$$\Delta = \int \frac{M\ m\ dx}{E\ I} \qquad \text{(11a)}$$

in which: Δ = the deflection at any point of the frame due to the loading on the frame; M = the bending moment at any section due to the actual loads (and reactions) acting on the frame; and m = the bending moment at any section due to the virtual or dummy load of unity (1-lb load) acting at the point whose deflection is desired, and acting in the direction of the desired deflection.

---

[19] Bronxville, N. Y.

[20] "Stress Analysis of Bow Girders," by A. V. Pippard and F. L. Barrow, *Technical Paper No 1*, Building Research Board, H. M. Stationery Office, 1926.

On the other hand, for a skewed frame or curved beam:

$$\Delta = \int \frac{M\,m\,dx}{E\,I} + \int \frac{T\,t\,dx}{G\,F} \quad \ldots\ldots\ldots\ldots\ldots (11b)$$

in which: T = the torsional moment acting at any section due to the actual loads (and reactions) acting on the frame; t = the torsional moment at any section due to the virtual or dummy load of unity acting at the point whose deflection is to be found and in the direction of the desired deflection; G = modulus of elasticity for concrete, in shear; and F = factor of torsion (a quantity corresponding to the moment of inertia).

It will be observed that Eq. 11*b* is a condensed statement of the relationship involved in Eq. 7*a*. Both statements (Eqs. 11*b* and 7*a*) are general and apply to any arch irrespective of its shape. To test the validity of this equation, it is best to deal directly with the simplest form of arch—namely, a straight slab clamped at each end. This selection has been made partly for the purpose of clearer exposition. However, the mathematical analysis to follow can be applied equally well to more complicated forms. In the example chosen (Fig. 7), the customary procedure of replacing the right support by redundant reactions has been followed. This operation transforms the slab from an indeterminate form to a determinate one. The number of equations due to displacement will be equal to the number of redundant reactions. Only the vertical displacement will be treated herein. The general equation of

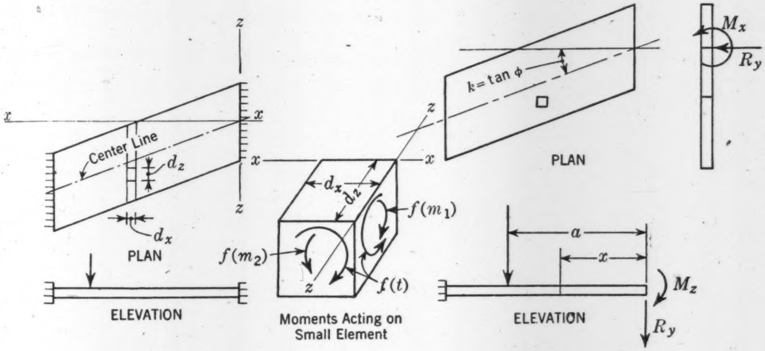

FIG. 7

$$\Delta = \int \frac{M\,m\,dx}{E\,I} + \int \frac{T\,t\,dx}{G\,F}$$

then becomes

$$\Delta = \int_a^l P\,(x - a)\,x\,\frac{dx}{E\,I} + \int_0^l [M_z\,x + R_y\,x^2]\,\frac{dx}{E\,I}$$

$$+ \int_0^l [R_y\,k^2\,x^2 + M_x\,k\,x]\,\frac{dx}{F\,G} + \int_a^l [P\,k^2\,(x - a)\,x]\,\frac{dx}{F\,G} \quad \ldots. (12)$$

In this case it must be borne in mind that the moments refer to the total moment acting on a cross section of the slab.

If the problem is attacked from the strain-energy conception utilized in the analysis of thin plates, the application of a vertical load Q at N will produce bending and torsional moments on a small element. (To avoid conflict with previous notation these moments will be labeled $f(m_1)$, $f(m_2)$, and $f(t)$.) Since the internal work and external work must be equal,

$$\frac{1}{2}\left[f(m_1)\frac{\partial^2\omega}{\partial x^2}+f(m_2)\frac{\partial^2\omega}{\partial z^2}+2\,f(t)\frac{\partial\omega}{\partial x\,\partial z}\right]dx\,dz=\tfrac{1}{2}\,(Q\,\Delta_1)\ldots\ldots(13)$$

in which Δ_1 denotes the deflection of N due to the deformation of the small element; and $\frac{\partial^2\omega}{\partial x^2}$ and $\frac{\partial^2\omega}{\partial z^2}$ = angular rotation of the small element due to the load Q. Let Q now be considered a unit load; then functions $f(m_1)$, $f(m_2)$, and $f(t)$ will be the moments created by a unit load at N. Hence,

$$\left[f(m_1)\frac{\partial^2\omega}{\partial x^2}+f(m_2)\frac{\partial^2\omega}{\partial z^2}+2\,f(t)\frac{\partial\omega}{\partial x\,\partial z}\right]dx\,dz=\Delta_1\ldots\ldots\ldots(14)$$

Eq. 14 expresses the relation between the deflection at N and the angular deformation at any point irrespective of the manner in which these angular deformations are produced. Now the angular deformations at any point are given by the expressions

$$\frac{\partial^2\omega}{\partial x^2}=\frac{F(M_1)+\mu\,F(M_2)}{(1-\mu^2)\,E\,I}\ldots\ldots\ldots\ldots\ldots\ldots(15a)$$

$$\frac{\partial^2\omega}{\partial z^2}=\frac{F(M_2)+\mu\,F(M_1)}{(1-\mu^2)\,E\,I}\ldots\ldots\ldots\ldots\ldots\ldots(15b)$$

and

$$\frac{\partial^2\omega}{\partial x\,\partial z}=\frac{F(T)}{(1+\mu)\,E\,I}\ldots\ldots\ldots\ldots\ldots\ldots(15c)$$

in which $F(M_1)$, $F(M_2)$, and $F(T)$ are the moments acting on the element due to actual loads (and reactions) acting on the slab. For simplicity, assume that μ, Poisson's ratio, is equal to zero; then

$$\frac{\partial^2\omega}{\partial x^2}=\frac{F(M_1)}{E\,I}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(16a)$$

$$\frac{\partial^2\omega}{\partial z^2}=\frac{F(M_2)}{E\,I}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(16b)$$

and

$$\frac{\partial^2\omega}{\partial x\,\partial z}=\frac{F(T)}{E\,I}\ldots\ldots\ldots\ldots\ldots\ldots\ldots(16c)$$

Making the proper substitution,

$$[F(M_1)\,f(m_1)+F(M_2)\,f(m_2)+2\,F(T)\,f(t)]\,\frac{dx\,dz}{E\,I}=\Delta_1\ldots\ldots(17)$$

If Δ denotes the deflection of point N due to deformations in all the elements, then

$$\Delta = \int\int [f(m_1)\,F(M_1) + F(M_2)\,f(m_2) + 2\,f(t)\,F(T)]\,\frac{dx\,dz}{E\,I} \ldots (18a)$$

Since the designer is not interested in the effect of the transverse moment, the terms occurring because of this factor are omitted. The subscript used to differentiate the moment terms is also no longer needed. Eq. 18*a* then takes the final form

$$\Delta = \int\int [f(m)\,F(M) + 2\,f(t)\,F(T)]\,\frac{dx\,dz}{E\,I} \ldots\ldots\ldots\ldots (18b)$$

Eqs. 11*b* and 18*b* are two different expressions for the vertical deflection at N. The validity of the expression presented in the first part of the discussion rests on the hypothesis that a slab subject to torsion behaves like a beam. The latter has been established on a more fundamental basis. Both should yield the same result and therefore Eqs. 11*b* and 18*b* can be equated:

$$\int \frac{M\,m\,dx}{E\,I} + \int \frac{T\,t\,dx}{G\,F} = \int\int \frac{F(M)\,f(m) + 2\,F(T)\,f(t)}{E\,I}\,dz\,dx \ldots (19)$$

Recalling that M is used to designate the total moment acting on a section and that $F(M)$ expresses the moment at any point:

$$M = \int F(M)\,dz \ldots\ldots\ldots\ldots\ldots\ldots (20a)$$

and

$$m = \int f(m)\,dz \ldots\ldots\ldots\ldots\ldots\ldots (20b)$$

In a similar manner, it can be easily shown that

$$T = \int F(T)\,dz \ldots\ldots\ldots\ldots\ldots\ldots (21a)$$

and

$$t = \int f(t)\,dz \ldots\ldots\ldots\ldots\ldots\ldots (21b)$$

Therefore,

$$\int\left[\int F(M)\,dz \int f(m)\,dz\right]\frac{dx}{E\,I} + \int\left[\int F(T)\,dz \int f(t)\,dz\right]\frac{dx}{G\,F}$$
$$= \int [F(M)\,f(m) + 2\,F(T)\,f(t)]\,\frac{dz\,dx}{E\,I} \ldots\ldots\ldots\ldots (22)$$

Since this is an identity, each term in the expressions must correspond. Therefore:

$$\int\left[\int F(M)\,dz \int f(m)\,dz\right]\frac{dx}{E\,I} = \int\int [F(M)\,f(m)\,dz]\,\frac{dx}{E\,I} \ldots (23a)$$

and similarly

$$\int\left[\int F(T)\,dz\int f(t)\,dz\right]\frac{dx}{F\,G} = \int\int\frac{2\,F(T)\,f(t)\,dz\,dx}{E\,I}\ldots\ldots(23b)$$

Concentrating on only one of the terms, the integration of expression on the right side of Eqs. 23 can be performed in any order. This means, therefore, that

$$\int F(M)\,dz\int f(m)\,dz = \int F(M)\,f(m)\,dz\ldots\ldots\ldots\ldots(24)$$

Eq. 24 can be satisfied only if the variation in moment across a section is constant; but this is in sharp contradiction to established fact. As a matter of fact, the primary purpose of an analysis of skew frame is to determine just what this variation is. Therefore, the basic equations used by Mr. Hodges are incorrect because they imply an assumption that is not consistent with the physical behavior of the skewed slab.

If the variation across a section is assumed to be triangular, the moment is a linear function of z. Then, if $F(M) = K\,z$ and $f(m) = k\,z$, Eqs. 23 become:

$$\frac{12}{E\,b\,t^3}\left[\int_0^b F(M)\,dz\int_0^b f(m)\,dz\right]$$

$$= \frac{12}{E\,b\,t^3}\left[\int_0^b K\,z\,dz\int_0^b k\,z\,dz\right] = K\,k\,\frac{12\,b^3}{4\,t^3\,E}\ldots\ldots\ldots\ldots(25a)$$

and

$$\frac{12}{E\,t^3}\int_0^b F(M)\,f(m)\,dz = \frac{12}{E\,t^3}\int_0^b K\,k\,z^2 = k\,K\,\frac{12\,b^3}{3\,t^3\,E}\ldots\ldots(25b)$$

A deviation of 25% is indicated in Eqs. 25. In general, $\int\frac{M\,m\,dx}{E\,I}$ is less than $\int\int F(M)\,f(m)\,\frac{dz\,dx}{E\,I}$.

It may be argued that the errors introduced apply to all terms and hence cancel. This would be true if the error in each term was a constant proportion. Such is not the case. The deviations will be more marked in terms involving the reactions than those due to loads. Therefore, the equations must lead to erroneous results. Because the final value of any reaction is the result of the difference of large numbers, it is difficult to predict in just what direction the error will lie. However, it appears that Professor Rathbun's method yields results smaller than those found experimentally.

How serious is this error? The method used to check the theory does not lend itself to an arithmetical solution. However, the results obtained experimentally and those obtained by Professor Rathbun's method can be compared, as shown in Table 12. Of all the differences to be noted between the experimental and theoretical values, the most significant is the complete lack of agreement in the values of the horizontal moment (M_y). The magnitude of the experimental values eliminates the possibility that the deviations are just due to chance and unavoidable inaccuracies in computing and testing. It would therefore seem that the theory does not represent the elastic behavior of the skewed arches.

[a] Reactions in pounds and moments in pound-inches.

In justice to the method described by Mr. Hodges it should be reemphasized that in the experiment conducted by the Committee on Concrete and Reinforced Concrete Arches much better agreement was obtained for loads near the free edges. The agreement obtained in this region does not constitute a sufficient proof of the reliability of the method however. For a theory to be tenable it must give reliable results at all points and above all for the conditions that govern the design; that is, for loads on the center line or loads symmetrical about the center line. As a matter of fact, loads symmetrical about the center line are handled as concentrated loads on the center line; that is, in the analysis identical results are obtained for these two types of loading. In the case of rigid frame bridges of average span, the weight of the structure forms a large part of the total weight. Because of this and moreover because wheel loads will usually be near the center line, the correctness of any analysis based on Professor Rathbun's equations or similar derivations will be measured by the reliability of the theory near the center line. Since appreciable differences exist for these loads, the results obtained are highly questionable.

It has been shown theoretically that the basic equations are not valid. Furthermore, experimental values have been compared with theoretical values. Both of these facts confirm the writer's contention that at present no simple correct solution exists. However, rather than close this discussion with a negative emphasis, the writer would like to make the suggestion that some means of correcting the equations by introducing factors to account for the variation of moment across a section be introduced. The revised method should then be checked by experiment or compared with results obtained by more precise methods. At present, this problem can be most readily handled by means of finite difference equations.

J. CHARLES RATHBUN,[21] M. AM. SOC. C. E.—There is a tendency among engineers to avoid reinforced concrete skew arches of the barrel type even when this type of structure would be more economical and would give a better alinement than the type adopted. Some designers have even used skew arches of rib construction with the floor slab cast integral with the rib. One such bridge was built with an added slab at the intrados. Of course those who try to dodge the problem not only fail in their purpose but introduce other problems, of a more difficult nature, in analysis.

Since 1924 a number of papers on the analysis of the skew arch have been published by the Society.[3, 6, 22, 23] These with their discussions give a complete view of the problem and its solution. Any engineer entrusted with a problem for which a skew arch would make a satisfactory solution owes it to his client to review this literature. A solution is offered for arches with fixed abutments.[3] The equations for hinged abutments were first developed by the writer in a report to the Westchester County Park Commissioners in 1925. Later they were published, along with the method of computing the steel reinforcement.[23]

In offering a practical application of that method, Mr. Hodges' paper is a distinct contribution to this series of papers. He has used it in the design of many skew arches for the past twenty years. It is hoped that this paper will impress the profession with the fact that an analysis of a skew arch can be made and that the stresses in the finished structure can be anticipated with design accuracy and at a reasonable cost.

The writer proved[24] that the "Rankine theory" (in which the force lines are parallel to the spandrel walls and stress distribution is uniform along the abutments) is very nearly correct for symmetrical arches loaded with symmetrically placed vertical loads. This is the condition for dead load and full uniform live load for symmetrical skew arches. The Rankine theory is not correct (often it is far from correct) for unsymmetrical arches, for unsymmetrical vertical loads, and for horizontal loads such as earth pressure and forces due to shrinkage and temperature.

[23] "An Analysis of Multiple-Skew Arches on Elastic Piers," by J. Charles Rathbun, *ibid.*, Vol. 98 (1933), p. 41.

[24] *Ibid.*, Vol. LXXXVII (1924), p. 620.

Soon after the publication of the writer's solution to the problem, A. G. Hayden, M. Am. Soc. C. E., suggested that the work of analyzing skew arches might be shortened by developing equations for the deviation of the stresses from those obtained by the Rankine theory. With these equations the preliminary analysis could be corrected. Mr. Hodges has used somewhat the same idea with the right arch as the basis of his work. The writer would have preferred to see Mr. Hayden's method used rather than Mr. Hodges' method because the magnitude of the corrections would have been less. Theoretically, the choice is of little importance, however, as both methods are correct. Perhaps Mr. Hayden's suggestion led to more involved equations and Mr. Hodges has found his solution more practicable.

The solution presented by the writer in 1924 has had considerable criticism because it does not conform to a preconceived idea that the "stresses take the shortest route to the abutments." The writer has yet to see a sound quantitative analysis of this tendency. Many tests have been made to show that the idea is incorrect. Three such tests have been made by the writer.[22, 25]

To test the correctness of the theory the Society had the late George E. Beggs, M. Am. Soc. C. E., conduct a series of tests on four arches. These arches all had fixed abutments and were tested for vertical loads. The reactions for these same loads were computed by the elastic theory under the writer's supervision. Contours of the influence surfaces of the components of the abutment reactions were drawn up for each arch and the two methods compared.[10] Models of these surfaces (see Fig. 8) were also made to assist in this comparison. The tests and the computations were in virtual agreement and the committee reported,[26]

> "For the practical design of skew arches, the limited number of tests which have been conducted indicate that Professor Rathbun's theory may safely be applied for the computation of the six components of the abutment reactions."

After these are computed the problem is a simple one in statically determinate stress analysis.

The models used by Professor Beggs were of rubber with the very high Poisson's ratio of 0.34, compared with about half this value for concrete. The committee decided that the discrepancy "would change the results of the calculations by only a small amount." [26] In fact the model surfaces showed that the change would occur in but few areas and for loads over most of the arch the effect would be very little. Designers of right arches, where the same effect occurs, have neglected to take Poisson's ratio into consideration, with no serious consequences.

---

[25] *Transactions*, Am. Soc. C. E., Vol. 98 (1933), pp. 26 and 66.

[26] *Ibid.*, p. 1572.

The writer believes that the report of this committee has convinced the most skeptical engineers that the elastic theory, as developed, is sufficiently correct for design purposes.

One reason that the elastic theory, as developed for the skew arch, has not been popular is probably the writer's fault. In the analysis he used a geometrical approach instead of the method of virtual work; he includes horizontal and radial shear deformations as well as shortening due to thrust; he also developed the deformation due to the several components of the moments. Many of these terms have since proved to be negligible. He covered both the symmetrical and unsymmetrical skew arch for all types of loading. The result was that the paper became long, cumbersome, and laborious to follow. One critic stated that "No arch can follow that much mathematics," to which Professor Beggs replied, "Four Princeton arches did." Mr. Hodges seems to have overcome this objection.

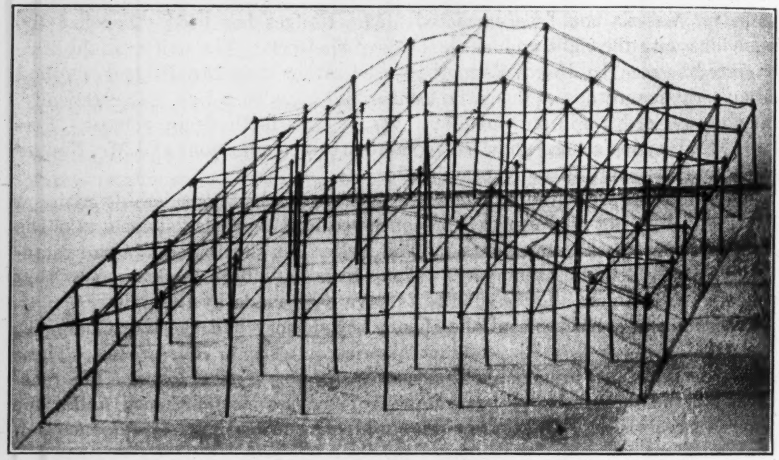

FIG. 8.—MODEL OF INFLUENCE SURFACE

With this paper of Mr. Hodges the question of the design of a reinforced concrete barrel skew arch should present little difficulty to those familiar with the analysis and design of the right arch of the same type. It is hoped that the paper will renew interest in the subject and encourage engineers who have arches to design to familiarize themselves with the basic theory and the literature on this subject.

MAURICE BARRON,[27] ESQ.—In 1932 the writer, under the author's supervision, made some of the computations for an investigation of the effect of variation in the skew angle on the reactions of skewed frames. The method then used was that first published in 1931 by Mr. Hayden[28] and the investigation was carried through the simultaneous solution of the elastic equations. In this investigation the writer was concerned with a structure of the standard concrete rigid frame type of bridge. Only the skew angle was permitted to vary. The conclusion was that, for all practical design purposes, and well within the limits of computational accuracy, the rectangular horizontal reaction is independent of the skew angle. This conclusion is the basis for the entire first part of the paper dealing with analysis.

---

[27] Designer, Office of Gilmore D. Clarke, New York, N. Y.

[28] "The Rigid-Frame Bridge," by A. G. Hayden, John Wiley & Sons, Inc., 1940, 2d Ed.

The writer has investigated the validity of this conclusion when applied to two reinforced concrete elliptical skewed barrel arches (for convenience identified as bridges A and B). Bridge A, designed by the writer, is a 45° skewed arch with a square span of 56 ft. Bridge B has a 36.5° skew and a square span of 57 ft.

In designing bridge A many short cuts (not approximations) were used including the principle of the elastic centroid, ordinary and torsional elastic weights, the shear increment method of computing moments, and Maxwell's theorem of reciprocal deflections. The four elastic equations (see Appendix, Eqs. 7) were thus greatly simplified; one or more coefficients in each equation, a total of eight, were reduced to zero. The solution of the four equations was correspondingly simplified and resulted in the following equation for the rectangular horizontal reaction: $65.7574\, R_x = +\, \delta_x + 1.042448\, \delta_z - 3.197289\, \phi_y$; or,

$$R_x = 0.0152074\, \delta_x + 0.0158529\, \delta_z - 0.0486225\, \phi_y \quad \ldots\ldots\ldots (26)$$

in which R_x is the rectangular horizontal reaction; δ_x is the deflection (including torsional effects) of the base frame in the direction and at the point of application of R_x, due to the load under consideration; δ_z is the deflection of the base frame in the direction and at the point of application of R_z, due to the load under consideration; and ϕ_y is the angular rotation of the base frame in the direction of M_y, due to the load under consideration.

For the proposed simplified method:

$$65.37016\, H = \delta'_x \quad \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

in which H is the rectangular horizontal reaction; and δ'_x is the deflection of the rectangular structure in the direction and at the point of application of H, due to the load under consideration. The coefficient of H is $\Sigma \frac{y^2}{I} \Delta s$ and does not contain torsional effects.

The values to be substituted in Eq. 26 for the unit vertical influence load are of interest because they show the contribution of each deflection to the total. Table 13 gives these values, as well as values for H, by the simplified method, for the unit vertical influence load, for earth pressure from the left, and for temperature change.

It is evident that, except for temperature change, δ_x is the predominant factor contributing to the reaction R_x. The other two values are not only of different order but are always of opposite sign. The close agreement in the data is added proof that the conclusion applies as well to elliptical skewed arches. The author has shown the proof that this conclusion is exact for flat-decked structures where the legs are vertical and the deck has a constant height.

The writer wishes to emphasize the manner in which Mr. Hodges has utilized this conclusion in his proposed simplified analysis. In step 1, the right arch or frame is analyzed for the redundant horizontal reaction, choosing as a base structure a statically determinate system, usually a simple span. This involves one unknown, H, and the solution of one elastic equation. In step 2, the final structure is analyzed using the foregoing system, with H and ϵH applied, as the base frame. Particular attention is called to the fact that the base frame in step 2 of the analysis is a statically indeterminate system; but it must be a system in equilibrium. Therefore, after H has been found and applied the second base system must be stabilized by the application of equilibrating reactions. This is possible only because the two elastic systems can be considered independently. In the analysis of bridge A the base structure chosen was a simple span with a rigid bracket from the hinge (on rollers) to the elastic centroid. For a symmetrical structure this centroid is on the center line. This procedure incorporates the desirable features of symmetry and agrees with the base structure ordinarily used in analyzing rectangular frames and arches—namely, a simple span. The writer believes this is another short cut that can be incorporated advantageously into the proposed simplified method.

[a] The points are equidistant and numbered from point 1 at the footing to point 10 at the crown. For points 1 and 2 the values are all zero since they are on the vertical part of the leg. [b] Values in kips. [c] Crown point for bridge B. [d] The details of the analysis for bridge B were the same as for bridge A and only the results are recorded.

The design of a skewed concrete rigid frame or arch bridge by the exact method is seldom attempted without the use of short cuts. Approximations should be accepted only where the limits of accuracy are understood and known. Any designer who has waded through this exacting work and the lengthy computations will appreciate any method that reduces the amount of computing or decreases the probability of error without sacrificing safety or economy. The proposed simplified method of analysis does this.

Comparisons, such as the foregoing, indicate that the approximation resulting from the neglect of the effect of the torsional elastic system on the rectangular elastic system is of the same order as the approximation usually made by neglecting shearing distortions when analyzing rectangular frames or arch bridges. The neglect of rib shortening due to axial thrust also falls in this category, except for flat arches.

Furthermore, in the solution of the simultaneous equations, analysis by the exact method encounters the troublesome problem of small differences. Only after considerable experience and numerous designs is it possible to know how many significant places are required in any particular case. Usually, therefore, the tendency is to carry the calculations to too many significant places. By using the proposed simplified method of analysis, this difficulty is overcome to a great extent. The problem is nonexistent in determining the horizontal rectangular reactions in step 1, since the solution of only one elastic equation is involved. In step 2, the number of simultaneous equations is reduced, and the occurrence of small differences is minimized.

Another interesting feature of this paper is its solution of the problem of foundation restraints. Rotation of the foundation because of compressibility of the supporting material is an unknown factor and therefore analysis for boundary conditions (full fixity and free rotation) is justified. Although the added refinement of including the soil modulus would show the effect of partial restraint, such an analysis would depend on the accurate determination of this modulus and its uniformity. For this reason the writer favors design for boundary conditions since the true condition must be somewhere between the limits. Rotation of the foundation about the vertical axis is usually impossible. Restraints due to friction and approach walls will prevent this rotation, and, even where the approach walls are separated by expansion joints, the foundations are usually poured monolithic.

Earth pressure, as a load, is much more important in a skewed structure than it is in a rectangular one. The analysis for this load is usually relegated to a minor rôle, but the author gives it some of the major consideration it deserves. In the proposed method step 1 is still the determination of the rectangular horizontal reaction, but step 2 is much more involved. The base frame for step 2 is again a statically indeterminate system with H (as found in step 1) applied at the hinges; and, exactly as before, this base frame must be stabilized by cross shear reactions before the computations for the torsional elastic effect of the structure are started. In previous methods this stabilizing cross shear reaction is not separated from the redundant, and the total is applied at the hinge. The author divides this stabilizing cross shear reaction into two parts, one applied at the hinge and the other applied along the back of the abutment. The first part is obviously the foundation restraint but the second part requires explanation. Since equivalent fluid pressure was assumed acting normal to the abutment, it seems logical that frictional resistance to distortion will develop along the back of the abutment, and that this part of the frictional equilibrating cross shear reaction cannot exceed the normal pressure times the coefficient of friction of earth on concrete. The author applies this part of the equilibrating cross shear reaction concentrated at the center of normal pressure. He then transforms it into a cross shear reaction applied at the hinge plus a moment about the x-axis. The net difference in results between the author's method and previous methods should be this additional moment of transformation. Since it is on the safe side to do so, this moment of transformation should be included in the analysis. There is also a transformation moment about the y-axis which has been neglected. The close agreement of R_x and H (see Table 13) for earth pressure from the left indicates that the basic conclusion stated in the beginning of this discussion is just as valid for horizontal loads as for vertical loads.

This simplified method of analysis may be applied to double-span skewed structures if the following logical deductions are accepted. The evidence shows that the two elastic systems of single-span skewed structures are practically independent for vertical and horizontal loads and equally independent of the shape of the structure. A double-span structure may be considered as a single span with an elastic bracket at the center, to the ends of which are applied forces equal to the redundant reactions. This logic may be extended to include three or more spans.

With all the available data, and this simplified method of analysis, there should be no necessity for avoiding the skewed barrel type concrete rigid frame or arch bridge.

PHILLIPS H. LOVERING,[29] ASSOC. M. AM. SOC. C. E.—The value to the profession of many papers in *Proceedings* is emphasized by predictions that the ideas and information advanced should prove important. The value of this paper does not rest upon prediction. Within nine months of its publication, the writer already had used this design method for four bridges and thereby saved at least seven days of design time on each bridge. The time required for checking the design is reduced about four days.

More important, for any method based on the trial of assumed sections, subsequent trial designs may sometimes have to be made; and, in the case of former procedure, the suitability of the sections tried could not be determined until the end of the design, whereas using Mr. Hodges' method the suitability of the sections is determined by the second day, or in about one tenth the time required by the former method. The value of dividing the design into two parts with the longer and subordinate part coming last is thus emphasized.

The writer has found that the difficulty of choosing correct sections increases with the skew, and is caused mostly by the high temperature stresses. As in other arches, the temperature stresses can be held to a minimum by choosing sections that have a moment of inertia just sufficient to satisfy the stress requirements throughout a large part of the arch. In applying this principle to the rigid frame bridge, it becomes evident that the $\frac{y^2}{I}$-values at the knee are so comparatively small that it is best to thicken the knee because, although this decreases these values still more, the reduction of moment obtained in the middle part of the arch allows a considerable reduction in I and a corresponding increase in the $\frac{y^2}{I}$-values. The difficulty of obtaining a smooth intrados curve under conditions of a thick knee and a thin section throughout the central part of the arch is partly overcome by using an ellipse instead of the arc of a circle for the intrados with possibly a short tangent at the crown. This expedient becomes valuable for skews of 45° and more. Lengthening the legs also somewhat lessens the temperature stresses.

---

[29] Structural Designer, W. Earl Andrews, New York, N. Y.

The high shears at the bottom of the leg are probably transferred across the construction joint into the footing mostly by friction. However, at least a large part of this uncertainty is removed by placing V-notches across the joint, and, if the longitudinal key occupies the middle third, the transverse V-notches should be set in the footing on either side of the key rather than across the bottom.

Jaroslav Polivka,[30] M. Am. Soc. C. E.—For some decades structural engineers and scientists[31,32,33,34,35,36] have grappled with the relatively simple problem of a rectangular slab or plate supported on two opposite edges and subjected to transverse loading—a problem that cannot be identified with the solution of a simple beam, due to the effect of Poisson's ratio. The problem of a similar plate, but one with skewed shape, has only recently been solved with any degree of exactitude.[37] These problems are much simpler than those involved in skewed frames and arches.

Structural engineers familiar with such analyses would be reluctant to apply any method which, in spite of the complex mathematics involved, yields only approximate results. Mr. Hodges is to be commended for simplifying the mathematical analysis and for bringing the subject for discussion. However, in the analysis of even less important structures, engineers are inclined to proceed with extreme caution, and in the matter of bridges they would seem certain to look with disfavor on a method of analysis which is only an approximation and which has not yet been corroborated satisfactorily by tests on models, and certainly not by tests on existing structures.

There are three possibilities for progress in the design of skewed frames and arches:

(1) To delve deeper into the study of the structural behavior and stress distribution in skewed structural members, developing an analysis on the basis of the exact theory of elasticity as it is used for plates and shells,[35] and checking such analysis with laboratory tests and field measurements;

(2) To use only the results of actual tests for the design of skewed frames and arches; and

(3) To discard the skewed slab in the design of frames and arches and to substitute another type of structure, more amenable to exact analysis, as, for

example, frame girders combined with continuous slabs, or heavy wall girders combined with cylindrical or arched shells in reinforced concrete (which may even prove to be more economical).

A. A. EREMIN,[38] ASSOC. M. AM. SOC. C. E.—An interesting method of analyzing the stresses in skewed rigid frames has been demonstrated in this paper. The tabulation of the equations, as in Table 6, serves to clarify the procedure and results in a saving of time and labor. Before this method can be used with complete confidence, however, further experimental study is needed. The equation for the torsion factor, *F*, cited by the author in his definitions was originally developed by C. Bach for the purpose of computing stresses in reinforced concrete arch ribs. The ratio of breadth to depth in a concrete arch rib section is generally about 1 to 4, whereas in skewed rigid frames the ratio is often as great as 1 to 20.

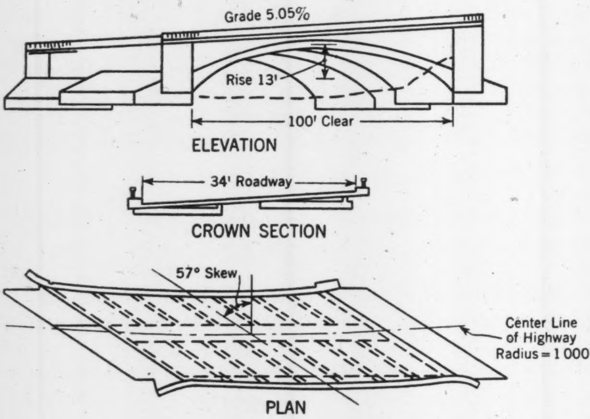

FIG. 9.—SKEWED ARCH BRIDGE

Loading on skewed rigid frames or arches often consists of concentrated forces eccentrically placed in relation to the longitudinal center line of structure. Such forces produce increased local stresses that are not considered in the equations of this paper.

In detailing skewed bridges the limitations of the torsion factor and local stresses may often be minimized conveniently. Consider, for example, the Gaviota Bridge in California, constructed in 1932, which carries a heavy traffic load on the main highway between San Francisco and Los Angeles.[39] This bridge, with an unusually large skew angle of 57°, was constructed with two separate skewed arch ribs as shown in Fig. 9. Therefore, the breadth-depth ratio was reduced considerably. The roadway slab is supported on the transverse rigid walls with resulting uniform distribution of the concentrated forces.

[39] *Engineering News-Record*, March 30, 1933, p. 399.

Mr. Hodges has stated that, in analysis of stresses in skewed arch ribs, the direct deformations may be neglected. In skewed rigid frames the direct deformations have negligible effect. However, in flat skewed arch bridges the direct deformations may often have a considerable effect and cannot be neglected safely.

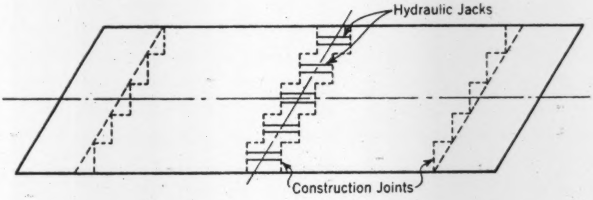

FIG. 10.—PLAN SHOWING HYDRAULIC JACKS METHOD OF POURING SKEWED ARCH

In designing skewed rigid frames and skewed arch bridges, attention should be given to the shrinkage stresses, which increase rapidly with corresponding increases in the skew angle—almost at the same rate as the temperature stresses shown by the author in his conclusion 3. A considerable part of the shrinkage stresses in skewed arch bridges may be reduced by a toothed construction joint, normal to the neutral axis, and in the arch and abutments,[40] as shown in Fig. 10.

RICHARD M. HODGES,[41] M. AM. SOC. C. E.—The writer is sincerely grateful to all who have gone to the trouble necessary to discuss this paper. In a few instances the comments seem to have particular reference to structures of such magnitude and cost that simplified methods would not be of much importance. It is to be hoped that all will lead, in one way or another, to a wider knowledge of what constitutes good practice in the analysis and design of concrete solid-barreled skewed frame and arch structures of moderate span.

The discussions plainly indicate the wide variation in the design methods now extant—from somewhat complicated attempts at theoretical precision at one extreme to rather rough approximations at the other. Perhaps it would be more correct to classify, at the latter extreme, the efforts being made to avoid the problem in various ways while still retaining the skew, such as the substitution of a ribbed structure for a solid-barreled structure, as mentioned in several of the discussions.

There is certainly something to be said in favor of attempting to make the design approach academic accuracy, in spite of resulting complications. (The writer is referring particularly to the effect on the design of the internal moments and stresses.) However, it is sometimes easy for those primarily interested in theory to overlook the practical elements of a problem. There is always a certain limit of justifiable precision in the practical design of a skewed frame or arch, or of any other structure. That limit is overreached when the degree of precision is such that (1) it cannot be warranted by the degree of accuracy attainable in the underlying data or in the basic assumptions; or (2) the cost of the design becomes unnecessarily disproportionate to the cost of the structure. There is even an element of danger in overprecision, in that it leads to a false sense of security. Another limiting factor of the utmost importance in connection with the design of moderate-span skewed frames and arches is established by the fact that, the more difficult or abstruse the design method, either to understand or to apply, the greater becomes the tendency of designers to go to the opposite extreme and to use inadequate approximations or rule-of-thumb methods, or even to shun this type of construction entirely. Of course any exact determination of any of the limiting conditions referred to is practically impossible—the least one should do about them, however, is to keep them in mind.

[40] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1329, Fig. 38.

[41] Chf. Structural Designer, Gilmore D. Clarke, Cons. Engr., New York, N. Y.

In several of the discussions, notably in those of Messrs. Parmé, Polivka, and Weiner, there has been a tendency to overlook the purpose and scope of this paper, which is merely an attempt, based on existing theory, to present a method of design, which, for the type of structure considered, will make it possible to meet the foregoing general requirements.

Mr. Geisler's discussion presents some interesting ideas. The tendency, to which he refers, of the forces to concentrate at the corners is shown graphically in Fig. 6. However, the effect on the longitudinal stresses is believed to be practically negligible, and, as stated by Mr. Geisler, there have been no indications of resulting distress in the numerous bridges designed and constructed without considering this effect.

It is common practice to construct the barrel with one or more construction joints parallel to the spandrel walls, as may be necessary, but the writer sees no advantage in dividing the barrel into comparatively narrow longitudinal strips, whether or not more or less effectively tied together. The only way to get rid of the increased corner reactions, as well as of other skew effects, would be to make the separations complete and effective all the way from the crown down to the bottoms of the vertical legs, and also to remove the earth pressure by some kind of open deck approach construction. The effect of Mr. Geisler's method seems to approximate the usual solid-barreled type of construction, with the transverse ties tending to perform the function of transverse reinforcement as designed by the method here adopted.

It is quite true that the corner reaction intensities increase with the width of the structure, but the effect is ordinarily not very serious. However, they should not be neglected entirely, as is too frequently the case. The increase in the vertical reactions at the obtuse corners is relieved by yielding, as Mr. Geisler states, when the structure is founded on compressible soil, and in such a case the bridge itself must resist the additional torsion. If the bridge is designed to withstand the extra torsion, as the writer has recommended, by assuming free rotation about the x-axes, there is no cause for concern. Incidentally, for severe skews extreme temperature rise leads to a reversal, and then the vertical reactions will increase toward the acute corners. A similar reversal also occurs in the normal direction of the lateral thrust along each abutment. These effects can become very important for a severely skewed frame founded on piles.

Mr. Parmé, as well as Mr. Geisler, mentions the tests made by the Bureau of Public Roads.[8] These tests were made on a model with one abutment hinged and the other fixed. The Society's Special Committee on Concrete and Reinforced Concrete[42] stated that "The results of these tests could not be used conveniently as a check of Professor Rathbun's theory." In fact, the tests were not of a skewed arch with either fixed or hinged abutments. This would seem to account for the discrepancies shown by Mr. Parmé. The tentative conclusions from these tests, as quoted by Mr. Geisler, may still be true (they agree in general with the writer's investigations), but no interpretation that could be derived from them would invalidate the elastic theory developed by Professor Rathbun.

In Mr. Parmé's discussion, and also in that of Mr. Polivka, the basic theory for finding the resultant reactions has been questioned in spite of the fact that its essential accuracy was confirmed, in 1926, by a comparison between theoretical analyses by Professor Rathbun and model analyses by the late Professor Beggs. Mr. Parmé's analysis appears interesting, but the preponderance of opinion seems to be rather solidly against his and Mr. Polivka's evaluation of previous investigations. Since Mr. Parmé attempts to show that Professor Rathbun's theory is incorrect, and, since Mr. Polivka seems to think that nothing that has been done to date is worth considering, the writer considered it proper that Professor Rathbun should be afforded an opportunity to present his views. Accordingly, in a letter addressed to the writer, he states:

> "*Transactions* [Vol. LXXXVII] 1924, p. 676 (3) covers the case analysed mathematically by Mr. Parmé and shows that his results are in 'sharp contradiction to established fact.' He will find, if he follows his analysis through all the terms, that he will arrive at the same results as I did, unless I misunderstand his rather short outline of his analysis."

Mr. Parmé cites but two experiments. One supports the elastic theory and the other does not. Four others that do support the theory are described elsewhere.[22, 43, 44, 45] Mr. Polivka cites no authority, but the foregoing also answers his statement that the existing method of analysis "* * * has not yet been corroborated satisfactorily by tests on models * * *."

The writer feels greatly complimented in having his paper approved, in general, by Mr. Hayden. An interesting feature of Mr. Hayden's discussion is his short history of the development of skewed arch and rigid frame design. The writer will take the liberty, when replying to Mr. Weiner, of filling in a few details which Mr. Hayden has omitted.

Mr. Hayden's idea (also mentioned by Professor Rathbun) of using the skew span, instead of the square span, as a basis of deriving the simplification, is well worth investigating. However, the writer thinks that it is more logical to develop a simplification along the lines of the universally applicable elastic theory than to attempt to use the Rankine approximation.

---

[42] "Concrete and Reinforced Concrete Arches," Final Rept. of the Special Committee, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1552.

[43] "An Analysis of Multiple-Skew Arches on Elastic Piers," by J. Charles Rathbun, *ibid.*, Vol. 98 (1933), p. 26.

[44] *Ibid.*, p. 50.

[45] *Ibid.*, p. 66.

Both Mr. Hayden and Professor Rathbun have called attention to the common fallacy that skew effects can be avoided by the use of ribbed construction. Many bridges have been designed and constructed in this happy belief, and no trouble has resulted, to the writer's knowledge, but nevertheless these bridges are incompletely designed, and headroom has been needlessly wasted in the process.

A more serious matter is the practice of using approximations without knowledge or discrimination. The writer has read several publications (although not very recently), which stated that the longitudinal reinforcement of skewed frames can be designed safely by multiplying the square span moments and thrusts by the square of the secant of the skew angle, without considering that temperature moments and thrusts (which are the controlling factors in proportioning a frame of moderately heavy skew) must be multiplied by the fourth power of the secant.

The responsibility for this type of advice can be placed squarely on those engineers who, knowing something about skewed arch and rigid frame design, not only have paid no attention to the necessity of making it simple enough for practical use in the design of small frame structures, but have seemed actually to resent any effort that may be made in that direction by any one else.

Mr. Weiner's discussion takes the form of a dissertation on the subject of skewed arches in general, in the course of which he often ignores the scope of this paper unnecessarily and takes frequent occasion to discuss his own paper[6] published in 1931. For instance, he states:

> "Much confusion indeed has been caused by the constant search for new 'methods.' * * * The writer has given complete equations[6] for both the symmetrical and unsymmetrical skew arch (single span) with the origin and basic structure chosen with this [simplification of equations] idea in mind."

and, subsequently:

> "* * * it was partly because the original skew-arch [Rathbun] theory was written on the basis of a space system that it had to be revised for efficient use in the drafting room, and this revision constitutes Part I of the writer's paper[16]—and is so stated therein."

It is significant that no mention of this revision by Mr. Weiner is made in the "Historical Perspective" part of Mr. Hayden's discussion. It was because Mr. Weiner's revision proved too laborious (except to Mr. Weiner and the men working in his squad) that it was considered necessary to make the subsequent adaptation of the original Rathbun method to which Mr. Hayden refers.

Mr. Weiner has brought up a number of points which are not directly related to the current paper but consist of criticisms of Professor Rathbun's previous contributions. In reply to an inquiry by the writer, Professor Rathbun states that his interest is purely in

> "* * * the development of the skew arch theory and its acceptance and use by the Profession. Mr. Weiner has written extensively on the skew

> arch. He stated that my 'theory [page 1330, 1932 *Transactions*] formed the basis of Part I of the writer's paper.' Mr. Weiner did revise the sign system and he changed the order of my equations. These were revisions which I consider unwise since they lead to confusion. He also introduced the idea of the ellipse of stress. As I have pointed out in previous discussions of papers, this idea is incorrect as here applied. To my knowledge Mr. Weiner has made no other contribution."

The writer is opposed to Mr. Weiner's ellipsoidal stress method for the additional reason that, even if it were theoretically correct in its application, it would still be unnecessarily complicated as a matter of practical design.

Opportunities to discuss the relative technical merits of Part II of Mr. Weiner's paper and of the design method originally proposed by Professor Rathbun were offered in their proper place and need not be extended in this closing discussion. The writer will not attempt to answer all of Mr. Weiner's numerous criticisms of this paper. He will answer the statements made in Mr. Weiner's opening paragraphs and will then attempt to use a sampling method on the others.

The first paragraph, under his side heading, "Step I. Reactions," is incorrect throughout. Mr. Weiner states,

> "The purpose of this part [computation of reactions] of the paper is to show that permissible approximations may be made in the frame constants with the result that the equations developed on the basis of the accepted theory (proved by tests) are simplified. In addition, the equations break up into groups, each of course containing fewer unknowns. That permissible approximations usually result in simplifications is, of course, obvious; nevertheless, the results are approximate and the paper has been misnamed. Neither proof nor data are given for the degree of approximation."

This paper is not concerned in the least with "permissible approximations" in "frame constants"; and it is misleading, at least, to state that the equations referred to are simplified. The "equations referred to" were not used at all. They were not simplified. New equations were derived on a simplified elastic basis.

Mr. Weiner has only described the process used by himself (and before him by Professor Rathbun) in arriving at approximate formulas for certain redundant reactions. These approximate formulas were derived simply by applying the original equations to a skewed frame with a perfectly flat top and vertical legs. When the writer first began to search for a reliable method of simplification, he tried this method and found it inadequate. Certain reaction components depending largely on deck curvature could not even be approximated roughly in this way. Others were close within certain limits of skew and curvature; but these limits were unknown. The only approximation that stood the test of comparative analyses was the well-known formula "$R_x = H$" (using the writer's notation), which was first published, not by Mr. Weiner, but by Professor Rathbun. In the "Appendix," the writer has given (as a matter of interest and not as an original contribution of theory) a derivation of this important relationship, as adapted to the system of coordinates used in this paper, showing the assumptions on which it is based. The method described by Mr. Weiner was found inadequate for obtaining the other redundant reactions. Instead of simplifying the existing equations as adapted from the original elastic theory, the writer derived new equations for Part 2, using only one instead of two elastic systems. There is no resemblance between the process used by the writer under the heading, "Derivation of Method for Determining Reactions," and the process attributed to him by Mr. Weiner.

The statements made in the last few lines of the paragraph previously quoted cannot be ignored. Before preparing this paper, the writer had obtained evidence of the closeness of the fundamental relationship that $R_x = H$ from comparative analyses of different frames of varying types. The writer stated this very clearly, and he had hoped that it would not be necessary to burden the reader with detailed descriptions and summaries of these comparisons, but Mr. Weiner has left no alternative. (Attention is called to Mr. Barron's discussion of this point, which represents a more constructive and useful form of skepticism than that of Mr. Weiner.)

The following summary is obtained from the results of comparative test analyses made in 1932 by the office force headed by Mr. Hayden, then Designing Engineer of the Westchester County Park Commission, under the direct supervision of the writer. Analyses were made of two bridges, representing different types of rigid frame construction. The Main Street Bridge, Central Westchester Parkway, White Plains, N. Y., is a rigid frame of average type (span 50 ft and rise 21 ft) with a comparatively small degree of deck curvature. The Loop Bridge, carrying the Bronx River Parkway Extension over the Taconic Parkway Connection, is an elliptical rigid frame, approaching a semicircular full-centered arch (clear span 42.5 ft and rise 23 ft). Both were constructed in 1931 and in both bridges the angle of skew was 38°.

Comparative analyses were made for various skew angles. For skews of more than zero, all reaction components were computed by Professor Rathbun's theory as adapted for the Park Commission. For skew angles of 0°, the reaction components R_x (or H) were computed by the ordinary elastic theory for two-hinged rectangular frames or arches. Calculations were made for a temperature rise of 50° F, for balanced earth pressure, and for unit vertical loads applied successively at three points which may be described approximately as near the haunch, quarter point, and crown. The results as given in Table 14 are for a unit width. The customary temperature corrections were applied in reverse, and the skew span reaction components were divided (instead of

TABLE 14.—SUMMARIES, VALUES OF R_x

Skew angle	Main Street Bridge					Loop Bridge (Elliptical)				
	Unit Load at			Earth pressure	Temperature	Unit Load at			Earth pressure	Temperature
	Haunch	¼ point	Crown			Haunch	¼ point	Crown		
0°	0.201	0.383	0.495	1.80	0.156	0.060	0.220	0.330	2.38	0.068
38°	0.202	0.384	0.499	1.75	0.158	0.059	0.221	0.332	2.33	0.072
45°	0.201	0.381	0.497	1.73	0.154	0.059	0.221	0.332	2.31	0.072

multiplied) in this case by $\sec^2 \theta$ to make them comparable with rectangular frame reactions.

Near the beginning of his discussion, Mr. Weiner states:

> "Many years ago the writer found that for a symmetrical structure the approximations were permissible and result in the simplifications stated."

Presumably Mr. Weiner is referring to the simplifications stated in this paper. The only approximation used in the paper was found by Professor Rathbun. The others are not permissible for a symmetrical structure except under certain restrictions of small deck curvature and skew. The results of Mr. Weiner's analysis, as well as the methods used, are totally different from those advanced in this paper. According to Mr. Weiner (and Professor Rathbun before him), $R_z = \epsilon R_x$, using the writer's notation. This is a fairly close approximation for restricted deck curvature and skew. According to the method presented in this paper, $R_z = \epsilon R_x + R'_z$, in which ϵR_x is the static equilibrant of R_x, and R'_z is that part of R_z which is due to the torsional elasticity of the structure. Since M_x and M_y are both functions of R'_z, and since R'_z does not appear in Mr. Weiner's approximate formulas, Mr. Weiner's statement is incorrect.

Mr. Weiner favors the location of the origin of the coordinate system at the crown, rather at one of the hinges, which is permissible, but the writer disagrees emphatically with the contention that this is more logical for a hinged structure. For those who are accustomed to designing rectangular frames with the origin at a hinge, the hinge is the logical point of origin for the design of hinged skewed frames. One advantage of this arrangement is that the sign system is much simplified.

Some of Mr. Weiner's comments, regrettably, serve only to introduce complications and confusion. For example, the method under discussion needs no elaborate sign system. No one has ever considered the introduction of such a system in the design of skewed frames as finally adapted for the Westchester County Park Commission, on which the method under discussion is based. It would have been unnecessary, and that is one of the chief advantages of this method over Mr. Weiner's adaptation. The best sign system in any case is the one that requires the very least in the way of "formal" explanation. Mr. Weiner states that the writer "does not give a formal statement as to the directions of the positive moments and thrusts." The statements made in the paper (see "Derivation of Method for Determining Reactions: Details of Derivation," fifth paragraph) are perhaps not as formal as they might be, but, in conjunction with Fig. 1, to which they refer, they make the sign situation very clear. Mr. Weiner states that "a 'picture' is not sufficient," which is true, but a clear picture, together with a simple explanation, is certainly the best way to avoid misinterpretation. (There is an oriental proverb that states, in effect, that "a picture is worth ten thousand words.") This is just as correct for multiple spans and multiple stories (which were not open to discussion) as it is for the simple one span frame which is the subject of this paper. Definitions can mean various things to various people, but a picture always means the same to every one.

The system of setting up formulas for each step in a design process, and having "juniors" perform blind substitutions, may be temporarily efficient under certain conditions, although pretty hard on the "juniors." It is certainly a poor way to develop future designers. The writer is convinced that this procedure would be inadvisable as a general policy for any engineer or any organization.

Mr. Weiner's comment on one of the recommendations in the paper is that

> "The writer [Mr. Weiner] also fails to understand the reasoning on the earth-pressure distribution. Once equivalent fluid pressure is assumed, it acts normal to the surface of the wall and that is all that there seems to be to it. It is true, of course, that the equivalent fluid pressure theory leaves much to be desired in the way of a rational theory, but this rather unfortunate situation is not unique with the skew arch; it is true of all structures subjected to earth pressure."

This statement indicates a misinterpretation of the recommendation. There is no "unfortunate situation" involved, and the writer's recommendation certainly does not apply to anything but skewed bridges.

Unbalanced earth pressure is rarely used in the design of symmetrical frames under ordinary conditions. With proper specifications and proper inspection (which the designer has a right to expect), the chance of such a condition is too remote to justify the extra time and trouble. There are so many combinations of active, passive, and unbalanced earth pressure and restricted sidesway conditions to be considered, that there would be no end to the time that might be spent on this kind of investigation. Failure to take advantage of the neutralizing effect of balanced earth pressure is failure to benefit by one of the principal intrinsic economies of the rigid frame type of construction.

The writer does not agree that vertical concentrated load tests supply the information obtainable from earth-pressure tests and temperature tests. Vertical loads placed in various positions would be of little value in deciding, for instance, how much (if any) of the lateral earth-pressure reactions is actually carried along the abutments in friction, or whether it is actually true, as far as temperature is concerned, that the structure can be made stronger by using inferior concrete.

Mr. Weiner asserts that the writer "quotes Professor Rathbun incorrectly when he states that the transverse shearing force is distributed parabolically * * *." The writer did not quote Professor Rathbun, nor did he make any such statement. What the writer did state was that "the direct transverse shear is assumed to be distributed parabolically * * *," and the quotation is in fact from Mr. Hayden's book. Mr. Weiner's error is in overlooking the phrase "is assumed to be." This assumption (which was used for many years before this paper was written) is one of several in Part 3 of the design which have led to modifications in the original method. The purpose has been to simplify the design computations further, and also to increase the margin of safety in proportioning the transverse reinforcement, thus making allowance for the uncertainties (frequently referred to in the paper) affecting this part of the design.

In "General Remarks," Mr. Weiner states that designing by the 1-ft strip method "is merely a minor arithmetic convenience which has no structural significance." The same can be said of any short cut. Such a statement may even apply to a slide rule or a calculating machine, and certainly any convenience that saves time and eliminates possible errors is justifiable.

The writer hopes, with Professor Rathbun, that this paper will renew interest in the subject and perhaps be the means of inducing designers to familiarize themselves with the basic theory. It is only by such means that, among other advances, improved simplifications for practical design purposes can be evolved.

The writer is particularly gratified by the contribution of Mr. Barron, who immediately understood that the fundamental basis of the method under discussion is predicated on a complete separation of the two elastic systems which have always previously been considered together, and then proceeded to explore the subject on this basis. He not only found that the rectangular reaction components R_x are independent of the skew angles in the case of the two elliptical bridges which he analyzed, but also gave a general demonstration of why this condition holds true for every rigid frame investigated. The elastic-center, elastic-weight method employed by Mr. Barron reveals this fact much better than the method of analysis customarily used by the writer.

Mr. Barron has also made a very apt comparison between the method under discussion and the usual practice of neglecting shear deformations, and, in most cases, rib shortening, in the design of ordinary rectangular frames and arches. The writer is in agreement with this statement. He has not claimed that the basic relation is mathematically exact, although it proved so close in the case of some of his comparisons that he was almost tempted to believe so.

Mr. Barron speaks from experience when he mentions the difficulties encountered in considering the flexural and torsional elastic systems together in one group of equations. In such case, the same difficulties and small differences are always encountered, no matter what method is employed.

The writer agrees that rotation about the "y-axes" is highly improbable. However, there have been cases of separate footings for abutments and approach walls, and very little complication is added if such rotation is considered as a possibility. Incidentally, Mr. Barron is the only discusser who has paid much attention to the special problem of earth-pressure loading.

Mr. Lovering's discussion is short, but much to the point in discussing the question on which the practical value of the writer's method entirely depends,—namely, how does it work? The discussion emphasizes clearly the fact that skewed frame designs cannot wait for the solution of theoretical niceties and academic abstractions. They must be turned out quickly to meet present requirements, if they are to be used to any appreciable extent. Professor Rathbun showed that he realized this many years ago when he originated the very simple and straightforward method of practical design for these structures which has been used by the writer, with certain modifications for the sake of further simplicity. Mr. Lovering has stated the practical advantage of being able to establish the proportions of the structure once and for all before considering the somewhat more complicated torsional effects that apply only to the subordinate part of the analysis and design. He has emphasized the fact that temperature is the controlling factor in the design of all rigid frames of considerable skew, and has shown a very practical and economical way of minimizing the temperature effects in such cases, making it possible to extend the practical skew limits of any particular skewed frame or arch. He has also recommended an effective way of transferring the shears between the legs and the footings which should be standard practice. The writer had hoped that there would be more discussions of the type submitted by Mr. Lovering, dealing with the more practical and more neglected aspects of the problem.

Mr. Eremin's reference to the unreliability of the torsion factor calls attention again to the fact that there is no such thing, at present, as an exact method of design for the torsional effects on a skewed frame or arch structure. This fact has been previously referred to as a good reason for avoiding all misleading methods of unwarranted precision. It has also been mentioned that torsional effects are not neutralized by ribbed construction or by dividing the arch or frame barrel into separate strips, and that they can be taken care of safely and without undue loss of economy by proportioning the transverse reinforcement on the basis of extreme assumptions for this subordinate part of the design. As Mr. Lovering has stated, the controlling design, from which the structure itself and its longitudinal reinforcement are proportioned, can be made independently. It is not affected in any way by such assumptions.

The problem of local stresses caused by eccentric loading is an uncertainty which applies to rectangular as well as to skewed solid-barreled structures. The writer questions the necessity of any expedients either in the design or construction of solid-barreled skewed frames or arches. Mr. Eremin calls attention to the necessity of considering rib shortening stresses, which multiply themselves in skewed structures in the same way as temperature stresses, in the design of skewed flat arches. This comment should also apply to skewed frames of exceptionally long span.

Since the inception of this paper, it has become increasingly apparent that, with the modern trend toward divided traffic arteries, double span rigid frames may soon become the rule and single spans the exception. The rather common practice of designing such double span bridges by methods similar to Part 1 of this paper and then more or less guessing at the transverse reinforcement is probably a reasonably safe procedure in most cases; but it is evidently not a very reliable or satisfactory one, particularly in regard to the transverse reinforcement. Although the first part of the aforementioned procedure may be correct enough for practical purposes, an attempt should be made to establish conclusively by comparative analysis (as a further check on Mr. Barron's reasoning in the last paragraph of his discussion) the fact that it is proper to separate the two elastic systems in the same way as for a single span structure. If this is true, as expected, it will be possible to derive comparatively simple equations for the torsional and shear redundants, especially for two equal spans, and to arrive at a reliable method of completing the design with much less work than is now required.

SLUDGE-DRYING DEVELOPMENTS AT CHICAGO, ILL.

By Lloyd M. Johnson,[1] Esq.

With Discussion by Messrs. C. W. Gordon, Paul Hansen,
Langdon Pearse, and Lloyd M. Johnson

Synopsis

Since the inception of the sewage treatment program, The Sanitary District of Chicago, Ill., has conducted many investigations on the dewatering and drying of sewage sludge. This paper is concerned with these investigations, particularly the results and conclusions as applied to the Southwest works.

The Sanitary District is served by four major sewage treatment works, as indicated in Table 1. The Southwest works and the West Side works are located on a common site although the treatment plants are about one mile apart. At the Southwest plant, complete treatment is provided for all the sewage from the Southwest area, and final treatment is to be provided for the partly treated effluent from the West Side works. This double function of the Southwest plant has caused it to be frequently called the West-Southwest sewage treatment plant. For the purposes of this paper it is to be identified as the "Southwest works."

TABLE 1.—Data on The Sanitary District of Chicago, Ill.

Plant	Design flow (mgd)	Method of sludge disposal	Date placed in operation
Calumet[a]	136	Incineration	December 3, 1935
North Side[a]	250	Pumped to Southwest works	October 28, 1928

West Side[b]	472	Sand drying beds	June 2, 1930

[a] Activated sludge. [b] Imhoff tanks.

Note.—Published in September, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Commissioner of Streets and Electricity, City of Chicago, Chicago, Ill.; formerly, Engr. of Maintenance and Operation, The Sanitary Dist. of Chicago.

The West Side works serves an area of 150 sq miles, and the population equivalent reaching the works in 1941 was 2,244,000, based on the 5-day B.O.D. analysis.

The treatment plant consists of a pumping station, grit chamber and screen house, skimming tanks, and 108 Imhoff tanks with a sludge volume of 10,532,000 cu ft. Two of the batteries were designed for 134 mgd each and a settling period of 2 hr. The third battery was designed for a flow of 204 mgd and a period of 1 hr.

Digested sludge is dried on open-air beds 80 ft wide with lengths varying from 800 to 1,398 ft and having a total area of 27.3 acres. The beds are in pairs with a standard-gage railway track between each pair. Dried sludge is removed from the beds by cleaning machines that span the 80-ft width, discharging the air-dried material to 30 cu yd side dump cars. The loaded cars are hauled to dumping trestles on Sanitary District property about 3 miles west of the plant. Three heavy switching locomotives are available for hauling sludge and switching service.

The Southwest works serves an area of 82 sq miles. In 1941 the load reaching the works was equivalent to the sewage from 2,770,000 persons. The area served includes the stockyards and packing-house district.

The plant equipment includes a pump and blower house, preliminary settling tanks, aeration and final settling tanks, sludge concentration tanks, and a combined sludge-handling and steam generation plant.

The main prime movers, all driven by steam turbines, consist of four sewage pumps, three blowers, and two electric generators. Plant effluent is used as condensing water in the surface condensers of the turbines.

The sewage pumps discharge to aerated channels leading to the preliminary settling tanks. There are twelve of these tanks, each 101 ft by 103.5 ft inside, and with the depth varying from 10.66 ft to 11.66 ft. Sludge and scum removal equipment is provided. The detention period is 34 min at 400 mgd.

The aeration and final settling tanks are divided into two batteries, each having eight aeration tanks and sixteen settling tanks. The aeration units are the spiral flow type, each 434 ft long inside, and 135 ft wide, center to center of pressure walls. A depth of 15 ft over the diffuser plates is provided. Each tank is divided into four passes by three nonpressure bearing walls. The aeration period is 5 hr at 400 mgd and 20% return.

The settling tanks are the center feed, radial flow type, each 126 ft inside diameter and 11 ft deep at the side-wall. A settling rate of 1,200 gal per sq ft per 24 hr is obtained with 400 mgd and 20% return.

The plant was designed for an average flow of 400 mgd, although at present the activated sludge treatment capacity is limited by blower and sludge-drying capacity. With the present blowers a flow of 300 mgd could be treated. However, the sludge-handling capacity of about 200 tons per day, about half of which is from the North Side works, further limits the present useful capacity to about 225 mgd.

Plant extensions call for an additional battery of aeration and final settling tanks, eight additional final settling tanks for each existing battery, three additional blowers, and six more sludge-drying units. These extensions will provide activated sludge treatment for the West Side Imhoff effluent and sufficient sludge-drying capacity for the additional solids load.

The magnitude of the sludge-handling problem of the District may be visualized from the fact that at present the four major sewage treatment works have a combined average capacity of 1,258 mgd. For 1941 the actual combined flow averaged 1,064 mgd, carrying a daily load of suspended solids averaging 729 tons, dry weight. Of this about 95% reached the Southwest works, since the North Side sludge is pumped to the Southwest works for disposal. The completion of the extensions of the Southwest works will increase the solids loads for disposal at the combined plants to more than 600 tons daily.

As early as 1914 thought was given to the dewatering and incineration of sludge by the Engineering Department of the Sanitary District. Between 1922 and 1930, full-scale tests were made at the Calumet and the Des Plaines River sewage treatment works on dewatering, drying, digestion, and other methods of disposal of activated sludge. These experiments were confined principally to various types of filter presses, dryers, centrifuges, etc. The digestion of mixed activated and fresh sludge was tried first in the operation of the West Side works. Relatively large volumes of digestion capacity and large areas of outdoor drying beds were found necessary. Difficulties in securing adequate areas, and opposition from adjoining property owners, were encountered. Consequently, a procedure was sought which could be used the year round, in which the sludge would be conditioned, dewatered to a cake, and heat dried for incineration, or placed on sale as a fertilizer. At the time, the idea of lagooning was dismissed as a temporary measure that might produce odors.

In 1932 the first tests were conducted at the West Side works on dewatering, drying, and incineration of sludge in a pilot plant handling about 20 tons of dry solids per day. Various mixtures of North Side activated sludge and West Side fresh sludge were used. In all tests the wet sludge was dewatered to approximately 80% moisture by means of a rotary vacuum filter having a net filtering area of 570 sq ft.

In the first phase of the test a rotary drier 70 ft long and 8 ft in diameter was used. Heat was supplied by an incineration furnace equipped with a stoker having a grate area of 80 sq ft.

Dried sludge from the drier was burned in the furnace along with coal, as required, to provide the necessary heat.

Vapors from the drier and the products of combustion were passed through a vapor condenser and scrubber.

The principal disadvantages of this system were:

(1) The difficulty in securing quick and responsive control; and
(2) Ineffective and inefficient deodorization of gases and vapors.

In February, 1934, the first test plant using the flash-drying system was placed in operation. Three impact mills were used for sludge, and one was provided for firing coal when supplementary fuel was required. Gases from the drying circuit were passed through the combustion zone of the furnace, and heat was recovered from furnace gases by means of a vapor heater.

The impact mills operated satisfactorily but it was found that the high degree of comminution afforded was not necessary. The mills were replaced by a cage mill with an evaporating capacity of 5,000 lb per hr of water. A substantial saving in power was realized by this change. Changes were also made to permit use of a vapor cycle instead of an air cycle in the drying circuit.

The tests in this plant were completed in August, 1935. The Calumet Sewage Treatment Works, having a capacity of 40 tons of dry solids per day, was the first plant built after these tests. Experience gained from the operation of this plant aided in the design of the Southwest works. However, the Southwest sludge-handling plant is more complicated than the Calumet plant, as the function of steam generation is combined with that of sludge drying.

In planning the sludge-handling system at the Southwest works, provision was made for handling the North Side sludge, in amount about 100 tons of dry solids per day. The North Side sludge and the Southwest activated sludge are mixed, screened through mechanically cleaned bar screens with ½-in. clear openings, and passed to six concentration tanks, each 70 ft by 46 ft 9 in. inside measurements. A centrifugal pump is provided at each tank to pump the concentrated sludge to the sludge-handling building. The supernatant liquor is discharged to the incoming sewer by gravity.

The concentrated sludge is pumped into the conditioning apparatus on the top floor of the sludge disposal building. The sludge is coagulated by adding a concentrated solution of ferric chloride in a dosing flume. The flow of ferric chloride is proportioned to the flow of sludge by the operator as required by changing sludge conditions. From 6% to 9% of ferric chloride is used, based on the dry weight of the solids. The best guide is the pH-value of the conditioned sludge, which is recorded in a continuous graph. From the mixing flume the sludge is discharged directly to the vacuum filters.

There are thirty-two vacuum filters, each with a drum 11.5 ft in diameter and 16 ft long, with drain valves at each end (see Fig. 1). The filters are arranged in groups of four, each group discharging cake to a common conveyer belt leading to one drying unit. A constant effort is being made to reduce the costs of dewatering. Various substitutes are under investigation to replace the monel metal mesh for supporting the filter cloth on the outside of the drum. The use of plastics for interior piping in place of copper pipe and bronze fittings is being tested. Stainless steel has been found best adapted for the scrapers, although plastics are to be tried as a substitute. The most satisfactory filtering medium is a long-nap, virgin-wool cloth, weighing 13 oz per sq yd. The substitution of a coated iron wire for bronze or copper as winding wire over the cloth is under trial. The cake is peeled off the filters at 80% to 85% moisture, depending on the type of sludge. The sludge will filter more readily to a lower moisture as its volatile content decreases.

As the cake moves along on the belt conveyer, it is weighed automatically. It is then mixed with previously dried sludge to produce a mixture containing between 40% and 50% moisture. The mixing is done in U-shaped troughs lined with stainless steel in which paddles mounted on horizontal shafts mix the wet and dry sludge and move it along the trough. In these units severe abrasion occurs, particularly at the tips of the paddles. The use of a chromiumtungsten-cobalt steel alloy reduces the wear. The mixing has been improved by reversing some of the paddles on each shaft. The mixed sludge is passed to the drying units.

Each of the eight sludge-drying units has a normal capacity to evaporate 20,000 lb per hr of water, based on 1,150° F vapor inlet temperature and 300° F outlet temperature. The drying units operate at a pressure slightly below atmospheric to prevent escape of odors from the process. As a further assurance that no odors will be released to the atmosphere, all waste vapor is passed through the combustion zone of the furnace. The mixed sludge from each group of four filters is divided between the two halves of the drying tower for each drying unit, the division being controlled by the vapor temperature in the cyclone separators. Each tower is about 12 sq ft in total cross-sectional area. A 3-in. thickness of insulating block is used, lined with stainless steel containing 18% chrome and 8% nickel. It is here that the sludge is mixed with the superheated vapor from the vapor heater.

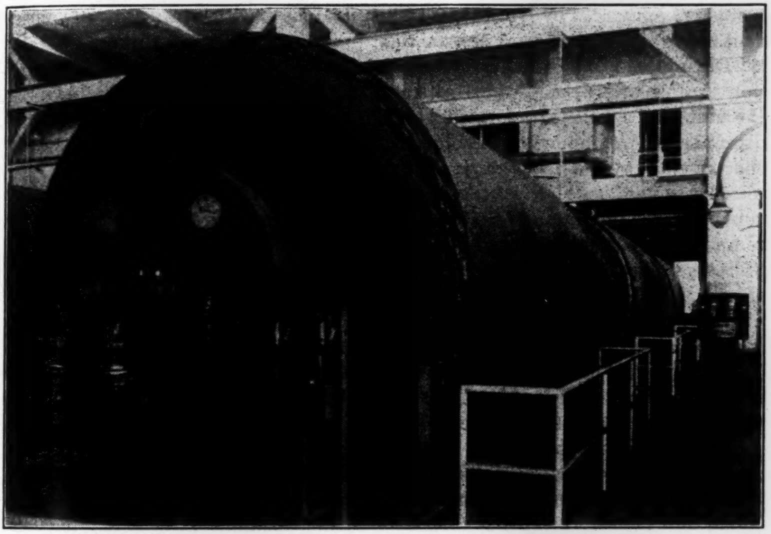

FIG. 1

At the bottom of the towers, the sludge and vapor mixture enters a squirrel-cage mill, which forms the flash drier. Each drier unit consists of two squirrel-cage mills mounted on a common shaft. The mill breaks up the sludge and brings the particles into intimate contact with the superheated vapor, resulting in very rapid drying. By the use of flash drying, cake at 80% moisture can be dried to 5% moisture in 5 min, as compared with 90 min in a modern rotary drier. The driers are subject to abrasion, but as yet this has not been serious. The wear is confined mainly to the liner plates and the cage bars. The renewal of cage bars has been made less frequent by the use of removable sleeves of alloy steel.

Each half of the sludge drier discharges to a cyclone separator from which the dried sludge is removed through rotary air locks and passed to a surge bin. The vapor passes from the separator to the circulating fan and thence to the vapor heater and through the circuit again.

The abrasion on the liner plates of the separators is serious. The original plates were made of ¼-in. steel and were very short lived. The separators were then relined by the gunite method, using lumnite cement and crushed trap rock (ganister) reinforced by No. 10 galvanized steel mesh with 3-in. square openings. This lining has proved very satisfactory.

During the first few months of operation the circulating fans required attention because of a deposit of grease and solids on the blades, which unbalanced the units. Deposits also formed in the ducts. This difficulty was reduced by diverting all preliminary tank solids to the West Side works, and handling only the activated solids in the drying plant.

The vapor heaters are subjected to high temperatures and require close supervision in operation. Room air is used as a tempering medium to hold the temperature of the inlet gas between 1,475° and 1,500° F. Particles of finely divided sludge may deposit on the plates during passage through the vapor side of the heater and may ignite if temperatures in the gas side become too high. The units are protected by thermostatically controlled steam valves which open into the hot gas duct if the temperature becomes excessive.

The surge bins receive the dried sludge from the cyclone separators and serve as distributors for supplying dried sludge to the sludge mixers and to the sludge burners or to the fertilizer conveyer. These units are insulated to prevent condensation on the walls.

Water-cooled butterfly dampers have been installed in the hot gas ducts between the furnaces and vapor heaters. The condensate from the sewage pump and blower turbines is used as a cooling medium, after which it is discharged to the de-aerating heater.

The heat required by the drying system is drawn from the four furnaces, each serving two drying units. They are of the water wall type, fired vertically through four burners for dried sludge and six burners for pulverized coal. They were designed for supplying heat under normal conditions to evaporate 40,000 lb per hr of water from sludge and also to generate 70,000 lb per hr of steam at 425 lb per sq in. gage and 750° F, total temperature, with feed water at 275° F. The boilers are the bent tube type with two drums. A superheater is provided.

The functions of steam generation and sludge drying were combined, not primarily with the recovery of heat from burning sludge as the end in view, but because most of the operating personnel and some of the physical structures of a steam generating plant are already provided in the sludge-drying plant. The only additional cost items for steam generation are fuel and fixed charges on steam generating equipment. Clarified plant effluent is used for condensing purposes. The ample supply has sufficient head to provide gravity flow and to eliminate the need for circulating pumps.

The waste furnace gases pass through an air heater, wherein the combustion air is preheated. After passing through this unit the gas mixes with the furnace gas withdrawn by the drying system. It passes through electrical dust precipitators and then to the stack. There are two dust precipitators, each rated at 180,000 cu ft per min of gas.

With fuel requirements dependent on two variables—steam load and drying load—the control of the furnaces is a delicate problem. Automatic control equipment is provided which ties in the control of the furnaces and drying systems.

In the tuning-up period, better control of steam temperature was secured by moving the superheater by-pass damper from near the top of the front baffle to the bottom of the by-pass passage. Furthermore, to secure higher superheated steam temperatures during high drying and low boiler loads, the side-wall tubes were covered with a plastic refractory, which permits higher furnace temperatures while reducing the heat absorbed by the water walls, thus increasing the heat passing through the main body of boiler tubes and the superheater.

Operating experience indicated the desirability of changing the control for the flow of combustion air. Originally the control acted through totalizing impulses from the flow of steam and waste vapor, which changed the position of the damper of the forced draft fan. This was altered to control the position of the damper by the rate of coal feed, balanced by the differential pressure across an orifice in the forced draft fan discharge duct. The new arrangement insures a definite quantity of air regardless of changes in the position of the secondary and tertiary air dampers.

A considerable amount of experimenting was done on the arrangements of secondary air ports. It was found necessary to reduce the number of ports and the total area of the openings to produce sufficient turbulence to insure complete combustion of the fuel.

Coal is delivered to the plant by rail to a track house south of the sludge disposal building. At this point it may be elevated to a conveyer leading to the bunkers or placed in storage in an adjacent area. A coal crusher is provided which may be used before the coal is elevated, if necessary. A belt conveyer with a traveling tripper distributes coal to the bunkers. This equipment has a capacity of 100 tons per hr. Each furnace is provided with a bunker holding 300 tons.

Coal for each furnace is drawn from the bunkers through two lines, each being equipped with a scale and feeder. Each furnace is served by two pulverizers of the bowl mill type with direct-connected exhausters.

When the firing equipment was designed and purchased the immediate production of fertilizer was not intended. Hence, with the entire sludge output being sold as fertilizer the pulverizing capacity provided is inadequate, since the heat value of each ton of fertilizer produced is equivalent to about 0.57 ton of coal. Also, the elimination of the preliminary solids presents a higher filter-cake moisture than would be the case with mixed solids, thus requiring more heat for drying.

Bottom ash collects in hoppers in the furnace bottom, below the superheater pass and below the boiler back pass, and also in the bases of the stacks. It is removed by hydraulic ash sluicing equipment and sluiced to a common sump, from which it is pumped to a dewatering hopper in the track house or to an ash lagoon. Ash pumped to the track house is loaded into railway cars and hauled to the sludge dumping grounds.

Fly ash is collected in hoppers below the air preheaters and dust precipitators. It is removed by a vacuum system discharging to storage hoppers in the track house. The material is moistened sufficiently to prevent blowing as it is drawn from the hoppers and then loaded into railway cars for hauling away from the plant.

CONCLUSION

Sludge disposal methods in use at the various works of The Sanitary District of Chicago were developed over a period of many years of operating experience and experimental investigation. Through the development of the flash-drying process, as installed at the Calumet and Southwest works, a method of handling sewage solids without the production of offensive wastes and odors was obtained. Although it is considered by those charged with the responsibility of design and operation that these installations have functioned, and will continue to function, in a very satisfactory manner, further improvements will no doubt be evolved that will decrease the cost of sludge disposal. There have been numerous problems attendant upon the operation of this new process, but in spite of these problems the method has proved its value as evidenced by the Sanitary District in enlarging the Southwest works along similar lines.

TABLE 2.—OPERATIONS RESULTS, 1941, MAJOR SEWAGE TREATMENT WORKS

Treatment works	Flow (mgd)	RAW SEWAGE (PPM)		EFFLUENT (PPM)		Solids removed; dry basis (tons)
		5-day B.O.D.	Suspended solids	5-day B.O.D.	Suspended solids	
Calumet	66.4	95	130	9	12	11,836
North Side	206.8	116	146	5.9	9	40,529
Southwest[a]	338	164	205	16[b]	17[b]	67,405
West Side	453.0	131[c]	198[c]	73	90	38,249

[a] Preliminary treatment only, 184 mgd. Activated sludge treatment, 154 mgd. [b] Activated sludge effluent. Weighted average of activated sludge effluent and preliminary tank effluent by-passed 72 ppm, both B.O.D. and solids. [c] Analysis includes preliminary tank sludge from the Southwest works.

TABLE 3.—SLUDGE-HANDLING PLANTS, CALUMET AND SOUTHWEST SEWAGE TREATMENT WORKS, 1941

Treatment works	PERCENTAGE OF DRY SOLIDS			Fuel value of dried sludge (Btu per lb)	Water evaporated (lb)
	Filter cake	Mixed sludge to driers	Dried sludge		
Calumet	17.3	73.4	93.9	5,920	95,380,000
Southwest	16.6	56.2	95.0	6,888	581,474,000

Although this paper deals chiefly with the Southwest sludge-handling plant, the magnitude of the sludge problems at the West Side works must not be overlooked. In 1941 the Imhoff tanks removed a total of 76,897 tons of dry solids, an average of 211 tons per day. The volume of wet digested sludge removed in 1941 was 644,055 cu yd. Of this amount 78,099 cu yd were discharged to temporary lagoons on the plant grounds, the remainder going to the drying beds.

An additional load was thrown on the plant in 1941 by the diversion of preliminary sludge from the Southwest works. This amounted to 132 tons of dry solids per day.

The capacity of the sludge-drying beds is inadequate even though worked to the limit. At times the air-dried sludge removed is rather high in moisture. The average for 1941 was 65.1%, compared to the previous maximum annual average of 54.0%. However, the sludge strippers handle this wet material easily.

Operating results for the year 1941 at the four major works of the Sanitary District are presented in Table 2. In Table 3 data on operation of the sludge-handling plants are presented for the same year.

DISCUSSION

C. W. **Gordon**,[2] **Esq.**—In presenting this paper Mr. Johnson has made available a wealth of design data, and he has discussed operating experiences frankly. This procedure gives the complete picture, and as such will be a great benefit to design and operating engineers. The Chicago Sanitary District was the pioneer in the field of sludge drying and incineration, and its method of sludge disposal is recognized as a success by sanitary engineers everywhere.

During 1940, multiple-hearth plants dried and incinerated 215,912 tons of filter cake. This is equivalent to 70,861 tons of dry solids. Since multiple-hearth plants are not generally designed for fertilizer production, only a small amount was produced on a casual basis.

A total of 651,869 tons of filter cake equivalent to 155,155 tons of dry solids was disposed of by drying and incineration in the United States during 1940. These data do not include the fertilizer production from rotary drier plants. Operations at Milwaukee, Wis., will make an impressive addition to this total. The production at Pasadena, Calif., Toledo, Ohio, Dayton, Ohio, and Grand Rapids, Mich., to mention only a few of the others, will undoubtedly swell the total dry-solids production to more than 200,000 tons.

At first glance one may well ask the question, "Is not this system unnecessarily complicated?" Taking into consideration the necessary functions will show that this is not the case.

First of all, "What is the problem?" The problem is to start with dewatered sludge ranging from 60% to 90% initial moisture, evaporate this moisture, burn the dry solids remaining, remove the odors and fly ash from the gases discharged to atmosphere, and pump the total ash to fill. The final products are then odor and dust-free gases and a sterile ash.

When only fertilizer is being produced, the problem is somewhat simplified. The problem then is to begin with dewatered sludge, evaporate the moisture, remove the odors from the gases discharged to the atmosphere, and transport the fertilizer to storage. The final products in this case are odorless gases and a valuable fertilizer. Thus in producing fertilizer the problem of ash disposal is eliminated. For large operations, such as at the West-Southwest works in Chicago, this is an important factor, since dry sludge normally contains at least 50% ash. Thus, when 300 tons of dry solids are incinerated per day, 150 tons of ash remain for disposal. This ash is quite abrasive, and the maintenance of a large ash handling system is no small item.

Each installation requires individual study, and economic considerations should govern the decision. When there is a question regarding fertilizer production, the better solution is to select a system which can produce fertilizer or incinerate with equal efficiency and without reduction in capacity.

---

[2] Chf. Engr., Drying and Incineration Dept., Raymond Pulverizer Div., Combustion Eng. Co., Chicago, Ill.

The value of the finished fertilizer will depend upon the origin and treatment of the sludge. Activated sludge, as produced at Chicago and Milwaukee, contains 6% nitrogen, whereas digested sludge contains about 2.5% nitrogen. This is not the entire story, since dry sludge fertilizer is a complicated compound; aside from being an excellent soil conditioner, it has numerous positive fertility values. The Research Department of the Chicago Sanitary District, through an extensive test program, has proved that its flash-drying system completely destroys all pathogenic organisms in the sludge. Thus it is a safe fertilizer.

To combine the functions of steam power generation with sludge drying and incineration is fully justified for large operations such as at the Southwest works. For smaller operations, the combination becomes less attractive, particularly when power is available at reasonable rates. The operation of the equipment is essentially automatic and does not require constant attention. For example, in one plant serving an equivalent population of 100,000, one operator supervises both the vacuum filters and the incinerator with entire satisfaction. This is possible in a properly designed plant when the filters and incinerator have a common operating floor.

This paper mentions abrasion at several points in the flash-drying system. Abrasive action at the points indicated is unavoidable. Experience at the Southwest works and all other plants indicates that maintenance costs from this source are very nominal, especially when related to the dry-solids production of the plant. For example, a set of mixer paddles will last from one year to three years, a steel cyclone lining from one year to five years, and a set of cage bars in the flash drier from one year to three years. These wide variations in life show the effect of silica content of the sludge. Obviously, it is desirable to remove all the silica in grit chambers.

Mr. Johnson has stressed the problems of the operating staff. This is perfectly natural for a front-line officer. To obtain the true perspective, it is necessary to balance results against costs and operating difficulties. The results speak for themselves at the West-Southwest works. Taking into account the fact that this is the largest sewage treatment and disposal plant in the world, together with the fact that this is the first time steam power generation has been combined with sludge drying and incineration, the accomplishments reported in this paper are amazingly good.

PAUL HANSEN,[3] M. AM. SOC. C. E.—To the extent that it details the problems resulting from sludge drying and incineration, this paper is of exceptional value. Such papers as this lead to a better understanding of sludge disposal by burning, and aid greatly in advancing current practice.

An installation whereby sludge, whether raw or digested, from the activated sludge process or from sedimentation only can be handled for the production of salable fertilizer, for steam production, and for the destruction of the sludge at high temperatures represents an almost ideal solution of the sludge problem, provided it can be done reliably and economically.

---

[3] (Greeley & Hansen), Chicago, Ill. (Mr. Hansen died February 6, 1944.)

The Chicago Sanitary District has been a pioneer in this field and has developed the process to a point of practicability and reasonable economy. On the other hand, many minor difficulties are still unsolved as suggested by the author. This is but natural, when the complex character of sewage sludge, and especially raw sewage sludge, is considered. Moreover, sewage sludges vary in different installations. In some cases, as at Chicago and a number of other cities in the Middle West, sewage contains large quantities of packing-house wastes introducing the grease problem. In other places, paper-mill wastes influence the character of the sludge. However, paper-mill wastes retard digestion because of their carbonaceous character; but they facilitate heat disposal. Some plants providing partial treatment by sedimentation and partial digestion, as at Buffalo, N. Y., produce a sludge low in fertilizer and heat value. Thus, the sludge varies greatly in its adaptability to incineration and in its value as a fuel and as a fertilizer.

There is also an interrelation, both economic and functional, between heat destruction of sludge, on the one hand, and prior treatment by storage and digestion, on the other. This relationship has not been exploited completely. At Buffalo, a cost analysis of three projects, comprising (1) incineration of raw sludge, (2) incineration of stored sludge (partly digested), and (3) incineration of fully digested sludge, indicated an economic preference for No. (2).

The experiences at Buffalo parallel somewhat the experiences at Chicago. At Buffalo, the cages in the flash driers wore considerably in the beginning. It is clear that the replacement of the bars in the cages must be considered as a regular maintenance problem. The labor and cost involved, however, have been substantially reduced by the utilization of sleeves of especially hard metal that would slip over the bars.

Another difficulty encountered was the wearing of bends in the piping of the ash handling and dry sludge feeding systems. Here again is another element that requires regular maintenance. Difficulties have been overcome by the use of a steam ejector, instead of a vacuum pump, with longer bends and couplings that can be taken apart readily, and with concrete jackets at the bends. Wear in the cyclones was encountered, as at Chicago, and this has been remedied by the use of renewable cement linings.

In a broad sense, the process of sludge handling by incineration, with provision for diverting the material of fertilizing value and with provision for utilizing heat, is in about the same status as the automobile was in the early years of its general use. It works, but it requires considerable tinkering with every hundred miles or so. Little by little the defects and limitations have been revealed and overcome. Today the automobile is reliable for thousands of miles and requires no more attention than systematic oiling and greasing. In the field of sludge incineration, it may now confidently be expected that the minor problems will be overcome and that longer life and more reliable service will result.

LANGDON PEARSE,[4] M. AM. SOC. C. E.—Sludge-drying development at Chicago has been presented briefly by Mr. Johnson. The West Side (Imhoff tank) plant provides a sludge digestion volume of 10,532,000 cu ft. It was expected to accommodate both the sedimentation sludge from the West Side and the excess activated sludge from the North Side. This proved inadequate, because the excess activated sludge would not concentrate within reasonable limits.

The sludge-drying beds were provided for the West Side only, with the expectation of immediate enlargement. The sludge stripping machines are unique.[5] The Sanitary District owns and operates four large and two small locomotives and forty-one side-opening dump cars for moving the air-dried sludge to a dump some 3 miles away. By moving the sludge in a wetter condition than heretofore, the output of the drying beds has been increased materially.

The Southwest works was left unfinished in 1939 because of lack of money. Two years later, when bonding power became available, construction was stopped because of the war.

The most recent data on the plant loading and over-all performance of each plant are given in Tables 4(*a*) and 4(*b*). The suspended solids record for the four plants was as shown in Table 4(*c*). At the West Side works, the record of dried sludge and scum removed from the drying beds was as given in Table 5(*a*).

In the operation of the Southwest works, certain changes have occurred. In the vacuum filters, plastic pipe is replacing the metal pipe in the pipe drainage system. The wire mesh underdrainage supporting the filter cloth is now replaced by a wooden drainage grid. The winding wire is being discarded for a system of crimping the cloth in grooves with locking splines.

Lately, the filter cake has been ranging from 83% to 86% moisture. This is fairly representative for past seasons at Milwaukee, Wis. Fly ash is disposed of in lagoons near the plant. It lacks commercial value.

Recently the grease collected from the preliminary tanks at the Southwest works was sold for 0.55¢ per lb, f.o.b. trucks at the works. The output is estimated from 5,000 to 20,000 lb of scum per day, with an average of 14,000 lb. This contains approximately 50% grease, of which 15% is unsaponifiable. The heat-dried activated sludge has been sold in bulk under a five-year contract to an exclusive purchaser, on an analysis basis. The average results are given in Table 5(*b*).

When sludge is sold as fertilizer, there is an additional expense to the Sanitary District for fuel and incidental charges, which reduces the gross receipts. At the Calumet works in 1941 this cost slightly exceeded the receipts. In 1943 the receipts will be somewhat greater than in 1942.

To take care of the large sludge load at the West-Southwest works, the Sanitary District has completed a 16-in. sludge pipe line, 4⅔ miles long, to discharge excess activated sludge for the duration of the war into 78 acres of lagoons, 16 ft deep, divided into 16 units. This will provide about 45,700,000 cu ft of storage. Sludge will be seeded with digested sludge from the West Side Imhoff tanks. The heat-drying plant will be operated to capacity. Any excess sludge will go to the lagoons. With the new blower just completed and with rehabilitated air-diffuser plates, the treatment of 300 mgd of sewage by activated sludge should be reached next spring at the Southwest works.

---

[5] *Engineering News-Record*, January 21, 1932, pp. 82–85.

Among the problems of the sewage works designer and operator is the tuning up of the works. The varied works of the Sanitary District have shown a marked difference. The West Side works went into service with but little difficulty. The North Side works also began operating smoothly, and continued with the least operating problems of any of the activated sludge works of the Sanitary District. This is due in part to the transfer of the sludge disposal to the Southwest-West Side works and in part to the character of the sewage.

The Calumet works was used as a pilot plant for the Southwest works in so far as dewatering, heat drying, and incineration were concerned. Various changes were made over a period of some three years before a complete working plant resulted. Industrial wastes presented other difficulties. The removal of waste-iron pickling liquor from the system greatly reduced the clogging of air diffusers.

The Southwest works began operation in May, 1939, as a partly completed plant. It remains such today. It is unable to give activated sludge treatment to the entire flow because of lack of air compressors. Further, it lacks adequate sludge-handling equipment. The diffusers have now become clogged to a degree requiring replacement in 1944. The air-cleaning devices need rehabilitation. Suitable grit chambers are required, as none were originally provided. The designers were handicapped by lack of funds. When funds became available, war conditions stopped construction. The operating force has done its best to cope with the difficulties of operating under war conditions.

[f] Entire Sanitary District. [g] Including miscellaneous plants and corn products waste.

Those interested can follow the various problems in the Annual Budget Report of the Chief Engineer of The Sanitary District of Chicago for 1940–1943, inclusive. The period of tuning up and rehabilitation of the Southwest works apparently will continue until several years after the end of the war. Meanwhile, the plans for completion of the West-Southwest works are in process.

This discussion is intended to add certain phases of the sludge-handling developments, which Mr. Johnson has omitted, to complete the picture of the sewage treatment problem at Chicago and the relation of the sludge handling to it. The recent developments are noted in the sale of scum, in construction of lagoons and pipe line, and in disposal of fly ash, as well as in the difficulties in tuning up and operating an incomplete Southwest works under war conditions.

LLOYD M. JOHNSON,[6] ESQ.—Mr. Gordon has properly indicated that the problem of ash handling and disposal is minimized when fertilizer is produced. There is a further benefit at the Chicago Southwest plant in that the slag formation on the wall and roof tubes in the furnaces is held at a minimum. In burning a material like sludge with a high percentage of ash (compared with coal), the amount of slag is an important operating factor.

Although, essentially, operation appears automatic in a plant combining steam generation and sludge disposal, the need for properly trained and competent operators cannot be overstressed. The balancing of the various elements introduced in this combination results in a more delicate plant to operate than a straight steam generation plant.

---

[6] Commissioner of Streets and Electricity, City of Chicago, Chicago, Ill.

Mr. Hansen notes the economy of handling partly digested sludge, where the treatment is sedimentation alone. Sludge from such a plant has a limited market as fertilizer, except in wartime, whereas with activated sludge treatment the economics may be different. The possibility of recovery of sludge gas for development of power is important.

Mr. Pearse has added data on procedures and operating results. In addition, the recent sale of grease-containing scum from a pumping station tributary to the Southwest works proves worth while at least during these times. Under a 2-yr contract, the Sanitary District receives 1.10 ¢ per lb for the scum at point of skimming. The contractor furnishes all labor for skimming and loading.

DEVELOPMENT OF THE CHICAGO TYPE BASCULE BRIDGE

By Donald N. Becker,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Alonzo J. Hammond, Clinton D. Hanover, Jr., Armour T. Granger, C. B. McCullough, and Donald N. Becker.

Synopsis

On the background of a description of the waterway system that serves the navigation needs of Chicago, Ill., the author describes the development of a bridge type that serves the peculiar local requirements. The evolution of the movable type of bridge is traced through several phases, including the early "jackknife," the vertical lift, the rolling lift, and, finally, the various developments of the bascule type.

Introduction

The Chicago River (see Fig. 1) lies along the north side of the central business district, branching just west of it, with the North Branch traversing the north side of the city in a more or less northwesterly direction and the south branch traversing the south side in a southwesterly direction. In the extreme south end of the city is the Calumet River system. In Fig. 1, the various bridges mentioned herein are given numbers that are identified as follows: 1. West Cortland Street (Clybourn Place); 2. West Division Street (River); 3. West North Avenue; 4. North Halsted Street (Canal); 5. West Kinzie Street; 6. West Washington Street; 7. West Grand Avenue (Indiana Street); 8. East 92d Street; 9. West 35th Street; 10. West Chicago Avenue; 11. West Webster Avenue; 12. West Belmont Avenue; 13. West Monroe Street; 14. North Franklin-Orleans Street; 15. West Adams Street; 16. East 106th Street; 17. West Roosevelt Road (Twelfth Street); 18. North Damen Avenue (North Robey Street); 19. South Damen Avenue (South Robey Street); 20. North Wabash Avenue; 21. West Ogden Avenue (Canal); 22. West Ogden Avenue (River); 23. Outer Drive (River); 24. Outer Drive (Canal); 25. South Ashland Avenue; 26. North State Street; 27. Weed Street Crossing of Chicago River; 28. Canal Street Crossing of Chicago River; 29. South Halsted Crossing of

System, Chicago, Ill.

Chicago River; 30. Van Buren Street Bridge; 31. Metropolitan Elevated Railroad Bridge; 32. North Halsted Street crossing of North Branch; 33. La Salle Street Tunnel; 34. Washington Street Tunnel; 35. Clark Street Bridge; 36. Wells Street Bridge; 37. East 95th Street and Calumet River; 38. West Division Street and North Branch Canal; 40. North Western Avenue and North Branch; 41. West Archer Avenue and South Fork of South Branch; 42. West Erie Street and North Branch; 43. West Lake Street; 44. Lake Street Elevated Railway; 45. West Lake Street and Elevated Railway; 46. Dearborn Street Subway System; 47. Northwestern Elevated Railway; 48. Michigan Avenue; 49. West Jackson Boulevard and South Branch; 50. East 100th Street and Calumet River; 51. Madison Street; and 52. South Torrence Avenue and Calumet River.

Before civilization reached Chicago these rivers were relatively shallow streams, navigable only in the sense that canoes and shallow draft vessels could enter them from Lake Michigan. With the development of the city, both of these rivers were deepened and widened so that they are navigable for considerable distances for the largest lake-going vessels. They are generally equipped with dockwalls providing channels varying in width from 100 ft to 250 ft.

When the early settlers traveling overland first reached the Chicago River, they established ferries, but these soon proved inadequate for the traffic, and as early as 1833 a crude float bridge, manipulated by cables, was installed. In 1834, a wooden drawbridge similar to a double moat-bridge was built across the river, only to be torn down five years later because it was an obstruction to navigation.

By 1840, however, the land traffic was so heavy that another bridge was built over the river. This time it was a pontoon type that could be pulled open when needed for river traffic. Several of this type were built in the next few years. In 1854, the first pivot swing bridge with wooden trusses was built across the river; and in 1856 the first all-iron bridge was built. By the time of the great Chicago fire (1871), there were twenty-seven movable bridges costing well over a half million dollars. The great fire destroyed eight of these. By 1890, the number of bridges had increased to forty eight, some through the annexation of adjacent towns to the city.

During this period many disadvantages of the swing-type bridge presented themselves, so that thought was directed to the new types that were being developed in the minds of embryo inventors. In 1890 a so-called "jackknife" bridge, built under patents issued to Capt. W. Harmon, was installed at Weed Street, the action of each half of the bridge resembling that of a loosely-hinged jackknife as it lowered from the vertical position. It was expected that, if experience showed that this type of bridge could be operated safely and economically, it would be preferable in most cases to the swing bridge. It was also thought that the raised floor, in the open position, would solve the street barrier problem.

In 1892 so much objection was raised to the swing bridge, built only two years previously at Canal Street at a bend in the river, that it was ordered removed and was replaced at a cost of $46,844.90 with a Harmon-type of jackknife bridge (Fig. 2) providing an 80-ft draw. From the beginning it was troublesome due to light construction and poor execution.

FIG. 2.—SOUTH CANAL STREET FOLDING BRIDGE OVER THE SOUTH BRANCH OF THE CHICAGO RIVER, 1892

In 1892 when it became necessary to replace the old swing bridge at South Halsted Street, the navigation interests and the Drainage Board (later The Sanitary District of Chicago) objected so effectively that the War Department refused to issue a permit for a swing bridge. After considering the Harmon jackknife and the Waddell lift bridge, the city decided in favor of the latter, which was completed and opened to traffic on March 22, 1894 (see Fig. 3). It consisted of a steel truss span, 130 ft long by 58 ft wide, with a single roadway 40 ft wide and two sidewalks 8 ft wide. Its weight (280 tons) was lifted vertically between two towers that were braced by a truss between the top of the towers at a height of 155 ft above the river level. The lift span was suspended by wire ropes that passed over sheaves at the tops of the towers and were connected to cast-iron counterweights within the towers. The bridge was operated by steam hoisting machinery located on top of the lift span at its center, which operated cables attached to the tops and bottoms of the towers. The total cost of the bridge was $242,880.

In 1894, when it was necessary to replace the Van Buren Street bridge, and the Metropolitan Elevated Railroad Company wished to build a bridge across the river a short distance north of it, conditions being such as to prohibit the use of swing bridges, a new type was adopted (see Fig. 4) for both locations. This bridge was hailed as the embodiment of an eleventh century idea brought up to date, as the combination of the bascule (which was the most common type of medieval moat bridge) and the latest electric and pneumatic appliances. It was equipped with air brakes and two 50-hp electric motors on each leaf. It cost $169,700.

In 1895 this gave the city three highly different types of bridges for comparison, the Harmon "jackknife," the Waddell "vertical lift," and the Scherzer "rolling lift." In 1896 a second Scherzer bridge was built at North Halsted Street over the North Branch.

From the Annual Report of the Department of Public Works of the City of Chicago for 1898 the following is quoted to indicate the conditions then:

> "There is no portion of the City's service that is in such need of immediate attention as the bridges and viaducts of the City, and it is to be regretted that appropriations of sufficient amount cannot be secured to make proper and necessary repairs. Many of the structures are old and dilapidated and have reached that stage of decay where wise expenditure of money cannot be made to repair them, and they should be replaced by new structures. All the bridges to be constructed hereafter should be constructed on such a plan that center piers will not be necessary. The practice of placing obstructions of any character in the Chicago River should be discontinued, with a view to accommodate navigation and to conform to the policy of the statutes governing the construction of the Sanitary Drainage Canal. While the importance of the Chicago River appears to be appreciated by the citizens in the discussion of the development of Chicago, no practical steps have been taken by the City to preserve it as a harbor for modern vessels. A reference to the tables submitted by the City Engineer in his report must convince anyone that the greater facilities offered in the Calumet River are diverting a large portion of the business from the Chicago River, and while the Calumet interest should be con-

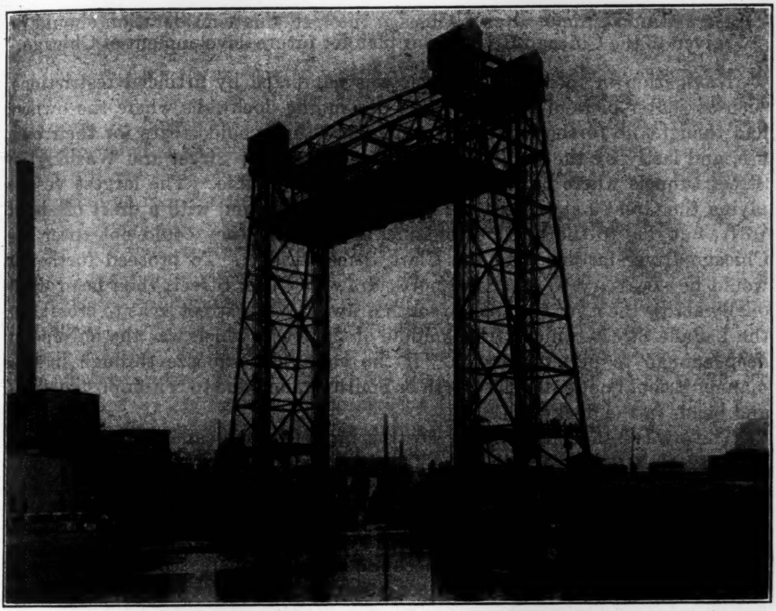

FIG. 3.—SOUTH HALSTED STREET BRIDGE, FACING NORTHEAST ACROSS THE CHICAGO RIVER, 1894

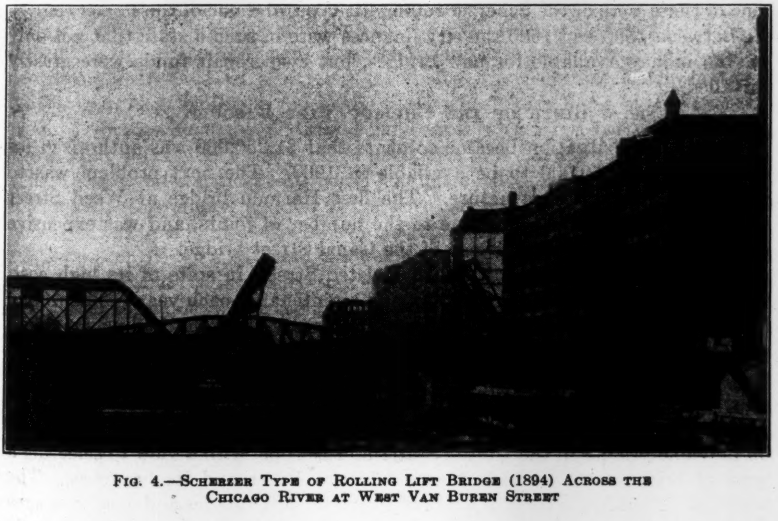

FIG. 4.—SCHERZER TYPE OF ROLLING LIFT BRIDGE (1894) ACROSS THE CHICAGO RIVER AT WEST VAN BUREN STREET

served and promoted as a Chicago interest, due consideration should be given to the Chicago River in our plan for future development of Chicago."

Navigation in the Chicago River was hampered by artificial restrictions, such as center piers of swing bridges, protruding dockwalls where the owners had thought no further than how much land they could create for their own use, and lastly by the shallow clearance over La Salle Street and Washington Street tunnels where only 17 ft of water was available. The largest vessels plying the Great Lakes were 432 ft long by 48 ft beam, with a draft of about 16 ft; but due to the tortuous channel in the river they could not enter the Chicago River farther than the Clark Street bridge. To proceed further it would be necessary to enter the north draw at Clark Street, then head diagonally across the river toward the south draw at Wells Street so as to cross over the LaSalle Street tunnel at the middle of the river, which was the only point deep enough to permit passage. If the vessel did squeeze through in this manner it could not enter the North or South Branch due to center obstructions and bends in the dockwalls.

The law creating the Sanitary District provided for a canal with a discharge capacity of 10,000 cu ft per sec. The District embarked on a policy of constructing a 200-ft channel in the South Branch with a center depth of 26 ft and a cross section of 4,800 sq ft so as to limit the current to about 1¼ miles per hr. Property was condemned and the docks were moved back. As the city was in no position to replace bridges to accommodate this increased flow, especially where bridges were in fair to good condition, an agreement was made whereby the District would rebuild certain structures and turn them over to the city. Under this arrangement ten bridges were completed between 1902 and 1907—nine of these were of the Scherzer rolling lift type, and one of the Page type.

Between 1896 and 1900 the city finances were in such a state that not only was no money available for new bridges, but even repair funds were greatly curtailed.

Birth of the Chicago Type Bascule

In 1900 the situation became so acute that $1,250,000 was authorized for eight bridges, $850,000 to be available in 1900. The next problem was to determine the type of structure. The first Harmon bridge at Weed Street was continually out of order, due to the number of joints, and was expensive to maintain. This was true also of the Canal Street bridge.

The vertical lift bridge at South Halsted Street, in spite of its high cost, was proving quite costly in operation and maintenance each year. The rolling lift bridge, although admittedly more satisfactory than the folding jackknife and the vertical lift bridge, had the very important disadvantage that the center of gravity traveled back and forth as the bridge opened and closed, thus requiring a solid foundation.

In 1899 the city's Bridge Division made a critical analysis of the literature on movable bridges in the United States and Europe, with a view to selecting a type of bridge most suitable to the Chicago River and its branches. The results were put in the form of a report giving the advantages and disadvantages of the various movable types in use. The type known as the trunnion bascule was considered to be the one that could meet Chicago requirements most fully and satisfactorily.

Three designs were prepared by the city, differing in appearance, method of mounting, etc., but all involving the principle of revolving on a fixed trunnion. The three designs were then submitted to a Board of Consulting Engineers, consisting of E. L. Cooley, the late Ralph Modjeski, M. Am. Soc. C. E., and the late Byron B. Carter. The Board selected and recommended the design designated as No. 3 with some modifications.

The design was described in the 1900 report of the Department of Public Works as a fixed-center, double-leaf, counterbalanced bascule bridge. Each leaf had three through trusses operated by racks on their curved tail ends, the tail ends descending into a pocket or tail pit in the abutments when the bridge was open. The total width of the structure was 60 ft, the trusses being 21 ft, center to center, and the sidewalks being carried by 9-ft cantilever brackets. The pivot bearings were 4 ft back from the center lines of the river piers and were carried by box girders spanning the tail pits in the abutments. The approaches were carried by I-beams, supported by cross girders resting on the box girders and extending from the river piers to concrete abutments independent of the abutments of the moving span. The bridge was designed to turn through a maximum angle of 76° 58′, which required a travel of 35 ft on the pitch line of the rack. The break in the roadway was on the river side of the pivot.

The machinery for operating each leaf was under the approach roadway, each leaf being operated by means of a pinion gearing with a rack on the curved tail end of each truss. The teeth on this rack had openings between them, preventing the clogging of the rack by dirt or ice. The teeth of the operating pinion dislodged any accumulation that would then fall through the rack. Along the top of the abutment a shaft carried three pinions and had two sets of driving gear, each set of driving gear being driven by an electric motor of 38 hp. On each motor-driven shaft was a wheel for a band brake, operated from the bridge house by a vertical hand lever with a latch handle. Besides these hand brakes there was a worm-resistance brake at the middle of the rack pinion shaft and a hand-brake wheel was fastened to the shafts of the worm. To prevent resistance or friction in the worm brake when not needed, the worm was revolved by a light continuous hemp rope that passed over grooved pulleys on the motor-driven shafts and the worm shaft. The band brake was applied to the worm shaft to introduce the resistance, thus checking the motion of the worm and consequently of the gearing by which it was connected to the main shaft.

The machinery was designed so that the opening of the bridge, from the moment it was closed to traffic to the moment when the leaves reached their highest position, would not require more than 1 min in calm weather or 2½ min with a 70-mile wind blowing in a direction unfavorable to the operation of the bridge. Pneumatic buffers arrested the motion of the leaf at each end of its travel.

When the bridge was closed, the center of gravity of each leaf was on the river side of the pivot, and as the movable part of the roadway did not extend back of the pivot it was only necessary to lock the leaf against further downward movement. This was done in connection with the bridge-closing buffers, by allowing the leaf to pull the lower buffer pistons against the cylinder ends, the cylinders being anchored to the masonry.

When the bridge was closed, the action of the buffer was as follows: As the leaf approached the end of its closing movement, a hooked lug at the lower end of the arched back of each truss picked up a 6½-in. pin, connected by eyebars to a combined cross head and piston. This pin forced the piston upward in an inverted cylinder, meeting the increasing resistance of the compressing air, which absorbed the energy of the closing leaf. When the pressure reached 350 lb per sq in., the air escaped through a relief valve and allowed the piston to rest against the cylinder head above it.

As the leaf began to open, a second lug near the aforementioned hooked lug returned the buffer and connections, by means of a hooked lever, to position in readiness for closing.

The action of the upper buffer in arresting the leaf at the end of the opening movement was similar to that of the lower buffer, the difference being that the upper buffer was operated through an intermediate lever pivoted to special pairs of stringers of the approach roadway, which stringers also supported the upper buffer cylinders. The rear end of the lever acted on the piston through a short link. The front end of the lever was operated in essentially the same manner as the pin of the lower buffer, by lugs in the upper end of the arched back of each truss.

Quoting from the Report of the Board of Consultants:

> "The principle of the trunnion bearing meets with our approval as a very simple solution of the problem, the chief advantages being the constant point and direction of application of the load on the foundation, whether the bridge is in motion or stationary, and the reduction of the number of moving parts to the minimum. The first advantage is of no great consequence if the piers are placed on an unyielding foundation, but with such foundations as can be obtained in Chicago at the majority of bridge sites, it is of great importance. The trunnion type of bridge used in these designs is an old and tried device, and is not covered by patents."

The consulting engineers called attention to the fact that the bascule design permits the center of gravity of the moving bridge to be placed in or near the trunnion axis. Placing the center of gravity a short distance from the axis of the trunnion toward the draw opening and the arrangement by which the fixed floor relieves the tail end from any possible live load, had the advantage of tending to hold the bascule firmly in position when closed, and so avoided the absolute necessity for heel locks. There was no tilting effect when a live load came on to the bridge.

The Board recommended a three-truss design, as had been prepared by the city, in preference to a two-truss design for the same width of floor, that the curved bottom lateral struts be omitted and a stiff lateral system used. Also, it was recommended that, when the bridge was raised, the floor beams be supported by angles running from the middle of each floor beam to the intersection of the lateral angles, and that the heel ends of the trusses be connected by a transverse brace, to add lateral stiffness to the racks and the counterweights.

The Consulting Board further recommended that adjustable resting blocks be placed in front of, and near, the trunnions so that when the draw was being closed, the load could be transferred from the trunnions to the resting blocks. This facilitated the lubrication and practically eliminated the starting friction of the trunnions. To meet all possible conditions of wind and incidental changes in the position of the center of gravity, pawls or heel locks were used with the resting blocks. They were capable of lifting the tail ends and holding them firmly against the anchorage. This arrangement was also claimed to facilitate the overhauling and adjustment of the trunnion bearings.

Air buffers were considered practical, provided they could be designed so that the pistons would not withdraw from the cylinders, and provided they were packed with cupped leather or other material, to prevent entrance of foreign matter or grit into the cylinders. Air was controlled in the cylinders by free entrance through check valves, and by allowing exit through adjustable openings, for buffing. Springs insured proper action of the pistons. Exceedingly strong racks on the heel of the draw, with through openings between the rack cogs, met with approval as they will not accumulate ice in cold weather. On those rare occasions when sleet may coat the racks with ice, it was considered that the shaft and pinions were strong enough to force the ice through the cog openings.

There was no practical difficulty in making the driving machinery strong enough to resist all probable strains, and, therefore, the engineers recommended the following general arrangement: The three pinions are mounted on one line of shafting, with specially strong bearings, being driven by two gears; these two gears are connected by a jackshaft and suitable pinions, with two gears mounted, and clutch-driven, on this jackshaft. The jackshaft gears are driven by two independent gearing trains to two motors. All these gears, shafts, and motors are arranged in a vertical or inclined train, so proportioned that all gears are between their respective shaft bearings, which were to have ample length and all were to be mounted, as far as possible, on one structure. The gearing could easily be made stronger and safer and more accessible for overhauling and repairs than that of any bridge then built in the city.

The worm-gear brake for emergency use had novel merits compared with the usual band brake on the motor shaft. If designed with large pitch and large angle of worm, running in an oil bath, the friction of the gears running light may not be large. By the ingenious application of a light rope belt (to revolve the worm), the friction due to the thrust of the worm was practically eliminated until the brake was applied. In the detail design, the desirability of friction brakes applied directly to the curved segments of the trusses can be developed. Finally, quoting the Report:

> "It is fair to state that the assumed wind loads against opening or closing the bridge may never prevail in the practical handling of the bridge, and may be regarded as so much additional security. The fact is that ships do not navigate when such winds prevail, and there would be

> no occasion to open the draw at such times. In the case of the Tower Bridge (London), the reserve power put in on account of extra wind loads was reported as 'never used' at the end of two years.
>
> "In general, our board is of the opinion that the flow of the river should be provided in the opening of the draw wherever practicable."

In the light of forty years of experience, the recommendations of this Board were almost prophetic, as so many of their recommendations have been adopted with the passage of years.

Early Examples of the Chicago Type

Meanwhile, the 95th Street swing bridge, over the Calumet River, had collapsed on August 17, 1899. This location was used as the site for a new bridge, the call for competitive bids to be opened on May 15, 1900. A similar call for bids was advertised to be opened on June 1, 1900, for a bridge at Division Street over the North Branch Canal.

The specifications were drawn very broad for the purpose of giving competitors as wide a scope as possible in their designs and selection of a new type of bridge. The only restrictions in regard to type were in both cases:

> "The bridge shall be a movable structure without center pier and shall leave a channel with a clear opening of 120 ft. at 95th Street and 80 ft. at Division Street. The bridge shall have two roadways 18 ft. in the clear, or one roadway 38 ft. in the clear between the wheel guards and two sidewalks 8 ft. in the clear, and shall have an overhead clearance of 16 ft. There must be an underbridge clearance of 16½ ft. above Chicago Datum for a space of at least 40 ft. at right angles to the center of the channel. The general appearance of the bridge shall be as graceful and attractive as the nature of the structure will permit."

Five designs were submitted by outside bidders, some of these bidders having two or more alternate designs differing in matters of detail. With one exception, the designs were for bridges revolving on fixed bearings.[2] The contract was awarded to a bidder following one of the city's designs.

Contracts for both 95th Street and Division Street bridges were awarded so that work was started in July, 1900. Meanwhile the city's design No. 3 was modified and arranged for a bridge at Clybourn Place (later Cortland Street) over the North Branch and contracts were awarded in the late fall. These plans embodied many of the alterations suggested by the Board of Consulting Engineers, especially, the use of a full tail pit instead of separate wells for each truss. Due to construction difficulties at both 95th Street and Division Street, the Clybourn Place bridge (Fig. 5) was completed first and opened to traffic on May 24, 1902; the 95th Street bridge was not opened to traffic until April 1, 1903; and the Division Street bridge on February 1, 1903. In the construction of the 95th Street and Division Street bridges, the bottom of the abutment was lowered to the elevation of the river piers but the separate pockets for the counterweight ends of the trusses were retained. These were made of sheet steel covered on the outside with concrete and have been a frequent cause of repairs. The machinery was set on structural supports, and it has been difficult

FIG. 6.—WEST DIVISION STREET CANAL CROSSING (1903)

to maintain alinement. Changes were also made within a year after completion of the bridges, in the braking system to make it more effective. Fig. 6 shows the Division Street bridge.

One of the earlier types of bridges was eliminated from further consideration when the Canal Street jackknife bridge was replaced by a Scherzer bridge in 1903, and the Weed Street bridge was finally removed in 1905 after having been out of service for several years. However, in 1903 a new type appeared with the completion of a Page bascule bridge at South Ashland Avenue.

In 1904 a new method of financing the construction of bridges was devised when the State Supreme Court ruled in favor of a bond issue for this purpose.

By the end of 1904 the city had five bridges of its design in use with further improvements in the last two, one at Division Street (Fig. 7) and one at North Western Avenue, both over the North Branch. In both of the two later bridges, instead of using shaped iron castings bolted to the trusses for counterweight as was done in the first three bridges, a structural box was framed between the tail ends of the trusses. These tail ends were sloped downward back of the trunnions, whose supports were changed to tapering box girders sloping upward at the back so as to pass over the counterweight box. The box was filled with the counterweights consisting of about 22% shaped castings and the remainder a mixture of pig iron, punchings, and cement grout to produce a material weighing about 375 lb per cu ft. The bottom of this box was floored with a grillage of old rails to carry the weight of the extremely heavy counterweight material to the main girders. There were many advantages in this type of construction. First, it allowed the center of gravity of the counterweight to be placed farther back from the trunnion, thus saving material. Second, it eliminated the necessity for the specially shaped castings with their greater unit cost. Third, the counterweight material did not have to be bolted piece by piece to the trusses with the danger, later, of dropping if bolts rusted away.

Four of these bridges were on pile foundations, but, at North Western Avenue bridge, piles could not be driven below −22 ft Chicago Datum because of a very hard indurated clay, which could safely sustain a load of 4,000 lb per sq ft. Accordingly, piles were omitted and the masonry rested directly on the soil. This bridge also had the tail pits especially waterproofed with a 4-in. layer of Portland cement mortar on both the inside and outside walls below water level. A distinct improvement in the machinery consisted of taking the motors from the two gear trains and combining them in a unit in back of the center trusses. Two sets of hand brakes were operated by hand levers in the operator's room. Also the pneumatic buffers at each end of the travel were eliminated and wooden bumper blocks were placed on the under side of the trunnion girder with which the top of the counterweight box came into contact in the closed position to limit the final position of the leaf. The decelerating speed of the trusses was entirely controlled by the machinery brakes. It had been found that the pneumatic buffers were too slow in operating and the pressure relief valves were too temperamental.

In 1903 plans were prepared for a double-leaf trunnion bascule bridge at Archer Avenue, over the South Fork of the South Branch, but later the federal government issued a revised permit with the clear channel reduced from 136 ft 8 in. to 107 ft. Investigation showed that a one-arm structure would be feasible, especially if the type of machinery worked out for North Western Avenue were adopted. By increasing the radius of the pin rack from 30 ft, used in the North Western Avenue bridge, to 36 ft, it was found that the machinery would have to be only a little heavier. The leaf was placed on the west side of the river with the idea that the prevailing west or southwest winds of the navigating season would assist rather than hinder the closing of the leaf. The trunnion supports were again changed, this time to an inverted triangular truss with the apex under the trunnion. This was necessary as the load was rather large for the tapered box girder type used at North Western Avenue. The bumper for the bridge, when down, was attached to the under side of this truss and, in addition, a bumper for the bridge in the open position consisted of a rubber block 7 in. by 8 in. in section attached to the top of a bracket on the fixed part of the steel, placed so that a bumper bracket on the top chord of the trusses came into contact with it when the leaf reached the fully open position. This type of bridge proved more economical than a double leaf. The only disadvantage was the open street on one end. At this end a counterweighted barrier was installed that raised above the roadway level when the bridge leaf was raised.

FIG. 7.—WEST DIVISION STREET RIVER CROSSING (1904)

In 1909 a single-leaf bridge was built at West Kinzie Street (Fig. 8) over the North Branch that was almost identical with the Archer Avenue bridge, previously described, with some improvements in the barrier. Two more double-leaf bridges were built, one at North Avenue over the North Branch and the other at North Halsted Street over the North Branch Canal. These showed only minor variations from previous practice.

In 1910 a double-leaf bridge was built at West Erie Street (Fig. 9) over the North Branch that was radically different from previous practice. The grade of the roadway is about 6 ft higher than on the previous bridges; hence it was feasible to approximate the outline of an arch. Two trusses were used instead of three, as previously, without overhead bracing. They extend only about 10 ft above the roadway at the rear ends. Due to reduction in depth of the tail end, the rear external pin rack was no longer usable, so the bridge was operated with operating struts. These struts were connected to pins cantilevered out sidewise from the bottom chords just ahead of the counterweight box. The machinery gear trains were placed in the rear of the bridge, as before, but at the sides just back of the trusses with the main pinions engaging racks on the struts held in contact therewith by guide rollers. Each train is assembled complete, including motors, in one unit and mounted upon a unit frame to keep parts in permanent alinement. Similar to earlier bridges, the trunnion supports consist of trusses, with the difference that the truss shape now is quadrilateral rather than an inverted triangle. This change was made to accommodate the heavier loads, this bridge having only four supports per leaf rather than six as with the three truss bridges.

THE IMPROVEMENT PERIOD

Between 1908 and 1911 several bridges were designed but it was not until a bond issue was passed in the fall of 1911 that funds were made available for their construction. This gave considerable time to develop new ideas and as a result there was a distinct change with the introduction of this new group of bridges. During this period the city became increasingly conscious of the appearance of its structures and, as a result, the bridges have been given considerable study to enhance their appearance. In 1909 plans were drawn for a new bridge at West Lake Street to provide for the Lake Street Elevated Railway in addition to street traffic. A vertical lift bridge was designed but public opinion was so against its appearance that the plan was abandoned. Later in 1913 a double-deck bascule bridge was developed which will be discussed subsequently.

With this group the method of operating the bridge was changed. In 1908 Alexander von Babo, then Engineer of Bridge Design, invented the internal rack for which he filed an application for a patent on June 26, 1908, and which was issued on August 29, 1911. This patent provided for a rack in the plane of the trusses on the trunnion side of the counterweight box with the truss members arranged so that the bridge could rotate the approximately 80° required without any of the truss members fouling the pinion shaft of the gear train which drives the bridge. The radius of this rack is necessarily considerably less than that of the external pin rack used in the older bridges; but the science of machinery design and manufacture had advanced sufficiently to take care of the larger rack stresses involved.

FIG. 9.—WEST ERIE STREET (1910)

In this same patent another feature was incorporated, called the cross girder, which consisted of a member being inserted through the truss to carry the inside trunnion journals. This girder was supported in turn upon girders parallel to the trusses, spanning from the front to back piers. In later years, this feature led to a suit for infringement by a competitor who claimed this same feature was incorporated in a patent granted to him earlier than Mr. von Babo's patent. This claim of both patentees was doubtless void as a feature similar to it was incorporated in a bascule bridge over the Tiber River built near Rome, Italy.[3] This cross-girder feature is only practical with two-truss bridges, as it would be impracticable to carry the heavy reactions of a truss on a girder except near the ends. The fixed part-floor system consists of stringers, supported upon this girder, passing over the counterweight box to supports over the anchor pier, instead of being framed between floor beams carried by the longitudinal supports for the inner trunnions formerly used.

Another change was made in the counterweight by forming the box large enough so that the necessary weight could be obtained with stone concrete, or, with only slight amounts of heavier aggregates to produce the weight required to adjust the center of gravity to its proper location to balance the remainder of the bridge.

The truss outlines were made more graceful by the use of trusses of the pony type. They were only deep enough at the rear ends to provide an economical cross section for the truss members, and then they dipped gracefully toward the center of the channel. The bottom chords were also given as much arching as the required underclearances prescribed by the U. S. War Department would permit. At this time the government specified a 16.5-ft clearance above Chicago Datum (normal water level) for 85% of the clear channel from which point the lower chords could be sloped downward.

A machinery girder was placed outside of, and parallel to, the longitudinal girder supporting the cross girder, at a distance of 6.5 ft, which girder, together with the longitudinal girder, supported the machinery gear train. The gear train, in turn, was mounted on a cast-steel pedestal base. These girders also transmit the couple of the wind and operating moments to the masonry at the front and rear piers. Fig. 10 shows the East 92d Street bridge.

With this group of bridges another new feature appeared in the substructure. At West Washington Street, completed in 1913, it had not been feasible to use piles to support the tail-pit boxes, due to the presence of the street railway tunnel under the river. Rectangular piers were sunk from the bottom of the piers to a point well below the tunnel where they rested on a hard clay stratum at El. −57.0 (Chicago Datum), capable of carrying a greater unit load than at higher levels. At the West Chicago Avenue bridge (completed in 1914, see Fig. 11), cylindrical piers were sunk to El. −82.0, where they were founded on rock. The spacing was sufficient to permit a future double-track subway tube to pass between them. Reinforcing trusses then had to be placed in the front and rear walls of the tail pit to carry the weight.

Following the bond issue of 1911, six bridges were placed under contract in rapid succession—five of the new double-leaf bascule type and one, a single-

leaf bascule at West 35th Street, which was a duplicate of the Archer Avenue and Kinzie Street bridges previously described.

Of the five bascules, two—the Washington Street and Chicago Avenue bridges—had enclosures of improved appearance. In the case of the Washington Street bridge, the house was covered with sheet copper, and the Chicago Avenue bridge houses and enclosures were made of concrete, suitably ornamented. In the case of the bridges following these, extensive architectural treatment was applied to the houses and enclosures, first in concrete and later in stone or other durable materials.

FIG. 12.—WEST LAKE STREET BRIDGE (1914)

In 1913 plans were prepared for a double-deck, double-leaf bascule bridge at West Lake Street (Fig. 12) to carry the elevated railway in addition to the street. Except for the necessary through-truss outline, this bridge had most of the features of the five previous single-deck bridges, such as the cross girder, internal rack, a longitudinal support for the cross girder (a triangular truss instead of a girder), machinery girder, unit machinery frame, and counterweight box with relatively light materials. Lead slag was used instead of stone to produce a concrete weighing 165 lb per cu ft. About the only unusual feature in this case was that everything was heavier, as witnessed by the fact that the trunnion load was about double that at the East 92d Street bridge, the heaviest to that time. With these very heavy loads it was decided to rest the tail pits on cylinder piers carried to solid rock at El. −113.0 and with a clearance of 36 ft to provide for a double-track subway at some future date. Chicago's subway has since utilized this space for a single bore of the Dearborn Street subway system.

With single-deck bridges it had always been practical to have the break in floor of the deck on the river side of the trunnion so that the raised leaf provided a barrier in the street. With a double-deck bridge, this was not possible so that a rear break in the floor was necessary, which does not provide a natural barrier in the street. Accordingly, it was necessary to provide some kind of a barrier at each end of the bridge. These were not put in at once but were installed at a later date. First, there was a semi-rigid type consisting of a timber pole that could be lowered into place and which would slide up an inclined grade if struck. Later a yielding barrier of the net type was developed, which plays out against friction drums when struck.

In many of the earlier bridges street traffic was accommodated during construction with a temporary bridge, usually of the so-called pontoon type. A truss span was supported at each end upon pile supports, and a scow placed beneath and near one end. By pumping water out of the hull, the truss at this end could be raised and the span could be rotated about a pin at the other end to clear the channel for navigation. At Lake Street, however, the presence of the elevated railway made this impracticable. After attempting to detour via other streets it was decided to maintain traffic by leaving the old swing bridge in place, and to support the approaches upon shoring. The length of the movable span of the new bridge was designed so that it could be erected in the vertical position clear of the ends of the swing bridge, and, as the bridge was erected, sufficient floor system was omitted to allow the elevated trains to pass through. When the leaf was ready to lower, traffic on the elevated railway was interrupted, the old swing bridge was turned on to the center pier, and the center section was cut out. The new bridge leaves were lowered after the omitted section of floor had been placed, the decking for the elevated railway was placed, and traffic was then allowed to pass over the new bridge with only a few days of interruption. No attempt was made to maintain traffic on the lower or street level.

Due to the fact that the bridge was balanced about the trunnion for dead load and had a rear break in the roadway, it was possible for live load to pass on to the rear ends only, which might place live load on the machinery brakes. Accordingly, heel locks were installed to take whatever live-load reaction might come on to them. These consist of toggle levers between the rear pier of the tail pit and a shoe on the rear of the counterweight box that were forced in place by machinery.

In 1922 a similar bridge was completed at North Wells Street to accommodate the North-Western Elevated Railway. In this bridge the cross girder was supported directly upon a column embedded in the side-wall of the tail pit, with a sub-pier under the tail pit carrying the load down to rock at El. −117.0. This obviated the necessity of providing a heavy structural truss to distribute the heavy load to front and rear walls, the loading being 25% greater than at the Lake Street bridge.

Short girders framed into these trunnion columns spanning to the rear wall to carry the machinery gear train. These were not so heavy as formerly due to the omission of the bridge weight and the shortened span. With this bridge the machinery stresses induced by a pressure of 20 lb per sq ft on the upraised leaf were considered rather beyond practical bounds, so it was decided to scale it down to 16 lb per sq ft for the gear train, but to attach a brake directly to the tail end of the bridge trusses. This brake was to be of the pneumatic type and to consist of shoes working on a curved rail set in the masonry. After further consideration it was thought not to be very practicable, because of variable operating characteristics from moisture conditions; hence the regular machinery was left to handle extreme conditions. There has been some distress in the gear train, which has been corrected by replacing parts with higher strength steels than those originally used. Traffic maintenance during the erection of the trusses was similar to that at Lake Street, but with the added feature that the lower-deck traffic was maintained as well as the elevated traffic. The change over from the old swing bridge to the new bridge was made in 72 hr for elevated traffic, but the lower-level traffic was interrupted for about a month.

FIG. 13.—NORTH MICHIGAN AVENUE BRIDGE (1920)

In 1920 the Michigan Avenue bridge was completed (see Fig. 13). This was the most unusual bridge built up to that time. As Michigan Avenue bridge was to be the link between the boulevard system of the north and south sides of the city, it was considered that a four-lane structure would not be sufficient. Furthermore, to separate commercial traffic from boulevard traffic, it was necessary to have two levels—the upper for boulevard traffic and the lower for commercial traffic. Accordingly, it was deemed necessary to have an upper level with six lanes and a lower level with four lanes. It was decided to use four trusses spaced 27 ft, 6 ft, and 27 ft, with separated roadways on both levels for each direction of traffic. In effect, there were two bridges, side by side, connected with diaphragms, that could be cut out to permit one half to be operated while the other was put up in the air for repairs. (This contingency has not been used in 20 years, mainly because necessary repairs have been on the deck which had to be left down to work upon.) The two bridges were supported upon separate cross girders supported near the center line of the bridge on columns to the floor of the tail pits and on trunnion columns in the side-walls. Yielding barriers were provided to protect traffic at both ends on both levels.

FIG. 14.—WEST MADISON STREET BRIDGE (1922)

Machinery for this bridge consisted of two gear trains per leaf, one at each outside truss. Due to the importance of this bridge it was considered desirable to have an extra pair of motors for stand-by use if the two regular motors should fail; all four motors were grouped in a unit at the rear of the bridge with a clutch to select the pair to be used at any time.

In 1922 another novel type of bridge was completed at West Madison Street (see Fig. 14). At this location there was a clear span of 188.75 ft and, although the street grade on the west side of the river was reasonably high, it was not high enough to permit a deck type of bridge and yet leave a sufficient depth for the trusses. Accordingly, a new idea was developed, called the "railing-height truss," which means that the top of the top chord is at about the same elevation as the top of the sidewalk handrail, about 4 ft above the walk. This gives the appearance of a deck structure from adjacent streets, as the top chord cannot be seen and, by the use of wide sidewalks, the trusses do not obstruct the walkways. Incidental benefits are that vehicles out of control on the roadway cannot get on to the sidewalk to crash into the river or injure pedestrians, and pedestrians are effectively barred from "jaywalking." By the use of nickel steel for main truss members, the sections were kept within reasonable bounds. Supports for the bridge were furnished by cross girders and trunnion columns as previously described for Wells Street.

Between 1911 and the end of 1923, thirteen city-type bascule bridges were built, three double-deck double-leaf bridges, nine single-deck double-leaf bridges, and one single-deck single-leaf bridge. The Sanitary District also built one single-deck double-leaf bridge on the South Branch at West Jackson Street. The total, to this time, was twenty-four city-type bridges.

THE REFINEMENT PERIOD 1923–1941

In 1920 funds were becoming scarce, with the result that in 1923, 1924, and 1925 no more bridges were added to the list. However, between 1924 and 1930 several more bond issues were approved by the electorate and in 1926 bridge development was resumed. This period, however, did not produce the radical improvements that marked the years 1911 to 1922. In 1924, when the 100th Street bridge over the Calumet River (see Fig. 15) was proposed, it was decided to avoid all patents, even the internal rack patent held by Mr. von Babo. Mr. von Babo's patent had been used by the city without compensation because he developed it while he was a city employee, although the patent had never been assigned to the city. To overcome this complication, a rack was attached to the side of the truss instead of in the plane of the truss. Instead of the cross

FIG. 15.—EAST 100TH STREET BRIDGE (1924)

girder the inner trunnions were supported on a longitudinal **S**-shaped box girder in which the rear end of the girder passed over the counterweight box, but yet under the roadway to a support over the anchor pier. In principle this was similar to the idea used as far back as the North Western Avenue bridge completed in 1904, where a tapered box girder was used. In this new development, by using curves it was possible to deepen the section for moment under the trunnion. Near the ends where the depth is less than under the load and where only shear governed, the web plates were reinforced with additional side plates. This support was only used for the inside journals, the outer ones being supported upon short stubby cantilever girders anchored in the side-walls and set transversely across the bridge, thus simulating a cross girder with the center section passing through the trusses cut away. A change was also made in the machinery supports, the unit bed frame being now set directly upon the masonry of the side-walls, which are suitably reinforced with metal grillages embedded in the masonry and with holding-down bolts effectively anchoring the machinery into the masonry. Here another of the recommendations in the 1900 Report of the Board of Consulting Engineers was finally, and most effectively, adopted.

One of the bridges of this period, that at West Adams Street, is interesting in that local conditions on each side of the river forced a different tail-end design on the two sides of the river (see Fig. 16). This bridge is set at such a high grade that a deck bridge was feasible; but, due to the shallowness of the rear arms, an internal or side rack was not feasible, so the rack was placed outside and below the bottom chord in the plane of the member The machinery on the east side rested directly on the masonry as described in the previous paragraph, but on the west side it was impossible to use the usual pit as a by-pass through the masonry because added flow area in the river was required. Accordingly, the outer trunnion supports and the machinery rest on longitudinal girders spanning from front to rear piers, whereas the inner trunnions rest on **S**-girders. On the east side the outer trunnions rest on trunnion columns and the inner ones on **S**-girders. The counterweight arm on the west side was so short that only a shallow pit was required, because (1) the by-pass, and (2) a railroad track on the west dock did not permit extension that way. This made it necessary to reduce the volume of the counterweight box below the most desirable dimensions. To overcome this condition and to provide the weight required, concrete made with steel punchings to produce a unit weight of 275 lb per cu ft, combined with shaped iron castings, and a small amount of lead pigs were used, thus adjusting the center of gravity to produce an over-all unit weight of about 330 lb per cu ft.

When the South Halsted Street bridge (see Fig. 17) was being designed, a problem was presented because the U. S. War Department urged higher river clearances. Combined with the fact that the street passes through a subway under a railroad just south of the bridge, this requirement would have made almost prohibitive grades on the bridge approach unless the bridge grade were kept as low as possible. The grade was reduced by using three trusses and a very shallow floor system, the floor beams consisting of 30-in. Carnegie beam sections with the total depth of the deck only 3.5 ft from the roadway grade to

the underclearance. As this bridge has two three-lane roadways, it does not give the same constricted appearance as the older three-truss bridges, with only 18-ft roadways.

These same plans were used at South Ashland Avenue bridge, a mile west of the South Halsted Street bridge (1938), not on account of local conditions but in order to use plans that would fit the location and provide a job under PWA without the delay of preparation of new plans. These plans, with the shallow floor, however, had the advantage of keeping the hump in the street profile at a minimum.

FIG. 17.—SOUTH HALSTED STREET BRIDGE (1933)

The railing-height truss idea, first used for the Madison Street bridge (1922), was used again at the North Wabash Avenue bridge (1930) and the North State Street bridge (1942). However, silicon steel was used instead of nickel steel. The Wabash Avenue bridge (Fig. 18) was awarded the first prize by the American Institute of Steel Construction as the best looking bridge completed in 1930 in the class costing more than $1,000,000. This bridge has a six-lane divided roadway. The center island was used as a protection for a row of T-shaped trolley supports, thus avoiding the necessity for arches over the roadway. These T-shaped trolley arches were preferred to rather flat arches otherwise required.

The North State Street bridge (Fig. 19) is a three-truss bridge because it provides for eight lanes of traffic, and it is not feasible to design floor beams to span the width required for two additional lanes, without a further rise in grade. With such wide roadways the old danger that existed with four-lane roadways of vehicles running head on into the center trusses is not so great; at least, it is not as bad as crashing head on with traffic traveling in the opposite direction at speeds varying from 30 to 40 miles per hr. This bridge has the further innovation of roller bearings instead of phosphor-bronze bushed bearings. These bearings also have spherical ball seats so that they adjust themselves for correct alinement in case of unequal deflection of the supporting structures. This feature reduces bearing friction to a minimum.[4]

Some other new ideas are incorporated in the design of the South Canal Street bridge. The design calls for a double-leaf bridge with a four-lane roadway of the open grating type. There is a great economy in this type of floor for bascule bridges, because the saving in weight of the floor not only reduces stresses in the truss members, but effects a reduction in weight of the counterweight of two to three pounds for each pound saved in the floor weight. Frequently, due to limited space for the tail end, this slight increase in weight can only be attained by the use of heavy unit-weight material which is usually more expensive than plain concrete that could be used otherwise; such a case was described previously in relation to the Adams Street bridge. Another innovation in this bridge is the use of hydraulic motors, instead of the usual electric motors, for driving the gear train. The prime power will be electricity as in the past but the electric motors will operate at constant speed driving an oil pump. By varying the displacement of oil by this pump (which displaced oil is used to drive oil motors at the gear trains), the speed of the bridge can be controlled more effectively than with electric motors which require considerable control equipment to handle the large currents involved. In this case, a simple push-button control is all that is needed to start and stop the constant-speed electric motors.

A total of 39 city-type bridges have been constructed in Chicago. Some of these were built by governmental bodies other than the city. The two on the Outer Drive at the mouth of the Chicago River were built in 1937 by the Chicago Park District and were designed by a local firm of consulting engineers, but following, carefully, the city's practice on fundamental details. These bridges provide two four-lane roadways on the upper level, and the lower level provides for railroad tracks if future developments in this part of the city require them.[5]

As a side issue, not exactly within the province of this paper, is a note concerning the construction of the only movable bridge, not of the bascule type, constructed in Chicago in the past 25 years, at South Torrence Avenue over the Calumet River. A vertical lift type was used, at a location where the center line of the river channel forms an angle of 50° with the center line of the street. Here the U. S. War Department required a clear channel of 200 ft with a 21-ft headroom for the full channel. Hence a bascule bridge would have had to have a clear distance between masonry of about 320 ft. As this bridge is in a commercial or manufacturing district, a skewed vertical lift bridge was not considered out of place and comparative estimates indicated the latter could be built for less than half the cost of a bascule.[6]

Fig 19.—North State Street Bridge

CONCLUSION

Figs. 5 to 19 indicate the development of the Chicago type bascule bridge from the Clybourn Place and Division Street bridges, down through the years to the latest structures. Table 1 gives statistical data, which, by comparison, show the development of this type of bridge better than meager words. This type of bridge has proved highly satisfactory and has solved most of the problems existing previous to its development, as discussed in the historical part of this paper previous to 1900.

[a] Key: SD = single deck; DD = double deck; DL = double leaf; and SL = single leaf. [b] Distance, center to center of trunnions. [c] Completion deferred until after the War.

The navigation requirements can be met ideally by the proper selection of size and location of the channel, almost without limit. The requirements of street traffic are satisfied by the provision of a structure that can be operated reliably in a minimum of time and which provides a measure of protection to the traffic when open, not provided by a swing or lift bridge. Maintenance is kept at a low figure by avoiding pin-connected linkages except for the trunnions upon which the movable part rotates.

The extra cost (if any) of this type of bridge over swing or lift types has been justified by its far better appearance especially when placed in a congested section of the city. However, the development of this type of bridge has not yet reached a point of stagnation as demonstrated by the various bridges built during the so-called Refinement Period, beginning in 1923, and many more refinements can be expected in the years to come.

In the development of this bridge, exclusive credit cannot and should not be given to any one engineer as it represents a development over a period of more than 40 years during which time many engineers have had an opportunity to add their bit to what has gone before. The complexity of such a structure, involving complicated foundation design conditions, unusual structural conditions, special mechanical and electrical features and, finally, architectural details in operators' houses and enclosures, is beyond the capabilities of almost any one man. Accordingly, credit is given to each and every one ever connected with its development in proportion to his contribution.

However, most of the early development was due to the efforts of the late John Ericson, city engineer, Thomas G. Pihlfeldt, engineer of bridges for more than 40 years, until the time of his death in 1941, and Alexander von Babo, engineer of bridge design for more than 20 years, until his death in 1920.

DISCUSSION

Alonzo J. Hammond,[7] Past-President and Hon. M. Am. Soc. C. E.—A valuable contribution to the literature on movable bridges is found in this paper. It is especially fitting and appropriate as coming from a bridge engineer who for some thirty years has participated in the design of such bridges in the City of Chicago which has, no doubt, a greater number and a greater variety of these bridges than any other city in the world, due to the required navigability of its two rivers, the Chicago and Calumet.

The writer's introduction to the bridge situation in Chicago was in the spring of 1912 when he was appointed engineer of bridges and harbors, at a time when a large bond issue was available for new bridges, and it was necessary to enlarge the bridge department materially to cope with the demand for new designs and construction. It may be of interest to note that the first problem "dumped into his lap" was a determination of the best type of movable bridge to replace the old swing bridge at Lake Street over the Chicago River. Submitted were two types of vertical lifts, and the Rall, the Scherzer, the Strauss, and what was then known as the City type. On esthetic grounds the vertical lift was eliminated and, on the basis of cost and also esthetic grounds, the City type was adopted.

Previous to 1912, little attention had been given to the artistic appearance of the bridges; as a matter of fact the bridge engineer had to make his dollar give the maximum of strength and stability; but the Chicago Plan Commission came into existence in 1912, so that the opportunity came to the new engineer of bridges to inaugurate the beautification of the new bridges immediately. During 1912 and 1913, the lines of the bridge trusses were simplified and where possible given an arch effect; the masonry abutment, bridge houses, and approaches were built of more permanent material of greater artistic design, due to the close cooperation of the engineer of bridges (who during 1912 and 1913 was given a comparatively free hand) with the Chicago Plan Commission and the Illinois Society of Architects. This period may be termed the renaissance in the designing of Chicago's bridges. The immediate results were seen in the Michigan Avenue plans, Lake Street, Chicago Avenue, and Jackson Street bridges. The latter was not designed by the City Bridge Department but the general plans were developed under the writer's direction and approved by him.

Mr. Becker properly has given credit to the long-time employees of the City who were participants in the earlier developments of the movable bridges and who continued over a long period of years to meet the requirements of the traffic successfully. Alexander von Babo was a very able designer, modest and retiring, who gave freely to the City his patented ideas on which he reaped little or no financial reward.

A movable bridge is a large machine which requires constant attention for successful and satisfactory operation. For one thing, power is important, so there were installed in 1912–1913 duplicate sources of supply of electric power.

---

[7] Cons. Engr., Chicago, Ill.

One of the early difficulties in the Scherzer type of bridges was the size and shape of the teeth on the horizontal rack, and a more effective design was developed to assure a more safe meeting of the demand. As a matter of fact the Canal Street bridge almost "walked into the river" one night; this possible situation is now avoided by the better designing.

Under the heading, "The Improvement Period," Mr. Becker refers to the Chicago Avenue cylindrical piers as founded on rock at El. – 82.0. Bids were received on piers stopping in the hard clay with cone shaped bottoms, flaring out to give a sufficient spread to take the loads, and also on cylindrical piers extending to rock.

It so happened that the less excavation and less concrete made the cylindrical piers cheaper, but it gave a star reporter on the leading morning Chicago paper a chance to write an article about political favoritism to the successful bidder, the article appearing on the front page in large type. Later the said star reporter denied the truth of the article, but this was buried on the inside pages of the paper.

One day the Mayor, Carter H. Harrison, Jr., came into the office and complained about the shock he got going over the center break in the floor of the State Street bridge. This was a very light structure, so the complaint led to the designing of the continuous-rail joint at both center and heel breaks, which were adopted against the objections of the supervising engineers and have proved to be a great asset.

As a matter of interest to those bridge engineers who may be designing double-leaf bascule bridges, the following incident happened in the case of the West Lake Street bridge shown in Fig. 12: When the writer took charge of the bridge department he found borings had been made on both sides of the river at Lake Street, showing rock at El. – 75.0. Suspicious that the elevations should be the same, where there was a possible dip, new borings were ordered, and at El. – 75.0, sure enough, rock was found, but only 6 in. in thickness—so the borings were continued down until bedrock was found at about El. – 113.0, as shown in Fig. 12.

Mr. Becker refers to a new idea as developed in the Madison Street bridge, in 1922, called the "railing height truss." As a matter of fact two designs were prepared in 1912 for the Jackson Street bridge, one a railing height truss and the other a deck span, and the writer approved the latter. At about the same time, preliminary measurements and studies were made under his direction for the Madison Street bridge, and these preliminary sketches were for a railing height truss. It will be of interest also to note that a temporary bridge was designed, at this time, of the retractile type to carry traffic across the river during the construction of the proposed new bridge. This was a very simply designed structure, as railroad tracks were laid at right angles to the dock on vacant ground at dock height. The design included car trucks, on top of which were trusses extending far enough to the rear to carry a counterweight and far enough in front to provide a span of about 60 ft—a balanced affair planned to run out and back. It was not used, however.

The Michigan Avenue double-deck bridge was designed under the writer's direction in 1912 and 1913 and had a novel history—the construction was paid for by property assessments, and the drawings had to be reduced. The latter, with the specifications, were made a part of the council proceedings and were published in detail. A close examination of Fig. 18 will show the Michigan Avenue bridge in the background—a bridge that carried an enormous automobile and bus traffic until relieved by the outer drive bridge.

Since 1912 river traffic has dwindled tremendously and the need of movable bridges has seemed to be approaching an end; but with the present war some bridges that were not in operation have been provided with operating machinery by the federal government; so it appears that the movable bridge is in for a long lease of life on the Chicago River.

The designing engineer of Chicago's bridges had to meet two rigorous conditions which taxed his designing ability to keep within limits. The grades on the approaches were kept to a maximum of 4% and the under clearance above river level was required to be not less than 16.5 ft for a certain width of space. The type of bridge to meet these conditions was a two-leaf bascule, and that which is known as the City type has proved a very satisfactory design.

CLINTON D. HANOVER, JR.,[8] ASSOC. M. AM. SOC. C. E.—As stated in the "Synopsis," this paper describes the development of a bridge type serving peculiar local requirements. Mr. Becker's treatment of his subject, in chronological form, is interesting as a record of the evolution of this one type of bridge and as a record of the experiences of one agency in the design and operation of movable bridges. Unquestionably, other agencies—such as states, other cities, and railroads, who design and operate movable bridges—have similar and parallel records of experience and development on various types of movable bridges.

The original sources of some developments in the art of movable bridge design might be hard to trace, since not only engineers employed by agencies owning the bridges, but also engineers employed by contractors, manufacturers, and consulting engineers, have from time to time added their share to the general development. Many of these improvements in design, especially improvements in the design of details, are reflected in the latest specifications prepared under the auspices of various engineering societies. These specifications are based on the experiences of many practicing engineers and apply to all types of movable bridges.

However, the choice of the general type of movable bridge is still a question for determination on the basis of conditions at the site and on the basis of the requirements of navigation and highway or railway traffic. For this reason, a full discussion of the advantages of any one type of movable bridge is of interest to engineers responsible for the selection of types for use at various locations.

Mr. Becker states that, with the development of the City of Chicago, the rivers were deepened and widened, providing channels varying in width from

---

[8] Chf., Bureau of Bridge Design, Dept. of Public Works, New York, N. Y.

100 ft to 250 ft. Table 1 gives among other things, the clear span and the width of the river channel for each of the Chicago-type bascule bridges on these rivers. It is interesting to note that, for many of the bridges, the clear span exceeds the width of river channel considerably. As an example, a few of these are as follows:

Location	Width of river channel, in feet	Clear span, in feet	Ratio, clear span to channel
West Division Street (Canal)	90	135	1.50
West Division Street (River)	100	155.67	1.56
North Western Avenue	121	184.58	1.52
North Halsted Street (Canal)	90	184.58	2.05
West Webster Avenue	120	161.25	1.34
West Belmont Avenue	75	161.25	2.15

It is the writer's understanding that in each of these cases the clear span exceeds the river channel because the bridge does not cross the channel at right angles but crosses at a considerable skew, and that in each case a normal bascule, or bascule without skew, was used.

As the leaves of a normal bascule bridge rotate on an axis which is normal to the center line of bridge and center line of roadway, it has been necessary at skew crossings to provide spans with a clear distance between piers considerably in excess of the clear width of channel. Also this condition has required that the large rectangular bascule piers be placed at an angle to the direction of the channel flow, thus disturbing the flow of the current as well as blocking off a greater width of the waterway to the flow of current. At such locations, in order to protect river traffic, it also has been necessary at times to provide independent fender systems of considerable cost extending along the lines of the real channel.

In 1940 the Department of Public Works of New York, N. Y., began studies for a new bascule bridge at Hamilton Avenue over the Gowanus Canal in Brooklyn. The intersection of Hamilton Avenue and the canal makes an angle of 56°. The old bridge at this location was a skew bascule bridge of the rolling lift or Scherzer type. The main girders of this bridge were framed normal to the channel lines, the axis of rotation being parallel to the channel. This resulted in the main girders being placed rather close together, thus limiting the available space for counterweights and machinery, and in large triangular parts of the roadway framing being cantilevered outside of the main girders. Although the clear channel width was only 46.5 ft, in order to obtain any semblance of substantial framing, a double-leaf bascule bridge was used. The bridge was built in 1905 and had proved to be structurally somewhat flexible, resulting in high maintenance costs.

In making studies for the new bridge several schemes were tried, among them a skew bridge, similar in arrangement to the original one, and a double-leaf bridge without skew. The skew design was not favored because of the experiences with the former bridge. A double-leaf bascule without skew would require a clear span parallel to the bridge approximately twice as great as the width of the skew channel. The estimate of cost of the bridge without skew was so great that it, too, was not considered with favor.

On further study, the writer developed a new type of skew bascule bridge that has the advantages of a bascule without skew, without the disadvantages attended by the extra length of span. The forward leaf of the bridge is made to fit the skewed channel crossing precisely, and the rear leaf is built normal to the channel lines, thus making the forward leaf as short as possible and allowing the center line of trunnions to be parallel to and as near to the channel line as possible. This gives the shortest span from center line of trunnions to toe end of span that can be arranged. The main girders are spaced as far apart as may be desired, thus permitting complete and substantial bracing systems to be used, allowing ordinary concrete in the counterweights for counterbalancing, and providing maximum room for locating the operating machinery between the main girders. Since the piers are built in line with the channel, the channel flow is obstructed the minimum amount.

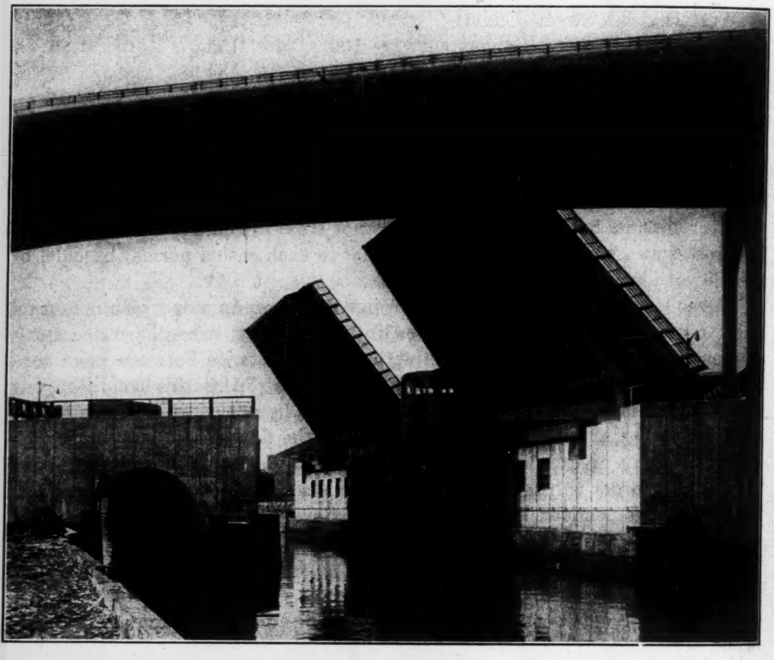

FIG. 20.—VIEW OF THE UNDER SIDE OF THE BASCULE LEAF IN OPEN POSITION

Although the center of gravity of the forward leaf is not midway between the trunnions or supports, the center of gravity of the counterweight can be midway between the trunnions, thus providing a counterweight of uniform section throughout its length. Fig. 20 is a view of the under side of the bascule leaf in the open position, showing the framing of the main girders as well as that of the other structural members of the forward leaf. The adoption of this type of bridge allowed the use of a single-leaf bridge and resulted in a great saving in cost. The same scheme can be used in a double-leaf layout for wider skewed channels.

This experience in the City of New York may be of interest in other cases where skew crossings are involved. It is the writer's belief that natural conditions of the relative alinement of roadway and channel result in considerably more skew crossings than square ones, especially since the tendency is to maintain a straight alinement on highways to accommodate modern high-speed traffic.

Mr. Becker states that in the design of the South Canal Street bridge some new ideas are incorporated, among them the use of open grating for the roadway pavement. This type of grating early was recognized as economical if used as a floor for movable bridges. The City of New York has nine bascule bridges with this type of decking installed, some of them older bridges on which the floor has been reconstructed. The Hamilton Avenue bridge shown in Fig. 20 is one of the new bridges on which this type of floor was installed. The writer agrees that its use saves weight not only in the floor but in the supporting members and in the counterweight. In addition, it reduces the operating forces required, as both friction and wind load are lessened, thus reducing the power and the weight of machinery required.

It is interesting to note that, on the South Canal Street bridge design, the use of an hydraulic drive is contemplated. In 1937 the writer made a study of this type of installation as it was recognized that speed control with the hydraulic drive could be very much more sensitive than with an alternating current electrical drive. However, at that time, the idea was rejected because the manufacturers of the various hydraulic drives available were not in a position to assist in the development of the automatic control necessary to duplicate the protection provided by limit switches in the standard electrical setup. Duplication of this protection required the redesign of the hydraulic units so that these automatic controls could be attached to them. Another factor against adoption of the hydraulic drive was that some systems worked on a high-pressure basis and others on a low-pressure basis, and, in case of emergency replacements being required, there necessarily would have to be full dependence upon only one or two manufacturers.

Armour T. Granger,[9] M. Am. Soc. C. E.—All engineers engaged in the design of movable bridges should be interested in this timely and valuable paper. The comprehensive account of the development of the Chicago bascules from the crude structures of the past century to the excellent and artistic spans of the present reveals strikingly the tremendous advances which have been made in the design of bascule bridges during this period.

Pound for pound and dollar for dollar, the bascule probably presents more intricate problems than any other type of bridge structure. The successful solutions of many such problems are presented in the paper. Certainly the engineers who have participated in the design and development of the Chicago bascules have contributed greatly to the science of designing movable spans.

---

[9] Prof. and Head, Dept. of Civ. Eng., Univ. of Tennessee, Knoxville, Tenn.

The writer is strongly of the opinion that the simple trunnion bascule, with the counterweight beneath the floor, as exemplified by the Chicago bridges, is in general the most desirable of all bascule types, including those types of double-leaf bascules which require the span to function as a simple span or as anything other than a pair of shear-locked cantilevers when the leaves are closed.

Among the many interesting and difficult problems requiring solution in the design of a bascule are the following: Method of supporting the inside trunnion bearings, details of floor breaks, rail joints, provisions for trolley wires during movement of span, span locks, arrangement of counterweights, arrangement of operating machinery (frequently in limited space), adequate provision for proper machinery alinement, prevention of moving interferences, and many others. Some of these have been discussed in the paper. Limitations of space doubtless have precluded the consideration of others of interest and importance. It is hoped that in his closure the author may comment on more of these details.

It would be of interest, for example, to have some information relative to the development of the center locks for double-leaf spans. Various types of locks have been devised and used and some of them have not proved satisfactory. (This statement is general and is not made in reference to the Chicago bascules.) A thoroughly satisfactory lock should grip both leaves firmly, without play or clearance, should be arranged to engage and disengage readily, and should be so designed that no part of the lock can foul either leaf. The lock mechanism, of course, should be so interlocked with the operating machinery that power to operate the span cannot be available until the locks are opened fully. Any lock which involves vertical play or clearances with the lock in closed position is likely to cause objectionable bumping or impact when loads pass over the floor break.

The details of the center floor break are also important. Such breaks should be designed to insure smooth riding over the joint under all conditions. The overlapping tooth joint, with teeth tapered in plan and rounded at the ends on a vertical radius, can be arranged so as to be entirely satisfactory for the center roadway break of a double-leaf bascule.

Some discussion of the choice of the type of trussing used would be of interest. Warren trusses were employed for the West Lake Street bridge (Fig. 12), but apparently Pratt trusses were used for all the other bridges. It has been the opinion of the writer for many years that, except for shallow spans with deep members where secondary stresses may be of consequence, Warren trusses are preferable to Pratt trusses for practically all riveted bridge spans and the great popularity of the Warren truss in recent years evidences the fact that many engineers are of this opinion. A statement of the reasons why Pratt trusses were selected for the Chicago bascules should therefore be of value to the profession.

Another detail of much interest is the use of the live-load bearing or forward support in the front wall of the bascule pier. It would appear that the desirability of using such supports is somewhat open to question. In designing double-leaf, deck-girder, bascule spans the writer has investigated their use on more than one occasion, but has omitted them. These supports will afford an appreciable saving in the weight of the forearm girders or trusses, but they have attendant disadvantages which tend to offset this. These disadvantages may be stated as follows:

(1) With the forward supports omitted, the double-leaf, trunnion bascule is statically indeterminate for live load to the first degree only, and the actual stresses can be determined quite closely. The introduction of a forward support in each leaf renders the span threefold indeterminate, and the computed stresses therefore are likely to be considerably more in error than if the forward supports are omitted. The fact that the inside trunnion support usually has a certain amount of flexibility contributes to the uncertainty as to exact stress distribution. Furthermore, since the relative simplicity of the trunnion bascule (as compared to other types) is one of its principal advantages, it seems rather a step in the wrong direction to detract from this simplicity.

(2) It is seldom, if ever, possible to make the forward support carry live-load reaction only. With full live-load covering both forearms between the forward supports, a part of the dead load on the trunnions will be transferred to the forward supports, and it is possible in some cases, where the live load is heavy, for the "live-load support" actually to be subjected to the full dead load on one trunnion in addition to the full live-load reaction.

The truth of this statement should be apparent from the following considerations:

With no live load on the span, the live-load bearing (forward support) and live-load anchor at the rear are adjusted presumably so that the parts of these details on the fixed and moving portions are just in contact. Now assume full symmetrical live load on both forearms—which condition will give zero shear at the center locks and negative moment for the full length of both leaves. As each leaf is held vertically at the forward bearing and rear anchor, that part of the span between these two points then will deflect upward. This upward deflection will reduce the dead load on the trunnion bearings; and, unless the trunnion supports are quite flexible, enough dead load will be thrown off the bearings to the leaf to balance the moment of the live load on the leaf about the forward support, with a consequent increase in the reaction on the forward support. As the distance from the trunnion to the forward support is small compared to the length of the forearm, this increase in the reaction is large, and, with some span dimensions and live loads, it is possible to take the dead load completely off the trunnion bearings and transfer it to the forward support.

Such behavior of the span calls for heavy forward supports. Although the total resultant load on the foundation, of course, is in the same location with or without the forward support, the manner in which it reaches the foundation is quite different in the two cases. It is sometimes difficult to care locally for the heavy concentrations resulting from the forward support and to insure that they are distributed properly over the foundation.

Transference of at least part of the dead load back and forth from the trunnion to the forward support seems rather objectionable and appears to detract from the simplicity inherent in the trunnion bascule.

The writer should state again that his investigations of this matter have been made only on girder spans, but a similar line of reasoning should apply to truss spans.

Probably more ingenuity has been exercised in devising methods of supporting the inside trunnion bearing than in connection with any other bascule detail. Some very ingenious ways of accomplishing this on the Chicago bascules are described by the author. Another method, similar to the longitudinal, S-shaped girders used for many of the later bridges, consists of supporting the inside trunnion bearing on a very short girder hung from a horizontal longitudinal girder overhead which is supported by the front and rear walls of the pier. This arrangement can be used where the distance from crown of roadway to center line of trunnion permits.

Another good arrangement (patented) consists of supporting the inside bearing on a bracket cantilevered longitudinally from an inside trunnion column which rests on the floor of the pier. The column is so shaped in elevation as to fit into a notch in the counterweight to clear the span in the fully raised position.

It is desirable, but sometimes rather difficult, to provide approximately equal rigidity in the supports for inner and outer trunnion bearings. If there is much difference in the dead-load deflection of these supports, trouble may be encountered during and after erection.

The writer has had occasion to investigate the matter of transverse centering devices for the leaves of girder bascules and always reached the following conclusions:

(*a*) Transverse centering was not needed; and

(*b*) Any device that would deflect the leaf laterally by any appreciable amount would need to be so large and powerful as to be impracticable.

There are a number of spans with wide roadways, having interlocking tooth center breaks and no transverse centering devices, and so far as the writer is aware there has never been any transverse fouling on these spans.

The author has made a few comments relative to the comparative appearance of bascule and vertical lift spans, and a word on this subject may be in order. Having been connected with the design of many spans of both types, the writer is decidedly of the opinion that the bascule span is not necessarily superior in appearance to the vertical-lift span. Certainly many deck or railing-height bascules are more attractive than many vertical lifts, but in the eyes of many engineers nothing is more hideous than some types of through bascules with overhead counterweights. With thought and care the lift span can be given a very fine appearance. In the opinion of the writer, the Harlem River (Triborough) lift span in New York, N. Y., is not excelled in appearance by any movable bridge in the world. Certainly, however, the required horizontal and vertical clearances at Chicago, in general, are not particularly favorable for lift spans.

In conclusion, the writer would like to state clearly that no statement made in this discussion is intended to imply unfavorable criticism of any point in the design of the Chicago bridges. They are certainly a worthy monument to the city and the engineering profession, and the paper is a valuable addition to the literature of movable bridges.

C. B. McCullough,[10] M. Am. Soc. C. E.—The development of the "Chicago type" bascule structure is an interesting and clear-cut illustration of the adaptation of design types to meet special or particular local conditions. Numerous advantages inhere in this type, principal among which may be mentioned:

(1) Exterior blocking of the channel is avoided during operation. This advantage over the swing bridge assumes considerable importance in localities where it is essential to maintain maximum docking facilities along the river close to the structure, especially in those relatively narrow waterways such as the Chicago River, where the movable span constitutes the greater part of the stream crossing.

(2) It is possible for river traffic to approach within a comparatively short distance of a bascule structure, whereas for swing spans, craft must stand off much farther on account of the difficulty in negotiating a split channel and swinging around the draw rest.

(3) A bascule may be raised slightly to permit the passage of small boats which fail to clear by only a small margin, whereas, in general, a swing span must be opened a full 90° for each vessel regardless of its vertical clearance. Because of this fact, bascule spans may be operated with much less interference to vehicular traffic, particularly in those instances wherein a great portion of the river traffic is relatively low-masted.

(4) For the bascule it is not necessary, as in the case of the swing span, to construct a large pivot pier in the center of the channel. In certain locations, such a pier structure operates to deflect shoreward currents, with consequent destructive erosion along adjacent banks.

(5) The bascule span, unlike the swing span, does not require the construction of a draw rest in the center of the channel, which construction always operates as a serious obstruction to the channel and a menace to water-borne traffic.

(6) It is possible to construct wide roadway structures (such as are necessary for traffic conditions in cities the size of Chicago) without the necessity of blocking the channel. This condition does not always prevail in the case of swing spans, for the reason that there is a definite relationship between the width of the roadway and the minimum dimensions that may be adopted safely for the pivot pier. If the roadway width is increased beyond a certain limit, the pivot pier becomes of such dimension as to obstruct the channel seriously.

(7) The bascule type lends itself to widening with a minimum of inconvenience to traffic because of the possibility of building additional roadway lanes immediately adjacent and alongside the existing structure, whereas such procedure is impossible in the case of a swing span because of the necessity for the maintenance of swing clearance during construction.

(8) In the bascule structure (in certain types at least), the raised leaves may be made to constitute an effective traffic barrier. This is a tremendous advantage as compared to the swing span, particularly in the case of heavy,

---

[10] Asst. Chf. Engr., State Highway Dept., Salem, Ore.

high-speed traffic arterials, whereon accident elimination and control pose serious and challenging problems.

(9) As compared with the swing span, in general, the bascule structure is safer from the standpoint of water-borne traffic in that it eliminates the possibility of collision with the open end of the span when it is swung.

Most of the foregoing advantages derive from a comparison of the bascule bridge with the ordinary swing span. However, some of them are also applicable when such type is compared with the vertical lift. In addition, it appears possible in the case of the bascule, particularly the double-leaf design, to develop a greater degree of esthetic or architectural excellence than in the case of either the swing span or the vertical lift.

The foregoing items constitute the principal advantages inherent in the bascule type, some of which were mentioned by Mr. Becker.

The paper covers the origin and development of one specialized form of bascule, which has justly been denominated the "Chicago type." The historical development which he traces is most interesting. Of special interest to engineers is his mention of the internal rack (heading, "The Improvement Period") developed by Mr. von Babo; the utilization of transverse trunnion girders; the gradual development of concrete as a counterweight material; the utilization in one instance of an operating rack attached to the side, instead of in the plane, of the truss; the utilization of roller bearings in lieu of phosphor-bronze bushings; and the use, in one instance, of hydraulic motors.

The Chicago type represents a particular adaptation to meet the demands imposed by local conditions. The entire movable ensemble rotates about one single trunnion. In comparison with the multiple-trunnion types, this development presents the advantage of simplicity in construction and at the same time operates to reduce to a minimum the number of parts needing lubrication. As compared to the rolling lift type, the Chicago type concentrates the center of gravity at one fixed point during all phases of the operation. This type also discloses certain esthetic advantages as compared to most of the other types in common use. As mentioned by Mr. Becker, it is possible through the utilization of an arched lower chord, a full deck structure, and an appropriate architectural treatment of the operators' houses to produce an ensemble much more pleasing than is generally possible in other types. Fig. 21 is a view of a structure in this category which spans the Siuslaw River on the Oregon Coast Highway. It is illustrative of the possibilities in double-leaf simple trunnion bascule design in combination with reinforced concrete approach construction. The flanking approach spans of this bridge are 154-ft reinforced concrete bow string arches.

Another advantage inherent in the Chicago type is the facility with which the raised leaf, in single-deck structures, can be converted into a traffic barrier. Fig. 22 is a line drawing of the shoreward end of a Chicago type span showing the location of the trunnion in reference to the break in the roadway floor. With a fixed total angle of opening, ϕ, the clearance C between the fully raised leaves and the fixed roadway deck may be varied simply by moving the roadway break fore or aft along the longitudinal axis of the deck; in other words, simply by varying the angle θ as indicated. In view of the difficulty in safeguarding the operation of modern high-speed highway traffic, a positive barrier of this kind presents an advantage that cannot be overestimated.

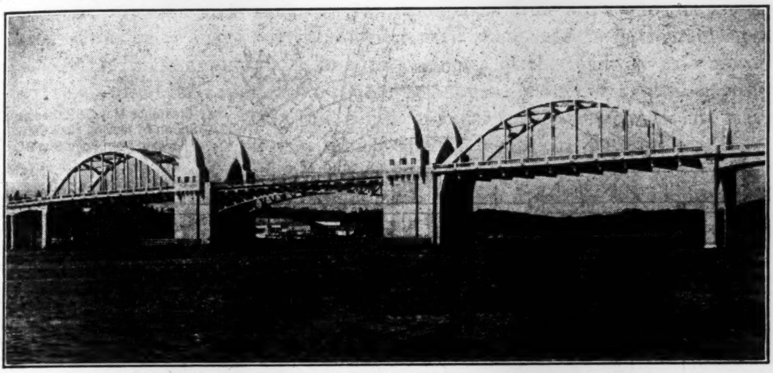

Fig. 21.—150-Ft Electrically Operated Double-Leaf Bascule Span Across Siuslaw River on Oregon Coast Highway

A most important feature in the design of bascule bridges is that of controlling the sequence of the various events that compose an operating cycle. In general, such a cycle comprises the following incidents, which should occur in the order given:

Opening Cycle

(1) Operation of warning lights, signs, or signals;
(2) Closing of remote roadway gates, if any;
(3) Closing of near roadway gates, traffic barriers, and the opening of derails, if any;
(4) Unlocking the leaves;
(5) Opening the span.

Closing Cycle

(1) Closing the span;
(2) Locking the leaves;
(3) Raising the traffic barriers, near gates, and closing the derails if any;
(4) Raising the remote gates.

The warning signs or signals may consist of bells, sirens, or whistles for the purpose of an audible warning, and the use of lights and semaphores for visual warning. The bells or sirens may be operated simultaneously with the closing of the gates or they may cease before the gates are lowered. In general, a prolonged siren is objectionable in that it may drown out signals from river

craft, for which reason it is generally the part of wisdom to terminate the siren signals before the roadway gates are lowered. However, this objection does not hold in the case of a traffic bell or gong, which may be kept ringing during the entire operation of the roadway gates. Lights or semaphore arms may be interlocked electrically with the roadway gates in such manner that the gates cannot be operated until such lights or semaphore arms are set to "danger." For example, an ordinary door-type switch may be cut into the gate circuit and installed on the semaphore arm in such manner that the roadway gate motor will remain dead or inoperative until the semaphore is set in its warning position, as indicated in Fig. 23. In a similar manner the traffic-light circuit may be interlocked to operate a relay which closes the gate circuit when, and only when, the light circuit is energized. It is also possible to arrange the circuits operating semaphore arms and traffic lights in such a way as to energize such circuits the instant the gate moves from its fully open position. Both of these arrangements and also a system of short-circuiting switches are indicated schematically in Fig. 23. In any interlocked operation of this kind, a short-circuiting arrangement is necessary; otherwise it is possible for electrical interlocking to interpose dangers as great as those which the ensemble is designed to avoid. The foregoing constitutes the essence of the first step in the electrical interlocking of operations.

If, in addition to the roadway gates indicated in Fig. 23, the installation comprehends a second system of gates (near gates), traffic barriers or derails, the interlocking obviously should be extended so that it is impossible to close these devices unless and until the remote gates are closed.

It is obviously necessary to lock the leaves of a double-leaf bascule bridge together in order that the structure may transfer live-load shear. This locking is usually accomplished by a center-locking arrangement, and, in addition, tail locks are sometimes used, as described by the author. Such devices are, in general, operated by means of a master switch or controller, and the wiring should be so arranged as to interlock with previous warning signals, gates, and barriers so that such locking devices cannot be released until all the signals, gates, barriers, etc., have been properly operated and set to warning. A schematic arrangement of this kind is indicated in Fig. 24.

In addition to the motors controlling the locking devices it is necessary, of course, to install motors for the purpose of operating the leaves. Such motors generally are controlled through a master switch. This switch should be wired through a contact on the center lock which is closed only when the center-lock pin is fully released, thus avoiding the possibility of damage by attempting, negligently, to raise the leaves before they are unlocked. A schematic arrangement of this kind is indicated in Fig. 25.

In closing, the leaves of a bascule structure are generally lowered to a seat on an outboard or live-load shoe at the stream edge of the abutment and anchored at a rear bearing, as indicated in Fig. 24, to preclude the possibility of live load on the trunnion. At either of these points it is possible to install a device to complete an otherwise open circuit for the center-lock or tail-lock motors in the "drive" direction, so that these devices will remain inoperative in that direction until the bridge leaves are down, fully seated and correctly alined. If this interlock is not provided, the center or tail locks can be driven while the bridge is in the open position. Although this in itself is not particularly objectionable (since the main motor circuit is wired so as to be inoperative except for these devices fully open or drawn) there is some danger of jamming the center or tail-locking devices by attempting to drive them when the leaves are not fully seated and exactly alined, except in those cases where the locks are designed so as to draw the leaves together during the last part of their movement. When the wiring is such as to permit the operation of the center-locking pins with the leaves partly open, it appears that provision should be made for making the roadway gates, traffic barriers, etc., inoperative when the leaves are raised, since otherwise such gates or barriers could be raised with the leaves partly or fully open. On the other hand, if the gate and barrier circuits are led through a pair of contacts, one on the center pin and the other on its mating seat, then it is obvious that the leaves must be seated and the locking pins fully driven before the structure can be cleared for roadway traffic.

FIG. 24.—WIRING OF CONTROLS ON THE CENTER-LOCK MOTOR

Fig. 26 is a schematic diagram showing interlocking contacts at the center lock for the barrier and gate motor circuits. If the two contacts are at A and B, it is apparent that the gate or barrier circuit can be energized whenever the pin is driven forward, regardless of the position of the leaves, in which case additional interlocking should probably be provided on either the live-load shoes or the anchor columns. On the other hand, if the contacts are located at A and C, no additional interlock appears necessary.

If the gate or barrier circuits are interlocked with the leaves but not with the tail or center lock, it is possible negligently to permit traffic over an unlocked span, thus inducing live-load stresses not contemplated in the original design.

In general, the sequence of all of the remaining operations should be controlled by arranging each circuit so that it remains open until all of those operations, which normally should precede it, have been completed.

FIG. 26.—METHODS OF INTERLOCKING CIRCUIT TO BARRIER OR GATE MOTORS

For low-power circuits, such as those for operating gates, signals, etc., the control switches may be cut directly into the line. For the main (high-power) operating circuits, however, magnetic contactors should be employed.

As an example of the dangers inherent in incorrect interlocking arrangements, assume that contact A in Fig. 25 were placed on the center-lock master switch instead of on the pin itself. In such a case, if the roadway gates or barriers were open, the circuit to the center-lock motor would be open and the handle on the center-lock master switch could be thrown to the draw-lock position with the pin still closed. Such an arrangement removes the safeguard of interlocking on the main hoisting motor circuit, thus making it possible for negligent operation to cause serious damage.

The foregoing are a few typical instances of electrical interlocking on bascule bridges. With the tremendous development in traffic densities and traffic speeds, the provision of adequate safeguards in this category becomes increasingly important. Each installation obviously presents its own interlocking problems. Sight distances, traffic speeds, traffic densities, etc., all operate to modify the arrangement of details. In a report covering this phase of bascule bridge design made by the writer in 1931,[11] the following general features of electrical interlocking were listed as necessary:

> "(1) Each control circuit should be so wired that the prior operation must be actually and completely performed before it becomes operative.
>
> "(2) Interlocking contacts must be positive in action and so located as to minimize the danger of short-circuiting or deterioration from moisture, ice, or mechanical injury.
>
> "(3) Contacts should preferably be made by a spring or snap device rather than by a sliding motion in order to avoid sparking and injury to contact points or tips, although a certain amount of wiping motion may be advantageous in tending to keep the contacts clean and bright.
>
> "(4) Make-and-break contacts for interlocking should not be placed directly in a heavily loaded power line but rather on an auxiliary or control circuit wired to operate a magnetic contactor cut into the main power line.
>
> "(5) Cross interlocking of operations should be provided wherever there is a danger due to the possibility of a failure of one phase of operation.
>
> "(6) Short-circuiting buttons or switches should be provided to permit operation in the event of a failure of any portion of the interlocking mechanism.
>
> "(7) In general, the entire interlocking arrangement should be as simple as possible, compact, sturdy, protected to the maximum possible extent, and so designed as to eliminate as far as possible every conceivable traffic hazard and every contingency or event that might expose the structure to undue stress."

In addition to the necessity for interlocking as a method of securing the correct sequence of operations, it is obviously necessary to provide devices in the nature of limit switches for controlling or limiting the movement of the leaves. Thus the wiring diagram for an electrically operated bascule structure becomes quite complicated.

It was with considerable interest that the writer noted the mention of Mr. Pihlfeldt (see "Conclusion"), who for many years was engineer of bridges for the City of Chicago. It was Thomas Pihlfeldt who took the writer on his first inspection trip over the bascule bridges of Chicago nearly a quarter of a century ago and who first impressed upon him the necessity for the bridge engineer becoming fully conversant with the principles underlying electrical operation and control.

---

[11] "Electrical Equipment on Movable Bridges," by C. B. McCullough, A. L. Gemeny, and W. R. Wickerham, *Technical Bulletin No. 265*, U.S.D.A., Washington, 1931, p. 38.

In closing, the writer wishes again to emphasize the importance of Mr. Becker's paper and its value to engineers engaged in this line of specialized endeavor. The writer has taken the liberty of adding these few pages in regard to electrical control and interlocking for the reason that this phase was not covered by Mr. Becker and for the further reason that credit for many of these features belongs to the Chicago group, to Mr. Pihlfeldt, to Hugh E. Young, M. Am. Soc. C. E., engineer of bridge design, and to others in the city bridge engineering force. Never has a group of engineers more successfully pioneered the development of a bridge type especially adapted to local needs. In the perspective of more than forty years, the wisdom of the early type selections stands out unchallenged.

DONALD N. BECKER,[12] M. AM. SOC. C. E.—Foundation conditions, especially the unreliability of some borings, are discussed by Mr. Hammond. For that reason borings made in later years have been continued 10 ft into rock to avoid the possibility that the first report of "rock" was merely a boulder. The accumulated mass of data that has been gathered through the years also tends to verify the results. Rock along the river in the downtown district is usually encountered at elevations slightly more than 100 ft below Chicago Datum (normal lake level) from Lake Michigan to the Lake Street bridge. The rock elevation then rises gradually southward with rock at about El. − 60 at the Roosevelt Road bridge and at about El. − 25 near 14th Street. Rock occurs at lower levels again south of 14th Street but not as deep as at the Lake Street bridge.

The rock is generally overlain with a fine water-bearing sand of varying thickness, covered by a hard clay layer of considerable thickness—say, as thick as 20 ft or 25 ft—which gradually softens as the elevation rises so that soft clay is reached usually above El. − 40.

The presence (in some cases, of as much as 15 ft or 20 ft) of water-bearing sand just above rock has made penetration to rock difficult and expensive. In some such cases sub piers have been belled out on hardpan after a test boring has been made to see that this layer is at least 15 ft thick. The belling out has usually extended until the unit pressure is reduced to 8 tons per sq ft. This practice has been found desirable in only a few cases in each of which rock was at, or more than, 100 ft below datum. No difficulties from settlement have been encountered.

Mr. Hanover presents a novel solution of the skew crossing problem, but the writer wishes to call attention to the relatively narrow channel in this case. Even if a similar leaf were placed on the other side of the channel to provide a wider opening, there would have been a channel of less than 100 ft. The bridges that Mr. Hanover refers to in Table 1 are rather old and in remote or narrow parts of the river system. In general, no channels of less than 140 ft are now permitted, and preferably channels should have from 170 ft to 200 ft clear span. With such great widths the Hamilton Avenue type bridge would not be practicable, especially where semithrough trusses are indicated instead of the deck girders at Hamilton Avenue.

---

[12] Engr. of Bridge Design, Dept. of Public Works, City of Chicago, Chicago, Ill.

In March, 1940, a bridge design was being developed for the proposed Congress Street superhighway where the skew is 62° 29′ and a 170-ft clear channel was required; the grade was high enough to permit deck trusses. As the proposed bridge was quite wide, 109 ft over-all, to provide two 44-ft roadways separated by a 3-ft center dividing fin and two 9-ft sidewalks, a square double-leaf bridge would have required from about 245 ft to 250 ft between masonry. A layout was finally developed in which two bridges will be placed side by side with a longitudinal joint in the center fin. In this layout one bridge will be set 31.61 ft ahead of the other. Thus, the clear span between masonry was reduced to 214.70 ft. These two bridges will be operated simultaneously by one operator on each side of the river as in the present Chicago double-leaf bridges. Arrangements will be made so that either bridge may be operated independently, which will permit one bridge to be placed up in the air for repairs and yet allow traffic on the superhighway to continue by using the other bridge for traffic in both directions on its 44-ft roadway until the repairs are completed.

Before this arrangement was developed, a study was made in which trusses were placed at right angles to the channel, with part of the outer truss in the acute angle of each leaf entirely outside of the bridge sidewalk. Since this plan produced a layout of questionable appearance, another layout was prepared in which the trusses were bent in a vertical plane with the trusses in front of the masonry parallel to the street but with the rear ends of the trusses normal to the channel. This layout was not considered desirable because of the difficulty of providing for the large kick reaction at the bend in the truss and the unequal power requirements on operating racks.

Mr. Hanover's remarks on the use of a hydraulic drive such as that adopted for the Canal Street bridge are not without merit. However, this installation is an attempt to develop a drive that will eliminate the complicated and expensive electrical control system of the present electric drives. It is being tried out as a transition from the usual electric drive to full hydraulic drive, and will have an auxiliary electric motor for emergency use. However, this electric motor drive will not have the complicated and expensive magnetic control equipment of the usual electric motor drives ordinarily specified in Chicago but will be controlled from a simple drum-type controller. If, after a few years of trial, the hydraulic drive proves reliable, future bridges may be equipped with it alone.

Chicago engineers also encountered Mr. Hanover's difficulties with control devices for the hydraulic drive and had to originate their own. A controller has been developed which operates the same as does the electric controller with which all the operators are familiar, in which the handle moves in a vertical plane—a pull on the handle toward the operator from a vertical position causes the leaf to rise and a push forward from the vertical causes the leaf to lower. The handle on the hydraulic drive is similarly arranged, and the greater the deflection of the handle is from the vertical the greater the speed will be. One great advantage of the hydraulic drive over the electric drive is that a return of the handle to the vertical automatically stops the leaf in its position without the application of the brake. A brake is provided, however, for emergency holding and for use with the auxiliary electric drive.

Professor Granger comments on the desirability of the simple trunnion bascule of the Chicago type. Its main advantages are: Freedom from linkages with pins that wear, and which may bind, in case of failure of lubrication; freedom from the hinged traps sometimes required with the rolling lift type; and other similar difficulties. Professor Granger is correct in his assumption that lack of space limited the discussion of details. However, these are so often affected by the requirements of each site that they can seldom be applied at another location and any experienced bridge engineer can easily develop details to suit his location. The main purpose of the writer was to chronicle the history and development of the Chicago type—the most significant phase of which was probably in support of trunnion bearings.

Professor Granger states that "A thoroughly satisfactory lock should grip both leaves firmly, without play or clearance, * * *." As against this need one should not lose sight of the necessity that the horizontal movement should allow for the temperature expansion of each leaf. It is not desirable to place one leaf on rollers so it can move in case of temperature expansion. (This was done in the case of the Soo Canal bridge where a full moment lock was provided to make the entire bridge function as a simple span under live loading. A failure of this lock for some undetermined reason was the cause of dropping one leaf of this bridge into the Canal on October 7, 1941.)

Locks on the Chicago bridges now consist of I-shaped bolts operated by electric-driven gear trains that force the bolts into the sockets on the other leaf. The sockets are provided with suitable adjustment features to allow for wear. The bolts are so designed that in case of necessity the leaves may be operated and the bolts can be withdrawn without damage to either bolts or sockets. Latest designs provide for the operation of these bolts by means of hydraulic pistons instead of motor-driven gear trains. Chicago's bridges have had their full share of difficulties with center locks.

Since before 1924, new bridges and some of the older ones have been equipped with intermeshing finger castings at the center roadway break. These do not foul each other when they mesh because the clearance tolerance of the teeth is greater than the clearance in the side cheeks of the center-lock castings which aline the bridge leaves before the teeth come opposite each other.

The writer admits that the general use of the Pratt type of trussing has never been given much consideration beyond the thought that with a curved bottom or top chord the difference in slope of the diagonals on each side of a vertical does not look well for Warren type trussing. A better appearance is obtained with the Warren type if parallel chords with attendant equal slopes are used. Also, the angle between the diagonals that were reversed and the sloping bottom chord would be so small that connection details would be difficult.

In regard to the use of a live-load bearing forward of the trunnion, several considerations have led Chicago engineers to this practice. First, the necessary supporting girders, whether of the **S**-type or cross-girder type, would otherwise have to carry the live load on the bridge and these girders are already of very heavy design. Second, in case of maintenance work the presence of the live-load support has provided a ready means of relieving the dead load from the trunnions by simply jacking up on the rear end. One such example was described by S. J. Michuda in 1942.[13] In this case because of a bump the entire east leaf of the East 106th Street bridge had shifted eastward and, by methods described in that article, the bridge was brought back to proper position and reanchored.

Unequal deflection between the supports for the inner and outer trunnion bearings is compensated by calculating the anticipated deflection of the **S**-girder and by setting the inner trunnion bearing higher. No ill effects have been experienced. Professor Granger comments on transverse centering and indicates that he has found no need for such devices. In Chicago bridges where the span is long enough to require trusses, designers usually provide cheeks on the center lock which guide the bridge into correct alinement within the allowed tolerances. Of course, where the end of the leaf is away from the trunnion 100 ft to 125 ft, only a relatively small force is necessary to deflect the leaves.

The writer agrees with Professor Granger on the merits of vertical lift versus bascule bridges. When a lift bridge can be placed out in a clear open location as was the Triborough Bridge in New York, it is definitely desirable. In the past too little attention has been given to the appearance of a structure and too much stress to the lowest possible cost, with the result that many monstrosities have been foisted upon the long suffering public. The writer believes that day is gone.

Mr. McCullough's comments are welcomed as helping to round out the entire topic by summarizing the numerous advantages of the bascule type bridge over other types and by outlining the necessity for, and the manner of, providing interlocking for the various operations.

Chicago's new bridges are thoroughly interlocked but by-passes must be provided so that a failure at any point will not stop the entire functioning. These by-passes are sometimes the cause of trouble if used inadvertently or otherwise when not actually needed, thus defeating the very purpose of interlocking. In this way one small human failure may defeat the best efforts of science.

SEDIMENTATION IN RESERVOIRS

By Berard J. Witzig,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. Joe W. Johnson, John W. Stanley, Stafford C. Happ, Thomas H. Means, Carl B. Brown, C. S. Jarvis, Hugh Stevens Bell, Harry F. Blaney, A. L. Sonderegger, L. Standish Hall, and Berard J. Witzig.

Synopsis

The principal phases of the problem of reservoir sedimentation are reviewed in this paper, including (*a*) the origin and nature of sediment, (*b*) its transportation to and through, or deposition in, the reservoir, and (*c*) remedies for reservoir silting. Quantitative study of sedimentation rates may be made from several approaches, none of which are sufficiently developed to permit more than approximate estimates of probable sedimentation rates. Such estimates may be of use to design engineers, who must allow for inevitable depletion of storage, but the real solution to the problem, both from the technical and social viewpoints, seems to lie in the prevention of sedimentation, and conservation of the available storage to the greatest extent possible.

Introduction

Studies by the Soil Conservation Service (SCS) of the U. S. Department of Agriculture (1)[2] show that, in the silt-carrying streams of the United States, the probable life expectancy of existing reservoirs is dangerously short. Detailed surveys of sediment volumes have been made in about 1% of all reservoirs in the United States. Assuming that these constitute a representative sample, that the long-term silting rate remains uniform, and that a reduction of 80% in the capacity of a reservoir terminates its useful life, these studies indicate that about 64% of all reservoirs have useful lives of less than 100 years, and only about 15% serve for more than 200 years.

Although it is a primary problem in badly eroding areas, silting of reservoirs is not the only manifestation of the silt problem. Among other aspects are sedimentation of navigable channels and harbors; aggradation of flood channels, causing increased frequency of flooding; silting of arable lands and destruction

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix II).

of fertility; increased cost of operating irrigation systems, due to the necessity of frequent dredging or provision of desilting works; increased cost of water supply treatment; damage to mechanical equipment by wear of gates, valves, turbines, etc. Some beneficial effects of sedimentation are decreased seepage losses from reservoirs and canals; decreased vegetation and algae growth due to absorption of sunlight; and fertilization of lands overflowed, when the silt has been produced by sheet erosion rather than by bank or gully erosion.

The factors involved in the production, transportation, and deposition of sediment are many and devious. Approach to the problems has been both empirical and rational: The former has generally seemed productive of the earliest applicable results, but often lacks a sound theoretical basis; and the latter seems more promising of establishing basic principles, but only a beginning has been made. Remedies for reservoir silting are costly and have been neglected, because of additional storage that ordinarily could be developed more cheaply, or because it was impracticable to evaluate the forces involved.

ORIGIN AND NATURE OF SILT

The problem of reservoir sedimentation and its solution are inextricably united with that of erosion. In regions where erosion is negligible, silting of reservoirs is generally not serious; and, where erosion is normally excessive, or has been accelerated by man's activities, reservoir silting is usually rapid.

The factors influencing the erosion cycle may be placed in two broad classes. "Eroding and transporting forces" include rate of runoff, turbulence of flow, fluid shear at boundaries and in eddies, fluid and particle impacts, surface and channel slopes, roughness, and sediment concentration. "Resisting and depositing forces" include gravity, adhesion, protective cover, impermeability, decrease in turbulence, local stilling, penetrable surface cover, and flocculation. Theoretical attempts to evaluate or relate more than one or two of these factors at a time end in practical confusion. The quantitative, empirical approach by way of field survey or reconnaissance gives probably the best data on erosion for engineering usage.

The major factors affecting erosion by water on land surfaces are precipitation and temperature. The impact of large raindrops is believed a significant fraction of the forces causing sheet erosion; the resulting overland flow is a vehicle for the loosened particles of soil. Changes of the overland sheet flow from laminar (streamline) conditions to turbulent flow result in additional erosion. The dynamic action of water in channels adds to the eroded burden. A drop in temperature to or below the freezing point may halt erosion temporarily, since frozen ground is more resistant than unfrozen, but the freezing and thawing cycle itself is a major force in comminuting large rocks and soil particles.

Origin of Sediment.—All sediment in streams originates in sheet erosion or in the various types of bank erosion. Robert Horton, M. Am. Soc. C. E., states that, of the total erosion in the evolution of a humid drainage basin, probably 1% was initially bank erosion, and 99%, sheet erosion (2). Studies of the SCS in the Piedmont (3) suggest that existing deposits within the flood plain of a stream are now often more important as immediate sources of sediment than concurrent sheet erosion, and it is evident in some cases elsewhere that bank erosion predominates over sheet erosion. Principles developed by the SCS indicate that gullying is more important than sheet erosion as a cause of harmful stream and valley sedimentation; that stream-bank erosion is an important factor in sediment production; and that valley trenching produces large amounts of fine sediment and facilitates downstream transportation.

The watershed characteristics most patently affecting sediment production, and hence the rate of sediment delivery to a reservoir are (4): Degree of erosion; relative extent and distribution of kinds of erosion (sheet, bank, gully, highway, etc.); soil type (size of particles); amount of runoff and character of discharge; and topographic form (colluvial and alluvial deposits).

Definition of Silt.—The erosion process ultimately reduces rock to the finest possible physical particles. The material that fills streams, valleys, and reservoirs actually varies from large boulders to grains just larger than colloidal size. In its widest application, the word "silt" applies to this entire range of sizes; in its more limited meaning, "silt" is a range of particle sizes between that of clay and that of fine sand. Only arbitrary definitions of size can be made, as shown (5) in Table 1.

TABLE 1.—SOIL SIZE CLASSIFICATION[a] (DIAMETERS IN MILLIMETERS)

Class	A.S.T.M. (1)	U.S.D.A. (2)	M.I.T. (3)	Park Service (4)

Department of Agriculture; in Col. 3 "M.I.T." refers to the Massachusetts Institute of Technology; and the last column contains the modified classification of the National Park Service, U. S. Department of the Interior.

The size of the silt particle affects the degree of concentration of a suspension for given conditions of quiescence or turbulence. When the vertical components of turbulence are sufficiently strong, no settling takes place. Research (6) indicates that for each reach of each stream, a "dividing grain size" exists between material which moves as bed load and material which moves in near-permanent suspension. Table 2 indicates the rate of settlement (7) of a particle in still water at 50° F.

Colloidal particles, which include the "fine clay" of Table 2, will not settle out in any practical period of time, due to the effect of like-electronic charges on the particles. Under certain conditions of salt content and temperature, fine silts tend to flocculate and have higher rates of settlement than are shown in Table 2. The existence of graded suspensions results also in greater rates of deposition of the finer materials than when the latter are isolated, as the coarser particles appear to drag down the finer. The presence of organic matter slows up the deposition process, because its weight is more nearly that of water. Coagulation, or the production of flocculation by chemical means, as in water supply reservoirs and treatment tanks, hastens settling. Flocculation is aided by calcium and magnesium salts, and counteracted or prevented by sodium or potassium salts; obviously, the geologic composition of a watershed may favor a flocculated silt in some instances.

TABLE 2.—Rate of Sedimentation[a] in Still Water at 50° F

Line	Coarse Sand		Fine Sand				Silt	Coarse Clay	Fine Clay
1	1	0.20	0.10	0.06	0.04	0.02	0.01	0.001	0.0001
2	100	21	8	3.8	2.1	0.6	0.15	0.0015	0.000015

[a] Line 1 contains the diameters of particles, in millimeters; and, Line 2 contains the rate of settlement, in millimeters per second.

Silt deposited in a reservoir varies greatly in weight and volume, depending on its source, the depth of deposition, and the degree of submersion or exposure. The percentage of voids in a deposited silt sample appears to be the most important criterion of silt weight and volume. Assuming an average specific gravity of 2.6, which varies little in any case, J. C. Stevens, M. Am. Soc. C. E. (8), presents the values for silt deposits shown in Table 3.

TABLE 3.—Weight of Silt, in Pounds Per Cubic Foot

Weight	Percentage of Voids:									
	0	20	30	40	47.8	50	60	67.5	70	80
Dry...............	163	131	114	98	85	81	65	53	49	33
Saturated..........	163	144	133	123	115	113	102	95	93	83

Silt from exposed beds in Elephant Butte Reservoir (Rio Grande) has been found to weigh from 97 to 124 lb per cu ft, and the dry weight of samples from various points along the Colorado River has varied from 37 to 102 lb per cu ft. Samuel Fortier and Harry F. Blaney, M. Am. Soc. C. E. (9), recommend for the Lower Colorado a specific weight of 62.5 lb per cu ft for suspended silt, and 85 lb per cu ft for deposits in reservoirs.

The space occupied by silt after deposition in a reservoir changes with time and with the method of operation of the reservoir. Superimposed sediment compacts the lower deposits, as also do exposure and drying. The degree of shrinkage upon drying is dependent upon the relative sand and clay contents of the deposit. Sandy deposits shrink relatively little, but fine, uniform clay deposits are subject to considerable shrinkage. Deltaic deposits, worked over by wave action, may be well graded and quite dense.

Borings in exposed silt deposits in storage basins indicate that a definite water table exists commensurate with the water level of the reservoir; deposits below the water table are flocculent; and deposits do not shut off spring-water inflow on the beds of reservoirs.

NOTATION

The letter symbols used in this paper are defined when they first appear and are assembled for convenience of reference in Appendix I.

TRANSPORTATION OF SEDIMENT TO THE RESERVOIR

The sediment produced by erosion finds its way to the reservoir by movement in suspension, and movement as bed load. The former accounts for the transport of most of the finer sediment, whereas the coarser sands and gravels, and boulders, are moved by rolling along the bed of the stream. A third, or intermediate, stage of transportation exists—that of "saltation"—whereby movement becomes a series of steps or jumps; but this process is more predominant in littoral transportation. Hunter Rouse, M. Am. Soc. C. E., pertinently states that theoretically there is no fixed dividing line between the two primary modes of movement, but that limited knowledge of the correlation between the two precludes any but an independent treatment for the present (10). As previously stated, however, there now appears to be at least an empirical and unique division between grain sizes carried by each mode of transportation in each stream reach.

One of the earliest and best known attempts to evaluate the effect of flowing water on sediment was the formula developed by R. G. Kennedy for the Bari Doab Canal in the Punjab, India, about 1900. This formula is of the general form:

$$V_c = C_k \, (y_d)^x \qquad (1)$$

in which V_c = a "critical" velocity that will neither scour nor deposit material; C_k = an empirical coefficient, depending on the kind of silt; y_d = depth of water in channel; and x = an exponent, obtained from plotting observed data on logarithmic paper.

Eq. 1 has been used widely for canal design, with more or less successful results, but the wide range of values for C_k and x indicates that almost every application is unique. The coefficient, C_k, has been found to vary (11) from 0.38 to 1.83, and the exponent, x, from 0.44 to 0.73. There appears to be no relation, inverse or direct, between C_k and x. It may be concluded, therefore, that the range of velocities in the non-eroding, non-silting state is either little dependent on the depth, or highly dependent on the nature of the silt. Other formulas have since been proposed, but these also require the evaluation of empirical constants. At best, the available formulas are but guides to judgment. No general or certain analytical method is available for the determination of the "critical velocity," as defined by Mr. Kennedy.

Suspended Load.—After material has been taken into suspension, turbulence theory offers an explanation of subsequent sediment transportation. The theory of fluid turbulence also suggests the principle of vertical distribution of sediment in a stream, and therefore permits more accurate estimates of silt load from sampling observations.

Turbulence in a fluid represents the transfer of energy or momentum in random manner from one particle of the fluid to another. If such a fluid contains silt, some of the energy is transferred from fluid to silt, and from silt particle to silt particle. In maintaining suspension, the net transfer of energy is the resultant of all upward forces against the forces of gravity and other deposition factors. G. I. Taylor defines turbulence as "* * * an irregular motion which in general makes its appearance in fluids, gaseous or liquid, when they flow past solid surfaces, or even when neighboring streams of the same fluid flow past or over one another" (12). Theodor von Kármán, M. Am. Soc. C. E. (12*a*), in substance defines the scientific term turbulence as implying irregular fluctuations, governed by laws of some statistical equilibrium between the random forces of turbulence and the force of gravity.

Various research workers have developed formulas to express the degree of turbulence, the turbulent energy, and its mode of transfer to other fluid particles and to the suspension of sediment. The formulas require a number of empirical constants, but the science rests on sound physical and rational foundations, a source of criticism against the purely empirical attack.

The present theory of fluid mechanics assumes a completely homogeneous and fluid substance. As soon as sediment is introduced into a stream, conditions depart from the ideal state, since both sediment and fluid are now moving, not only with respect to the boundaries of the fluid, but with respect to each other. Professor Rouse (10) as well as Morrough P. O'Brien, M. Am. Soc. C. E. (13), have reviewed the relation of turbulent flow to sediment transportation in some detail, and reference to their work is suggested.

Research has established fairly well that the concentration is dependent on sediment grain size, water discharge, and the degree of turbulence, at a particular instant. The total quantity of sediment is not necessarily related directly to discharge at all times, because of seasonal variations in the supply and source of sediment, and distribution of rainfall and runoff from the watershed, so that a measurement of the sediment load for a given discharge does not indicate the amount which may be carried by an equal discharge at another time. E. W. Lane, M. Am. Soc. C. E., and A. A. Kalinske, Assoc. M. Am. Soc. C. E. (14), have developed analytical expressions, based on the theory of the mechanics of fluid turbulence, for the distribution of sediment concentration in a vertical, and for the total suspended load in a unit width of a "wide" stream. Simplifying assumptions are that: The stream is "wide"; the kinematic viscosity is constant throughout the depth; the turbulence is due to an unconsolidated stream bed; and the sediment composition by sizes is known. The formulas permit estimating sediment distribution and load in a unit section from a single silt and velocity measurement in the section. The formula for distribution of sediment concentration in a vertical is:

$$N = N_a \, e^{-15t(z-y_a)} \ldots\ldots\ldots\ldots (2a)$$

and that for total sediment load in the unit section is:

$$W = V_m \, y_d \, P \, N_a \, e^{15 t y_a} \ldots\ldots\ldots\ldots (2b)$$

In Eqs. 2, N = sediment concentration at any point in the vertical, at a distance, y, above the bottom; N_a = measured sediment concentration in the vertical, at a distance, y_a, above the bottom; e = base of Napierian logarithms (2.718); t = a dimensionless parameter $= \frac{c}{\sqrt{g\, y_d\, S}}$; c = mean velocity of fall of sediment within a selected size range; g = acceleration of gravity; S = slope of energy gradient of the stream at the time of measurement; z = relative depth of point, above the bottom $= \frac{y}{y_d}$; y_a = distance of sampling point above bottom; y = distance above bottom of the point for which the concentration is desired; V_m = mean velocity in the vertical (or in the unit section); P = ratio of mean concentration in the vertical to the concentration at the bottom; n = Manning's roughness coefficient; and W = total weight of sediment within a given size range in a unit width of stream.

Eq. 2*a*, with z plotted arithmetically against N on semilogarithmic paper, results in a straight-line curve having a slope of $-15\,t$. In 1941 a report of the U. S. Engineer Office (15) showed the slope as $-16\,t$, and presented a plot of P versus t for three values, 0.01, 0.02, and 0.03, of the relative roughness. Eq. 2*a* may therefore be solved graphically if N_a is known. Eq. 2*b* represents the integration of Eq. 2*a*, after inserting a term for velocity. The term, P, is approximated by the following expression (15), and must be evaluated for the proper conditions:

$$P = \left\{ \left[1 + 9.50 \frac{n}{(y_d)^{1/6}} \right] \int_0^1 e^{-15tz}\, dz \right\} + \left\{ 9.50 \frac{n}{(y_d)^{1/6}} \int_0^1 e^{-15tz} \log_e z\, dz \right\} \qquad (3)$$

Eqs. 2 and 3 permit more accurate estimates of suspended sediment than by averaging a few measurements at arbitrary sampling points. However, very fine suspended sediment is so evenly distributed through the depth that a single measurement in a vertical or unit section suffices for silts and finer sediments as defined in Tables 1 and 2. It is dependent on the individual investigator whether the increased accuracy warrants the considerable increased time and expense involved in making the necessary measurements and analyses.

If a reasonably long record of suspended sediment measurements is available, a correlation between suspended sediment and discharge may be observed by plotting the data on logarithmic paper. A straight line usually fits the data as well as any other curve, and Frank B. Campbell, M. Am. Soc. C. E., and H. A. Bauder (16) call the relation a "silt-rating curve." However, the scatter of points is deceptive on logarithmic paper, and, for reasons previously stated, an estimate therefrom of silt load in an unsampled flow may be considerably in error. Nevertheless, the curve may be used as an indication of the probable average relation and, hence, it is sufficiently accurate for use in estimating the average annual silt quantities delivered to a reservoir. Messrs. Campbell and Bauder made such use of data for estimating the probable rates of silting for the reservoir above Denison Dam on the Red River, Texas. The equation of the curve is of the general form:

$$G_s = C_s\, Q^x \qquad (4)$$

in which G_s = suspended sediment, in tons per second; C_s = an empirical coefficient in suspended sediment rating curve; Q = water discharge, in cu ft per sec; and x = an exponent (the slope of the logarithmic plat).

Fig. 1 shows such "silt-rating curves" for the Black, Cuyahoga, and Grand rivers, in Ohio, based on several years of daily measurements taken in 1902–1904 (17). The data are admittedly of limited accuracy. The samples were obtained near the mouths of the streams by submerging rapidly a wide-mouthed 8-oz bottle at midstream to about 10 ft; and the discharges, based on a metered rating curve, are the averages of twice-daily readings. The silt measurements for the Denison River, on the other hand, appear to be of a higher order of accuracy, in that they represent averages of samples taken at 0.6 depth at 1/6, 3/6, and 5/6 of the river width, with the center sample given a weight of 2. The scatter of points above and below a certain range suggests the existence of different correlations. The lower values are of relatively little importance compared to the total annual silt load; the higher values accompany only extreme floods of comparatively rare frequencies and, although of weighty magnitude, also represent but a small part of the average annual load. The equations of the three curves of Fig. 1 are compared in Table 4 with that derived by Messrs. Campbell and Bauder, for the Red River (16).

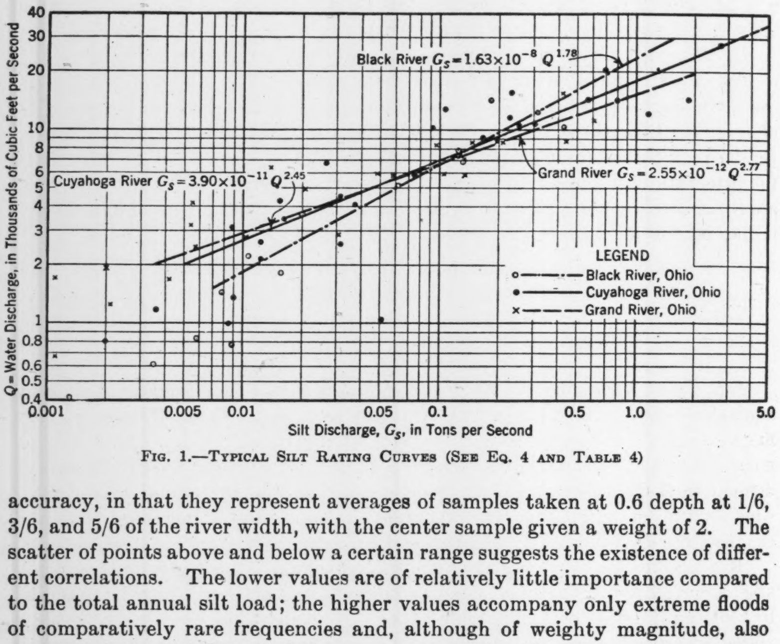

FIG. 1.—TYPICAL SILT RATING CURVES (SEE EQ. 4 AND TABLE 4)

The average annual suspended silt load can be computed by a combination of the "silt rating curve" and the discharge-frequency curve. It is first necessary to compute the ratio of silt load to corresponding discharge for a sufficient range of points, and then to plot the ratio $\frac{G_s}{Q}$ against the percentage chance of occurrence for the proper discharge, on arithmetic paper. The area under the curve represents the average annual suspended silt load per cubic foot per second of water discharge and is reduced to total average annual load by multiplying by the total average annual volume of discharge. Based on the equation in Item 3, Table 4, and on discharge-frequency relations adopted for an unpublished Engineer Department report, the area under the curve in Fig. 2 indicates that the probable average annual silt load of the Cuyahoga River at the mouth is about 0.0425 lb per cu ft of water, or, for a mean annual discharge of 794 cu ft per sec, about 532,000 tons per year. U. S. Engineer Department records show that about 650,000 cu yd of silt (or about 526,000 tons, assuming a concentration of 60 lb of dry sediment per cubic foot of deposit in place) are removed annually in maintenance dredging of the navigable areas of Cleveland Harbor, most of which comes from the Cuyahoga watershed. No reservoirs of adequate size exist on the Black, Cuyahoga, or Grand watersheds, to permit a comparison with actual rates of reservoir silting, and similar data for other areas are not available. Rates of silting in harbors are not directly comparable with those in reservoirs, and it is unlikely that the total load of the Cuyahoga is deposited in Cleveland Harbor. Some undetermined amount reaches the open lake. Also, part of the deposition in Cleveland Harbor is due to bed load

TABLE 4.—TYPICAL "SILT RATING CURVES"

No.	Geographical region	River	Place	Curve	LIMITS OF DISCHARGE (CU FT PER SEC)	
					Lower	Upper
1	Southwest	Red[a]	Denison, Tex.	$G_s = 9.5 \times 10^{-9} Q^{2.036}$	1,000	20,000
2	Great Lakes	Black	Lorain, Ohio[b]	$G_s = 1.63 \times 10^{-8} Q^{1.78}$	2,000	30,000
3	Great Lakes	Cuyahoga	Cleveland, Ohio[b]	$G_s = 3.90 \times 10^{-11} Q^{2.45}$	2,000	30,000
4	Great Lakes	Grand	Fairport, Ohio[b]	$G_s = 2.55 \times 10^{-12} Q^{2.77}$	1,500	25,000

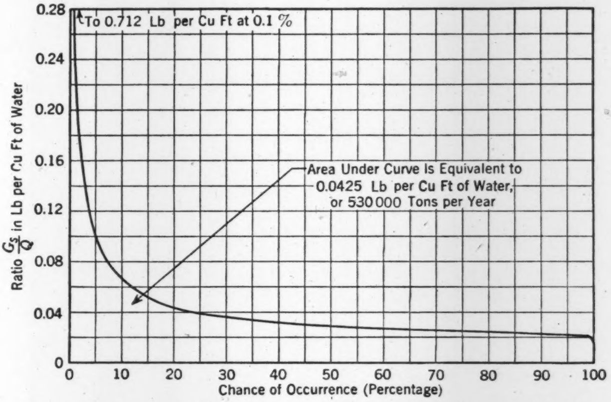

FIG. 2.—GRAPHICAL DETERMINATION OF PROBABLE ANNUAL SUSPENDED SILT LOAD OF CUYAHOGA RIVER, OHIO, AT THE MOUTH

from the river, subaqueous erosion from undredged areas, and possibly a small volume carried into the harbor by littoral forces. Considering the accuracy of the data in this example, the method seems reasonably applicable in determining the average annual suspended silt load of a stream.

Bed Load.—The problem of evaluating the bed load of the stream remains. Bed load appears to move first in a uniformly distributed layer, which begins when the tractive force reaches a certain value, and then in riffles which travel downstream, beginning at some larger critical tractive force (18). Bed-load sediment consists of those particle sizes which are too large for movement in suspension by the available suspending forces. The line of demarcation, as noted under the heading "Origin and Nature of Silt," is flexible, and, to the writer, it appears probable that this "limiting size" might have to be evaluated for various ranges of discharge, as well as for individual reaches in a stream. Investigation of the phenomenon indicates that bed load, unlike suspended load, is directly related to the discharge at all times, because the sediment supply for the bed-load forces is nearly always available, except on debris-clear rock-lined channels.

A greater amount of work appears to have been done on developing formulas for the amount of bed load than for suspended load. Experiments on flume traction by G. K. Gilbert (19) pointed the way for other workers. Two typical formulas are the Schoklitsch and the M.I.T. formulas. Investigations for the design of the All-American Canal (20) indicated that "the Schoklitsch bed-load formula is still a reliable instrument for the hydraulic engineer * * *." This formula, expressed in English units, is:

$$G_b = \frac{86.7}{(D_g)^{1/2}} S^{3/2} (Q_i - b\, q_o) \qquad \text{(5a)}$$

and the M.I.T. formula (18) may be expressed as follows:

$$G_b = C_b\, S^{x+1} (Q_i - b\, q_o) \qquad \text{(5b)}$$

In Eqs. 5, G_b = total bed load, in pounds per second; D_g = effective grain diameter, in inches; S = slope of the energy gradient; Q_i = total instantaneous discharge, in cubic feet per second; b = width of river, in feet; q_o = critical discharge, in cubic feet per second per foot width at which movement begins $\left(= \frac{0.00532\, D_g}{S^{4/3}}, \text{ in Eq. } 5a\right)$; and C_b and x = constants in Eq. 5*b*, depending on the specific gravity and mechanical composition of the bed material. The application of Eq. 5*b* is obscure since C_b and x "are yet to be related to sand mixtures so as to be determined directly from mechanical analysis" (18).

An approximate solution for bed load by the Schoklitsch formula can be made by determining or assuming a single representative grain size of the bed-load sediment, and mean values of the slope and discharge. However, it is obvious that the "critical" grain size varies within a given reach of a stream with different flows, so that only very limited accuracy can be expected. An estimate of the finest bed-load grain size for particular discharge and slope conditions may be made by analyzing the bed-surface material immediately after a flood. Assuming a mean grain size of 0.04 in. (about 1 mm) for the Cuyahoga River bed sediment near the mouth, an average slope of 1.0 ft per mile, and a mean annual discharge of 794 cu ft per sec, the total annual bed-load movement would be about 9,000 tons per year. Accurate computations of bed load are not possible because of variations of bed material from time to time, shifting of the effective width of bed that is actually scouring, and the necessary assumptions that must be made.

The practical and successful application of available formulas depends on expressing the nature of a mixture of grain sizes in some equivalent mean diameter, and evaluating the initial transporting force. No simple mathematical means of doing so are available. The theoretical functions presented by H. A. Einstein, Assoc. M. Am. Soc. C. E. (21), eliminate the idea of a "critical" force or state, and include the characteristics of the particles, but, although these functions describe experimental data, they are quite complex, and do not readily permit estimates of bed load for the varied conditions met in the field.

THE ACTION OF SEDIMENT IN RESERVOIRS

Some streams carry appreciable quantities of sediment only during floods, whereas others are burdened constantly with large silt loads. Whether the major part of silt damage is done intermittently or continually, the process of deposition is essentially the same. Some phenomena, however, are evident in reservoirs that are not so obvious in natural lakes or in the sea. Deposition of sediment results from the removal or dissipation of the transporting forces. The heavier silt sizes are naturally the first to be deposited, with the smaller sizes being carried farther out into the reservoir or not being deposited therein at all. The late O. A. Faris, M. Am. Soc. C. E. (22), partly describes the process thus:

> "Suspended silt settles to the reservoir bottom soon after entering the slack water and, having a greater specific gravity than water, flows, in the form of liquid mud, down the slopes into depressions and along the main channel until blocked by the dam. Owing to its greater density, silt-charged water entering a reservoir partly filled with clear water does not mingle with the clear, but forces it downstream toward the dam. No suspended silt is carried through the reservoir and over the spillway until all of the clear water has been discharged."

Deltas.—However, the sedimentary load of a stream is actually reduced considerably by valley aggradation above the reservoir. The remaining coarse-grained sediments, whether carried in suspension or as bottom load, tend to form deltas at the points of inflow. These deposits may be greatly altered from the ideal delta form by variations in reservoir level. Where the reservoir level is fairly constant, the characteristic bottom-set, fore-set, and top-set beds of a conventional delta are present, and the delta is subject to subsequent entrenchment by the stream with redeposition of the material farther out in the reservoir. If coarse sediments are lacking, no delta may be formed. The presence of deltaic deposits in a reservoir too frequently distracts attention from the unseen bottom deposits.

Bottom Deposits.—The fine-grained sediments carried by a stream into a reservoir spread over the bottom, and tend to concentrate in the deeper areas, especially immediately above the dam. This action is aided by the flow of the heavier turbid water along the thalweg beneath the lighter clearer waters of the lake. When the stilling effect of a large storage basin is available to an incoming sediment-laden stream, practically all of the sediment may be deposited in the reservoir cavity, and the outflow may be almost crystal clear. In such cases, an estimate of the probable average silt load of the tributary streams will indicate the rate of silting of the reservoir. Carl B. Brown of the SCS states that most of the reservoirs surveyed thus far trap between 70% and almost 100% of incoming sediment (23).

Effect of Reservoir Shape.—The distribution of sediment in a reservoir depends on the shape of the basin. If the reservoir is regular in shape, deposits from suspension will be distributed quite uniformly along its axis, decreasing in depth with distance above the dam. If the reservoir is irregular, there may be marked irregularity in the depths of the bottom-set beds. This is illustrated in the case of Elephant Butte Reservoir, where a section, known as "The Narrows," exists from about mile 15 to mile 19 above the dam. Profiles of silt deposits (1*a*) show that the silt surface here is almost horizontal, instead of following the grade of the original valley floor. However, the upper end of Elephant Butte is partly affected by seasonal drawdown.

Density Flows.—Considerable sediment is distributed to the deepest parts of a reservoir by the denser silt-laden water flowing beneath the lighter desilted water. Such flows sometimes dispense their load by diffusion and mixing or by settlement, thus losing their identity. However, it has been observed frequently in Lake Mead (above Boulder Dam), at Elephant Butte Reservoir, and in various reservoirs in Texas and in the Piedmont, that muddy underflows often extend to the outlet through a superficially clear lake. Ultimate understanding of the principles of density flows may lead to some control of reservoir silting. If the flow is allowed to stagnate, the silt will be deposited in the reservoir; if such flows could be induced and controlled, much of the sediment entering a reservoir could be voided before deposition. However, density flows are sometimes of quite low silt content, with the greater part of the difference in density from the reservoir water due to salt content or temperature.

Study of density flows in the past was generally neglected, because such flows are mostly invisible or hidden in the depths of the reservoir. However, two visual characteristics of underflow in reservoirs are the sharp line of demarcation near the head of the reservoir where the muddy water plunges below the clear water, and the localized zone of floating debris created at the upper end of the reservoir by a return current induced at the surface.

Density Flows in Lake Mead.—With reference to three observed occurrences of silty discharges at Lake Mead during 1935, Nathan C. Grover, M. Am. Soc. C. E., and Charles S. Howard (24) state that the flows apparently passed entirely through the reservoir, "essentially unmixed," and ascribe the phenomenon to the greater specific gravity of the incoming silt-laden water with respect to the clearer water at the surface of the lake. They estimate that these three silt flows carried some 6,000,000 tons of sediment, or about 2.5% of the average annual silt load brought to Lake Mead. Although measurements were made at Willow Beach about 10 miles below the dam, these quantities apparently do not include any materials scoured from the river channel below the dam. Mr. Faris (24*a*) disagrees with this theory and suggests that such discharge is the result "* * * of disturbance of silt which was virtually in place; that is, was no longer in suspension * * *." He implies that operation of the gates disturbed the equilibrium of this almost-liquid deposit and caused it to flow out of the reservoir. Ivan E. Houk, M. Am. Soc. C. E. (24*b*), suggests that lake temperature distribution is an important factor in density flows. In the case of a deep lake, movement may occur at some intermediate level rather than along the bottom of the lake, depending on the density of the silt flow. In order that silt may appear at the outlet of a lake, Mr. Houk believes that a relatively large inflow must continue until the silty flow has had time to reach the gates. On the other hand, Paul A. Jones, M. Am. Soc. C. E. (24*c*), suggests that the density flows of 1935 were due to the initial submergence and resulting erosion of unstable existing deposits as the reservoir filled. Hugh Stevens Bell (25) evaluates knowledge gained at Boulder Dam since 1935, and estimates that silt-laden density flows in Lake Mead carry about 24% of all sediment deposited in the lake.

Formation and Dispersion.—Experiments conducted at the California Institute of Technology, in Pasadena (26), show that "* * * density currents are not delicate or easily destroyed, but are difficult to prevent and more difficult to destroy." The loss of energy as the stream enters the reservoir is not generally sufficient to prevent the formation of a density current. Once the current has formed, only mixing across the "interface" can disperse it. The particles in suspension in the flow are believed to furnish most of the "driving force" down the slope of the reservoir bed, by virtue of their relatively greater specific gravity over that of water, so that the silt conveys the water rather than the water carrying the silt. Observation verifies the hardiness of density flows in the laboratory and in natural lakes and reservoirs. Density currents are known to have flowed for 100 miles through Lake Mead, and for 35 miles through Elephant Butte Reservoir. After storms on Lake Erie, the Niagara River carries considerable sediment into Lake Ontario. At the mouth, part of the river current flows out into the lake and part turns almost 90° to the east, flowing as a distinct stream at various distances offshore, depending on wind and wave conditions.

Mr. Einstein (27) infers that density flows may be considered laminar, and that dispersion, or mixing across the interface, will occur only when the flow is "unstable" and turbulence is caused. The turbulence must not be so great as to overcome the depth of the density current and break through the interface. He states that "* * * if the depth and concentration of the suspension are sufficiently high, and the sediment is flocculated, even violent turbulence will not reach the interface from the bed." Existing knowledge does not indicate the quantitative influence of dissolved matter, such as salts, and of temperature. No methods are known for quantitative analysis of density flows. Mr. Einstein states that "* * * not enough is known of turbulence structure to permit even estimates * * *." Additional field data are especially needed to substantiate the results of laboratory study. A fuller understanding of the phenomena involved may well lead to a utilization of density flows for controlling the rate of reservoir sedimentation to some extent.

Silting of Flood Control Reservoirs.—Few observations of silting have been made in flood control reservoirs. In general, however, silting therein appears to be a less serious problem than in storage basins. Due to drying and shrinking of silt beds in flood control reservoirs which are emptied after each flood, the silt consolidates and does not regain its original volume when submerged. Studies made on the Germantown and Englewood detention basins of the Miami Conservancy District by E. W. Lane and J. C. Kennedy (28) suggest that retarding basins do not silt up quickly, since a large part of silty and clayey sediment passes through without being deposited; that the proportion of clay to sand deposited increases with the time of detention; that recreational or other permanent storage pools within a retarding basin may be seriously silted within a short time; and that, unless the inflow contains high sediment concentrations, or the detention period is unusually long, sedimentary deposits are unlikely to become serious for many years. No evidence is available, but it seems improbable that density flows as previously described could exist in purely detention-type reservoirs, because of the more or less thorough mixing of the inflow.

ESTIMATING THE RATE OF RESERVOIR SEDIMENTATION

Methods of estimating the rate of sedimentation in a proposed reservoir are desirable, technically and economically, and may be approached at present from several angles. Comparison may be made of sedimentation rates in other reservoirs exposed to similar conditions; or an estimate may be made of the probable quantities of silt that will be delivered to and trapped by the reservoir. Unless specific remedies are to be undertaken to prevent sediment production and delivery, it is necessary to make proper allowance for silting, but even the fullest possible measure of control of sediment production will not eliminate partial depletion of storage.

Effectiveness of Reservoirs as Sediment Traps.—The quantity of sediment deposited in a reservoir is dependent on the extent to which deposition can take place. For complete deposition of the silt load, the capacity of the reservoir would have to exceed the volume of the incoming flood, and would have to retain the flood sufficiently long to permit all of the sediment to settle out. A criterion of reservoir effectiveness as a trap is the ratio of reservoir capacity to the drainage area above the dam. It appears that reservoirs having more than 15 acre-ft of capacity per square mile of drainage area (about 0.023-ft depth on the watershed) are comparable for rates of silting, whereas those of smaller capacity are not (29). The latter reservoirs either are filled by bed load, with little retention of flood waters, or a large part of the deposits are vented by operating the gates at the dam.

"Regional Indexes."—The SCS has given considerable study to sediment surveys in existing reservoirs, and the data thus obtained are presented in their official reports (1). Fig. 3 presents graphically the average sedimentation rates for various reservoirs reported by the Service (1*b*). The writer has drawn

envelope curves for storage reservoirs in the four geographic regions noted in Fig. 3 and in Table 5. The envelope curves have been drawn in "by eye"; the two points above curve I were neglected because of the small storage involved or the short time elapsing between surveys. The equation is of the general form:

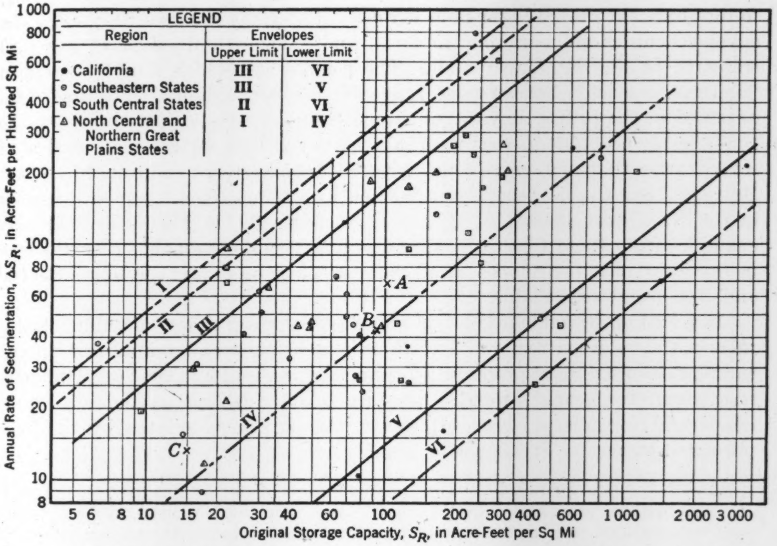

FIG. 3.—SEDIMENTATION RATES IN EXISTING STORAGE RESERVOIRS

$$\Delta S_R = I\,(S_R)^x \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which ΔS_R = annual silting rate or depletion of storage, in acre-feet per 100 sq miles of drainage area; I = coefficient, herein termed the "regional index"; S_R = original storage, in acre-feet per square mile of drainage area; $x = 0.83$ = the graphic slope of the plat on logarithmic paper.

TABLE 5.—"REGIONAL INDEXES" (EQ. 6) OF STORAGE RESERVOIR SEDIMENTATION

Region (data are from reservoirs in the states indicated)	UPPER LIMIT		LOWER LIMIT	
	Envelope	I	Envelope	I
Southern Pacific Coast				
California	III	3.75	VI	0.167
Southeast				
Alabama, Georgia, Maryland, North and South Carolina, and Virginia	III	3.75	V	0.307
South Central				
Arkansas, Missouri, Oklahoma, and Texas	II	6.24	VI	0.167
North Central (Including the Northern Great Plains)				
Illinois, Kansas, Montana, Nebraska, and South Dakota	I	7.56	IV	1.01

The data of Fig. 3 are from large geographic regions, differing considerably in soil, erosion, meteorologic, and hydrologic conditions. It should be expected, therefore, that distinct indexes could be determined for each region; but, as the envelope curves of Fig. 3 indicate, there is considerable overlapping, so that only the probable range of sedimentation rates can be estimated. The envelope curves are parabolic in form, and a logarithmic slope of $x = 0.83$ seems to fit the data fairly well. The coefficients, which might be termed "regional indexes," have a wide range for a given region. Of course, data obtained in the future may either spread the envelopes, or narrow them; the latter seems probable in that reservoirs surveyed thus far are more typical of severe rather than of average conditions. It is of interest to note that Elephant Butte and San Carlos reservoirs in the Southwest, and Black Canyon Reservoir in the Northwest (points A, B, and C, respectively, in Fig. 3) are the only examples from these two regions; and yet they plot reasonably near the geometric mean of the envelopes for all the stated regions except the North Central and Northern Great Plains.

It would be desirable if the data indicated narrower ranges of sedimentation rates within a given region. Isolation of such factors as annual rainfall and runoff, rate of sediment production (erosion), variations in operation of different reservoirs, etc., would probably produce this result, but available data are insufficient for this purpose. However, the data accumulated by the SCS, presented in part in Fig. 3, are invaluable in that

> "* * * the principle of the limited range of debris production makes it possible henceforth to take this factor into account in design, and to predict from regional indices of sediment production developed through widespread reservoir surveys and sediment load measurements, the order of magnitude of the silting rate, and the relative need for sediment control measures within the limits of design to which a specific reservoir must be limited" (29).

Sediment Trap Efficiency.—In an attempt to narrow the range of sedimentation rates indicated by considering only the rate of silting and volume of reservoirs, as in Fig. 3, G. M. Brune and R. E. Allen, Jun. Am. Soc. C. E., of the SCS studied the effectiveness of a single type of storage pool in trapping sediment (4). The rate of erosion was estimated from erosion surveys or reconnaissances; the rate of silting, from reservoir studies; and the percentage of eroded soil trapped was computed. Data for twenty-five reservoirs in the Ohio Valley region (Indiana, Kentucky, Michigan, Ohio, and Tennessee), plotted logarithmically against storage volume in acre-feet per square mile, produced a "band" of values indicative of the "trap effectiveness" of storage reservoirs. The envelopes and median curve may be closely defined by:

$$100\left(\frac{\Delta S_R}{E}\right) = C_T\,(S_R)^x \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

in which: E = sediment produced annually on watershed (annual rate of erosion); and C_T = "trap efficiency" coefficient for the reservoir. For the Ohio Valley region, $x = 0.5$, which may also hold for other regions. The coefficient C_T has a range from 0.91 to 4.34, with a graphic mean of 2.00. In applying to tentative designs, it would be necessary to select a value of C_T that would properly allow for the contemplated operating conditions, and any abnormal soil, erosion, or reservoir conditions. If the reservoir were to be used primarily for storage, selection of a high value of C_T would be conservative; if an estimate of the desilting efficiency were desired, assumption of a low value of C_T would be on the safe side.

Eq. 7 would give only the probable percentage of eroded sediment that would be caught by a reservoir. The annual rate of depletion of storage may be computed by estimating the rate of erosion on the watershed, for those cases where survey data are available. An assumption must be made of the probable density of silt deposits under proposed conditions. As stated, the SCS has found that storage reservoirs trap "between 70 and almost 100 percent" of the sediment delivered to them (23).

Estimates of sediment delivery to a reservoir may be made also on the basis of suspended silt and bed load carried in by tributary streams, in accordance with procedure and formulas given in a previous section of this paper.

In designing a reservoir, estimates should be made of probable silting rates by all feasible methods. The general lack of data and knowledge concerning the process does not permit very great accuracy, but judgment may reach reasonable conclusions by considering such "regional indexes" as are now available, the effectiveness of vari-sized reservoirs as sediment traps, the rate of erosion on the watershed, and the rate of sediment delivery by tributary streams. These factors all can be measured or estimated. Data already accumulated are of great value, and the continuation of such studies is highly desirable from the practical engineering viewpoint.

REMEDIES FOR RESERVOIR SILTING

Authorities generally agree that redemption of lost reservoir capacity is practically impossible, due to the nature of silt, its distribution in a large reservoir, and the usually large quantities present. The most practicable means of avoiding this loss are to prevent the formation of permanent deposits, and to control the rate of sediment production from eroding areas. When this cannot be done, sufficient storage space must be provided to compensate for depletion by silting during a reasonable economic lifetime.

Two general methods in use to remove silt from reservoirs after deposition are mechanical excavation, as practiced in the debris basins of California, and in some small municipal and industrial reservoirs; and removal of silt by sluicing above the dam.

Excavation.—Removal of silt by mechanical excavation involves high maintenance costs. It has been found feasible in California only because of the severe damages caused by debris flows from arid eroded watersheds. The basins are built especially to trap the debris, often comprising as much as 90% of the total flood volume. The sediment is removed from the basin by steam shovel, or other mechanical means, at a cost of about 30¢ per cubic yard. A related problem affecting costs is the disposal of the excavated material, which sometimes must be hauled several miles from the basin (30). The debris problem in California is unique, and the social and economic aspects differ considerably from the reservoir silting question in other regions. Mechanical removal of silt does not appear to have widespread practicability.

Sluicing.—Silt may be sluiced from a reservoir by the provision of small gates to drain the reservoir when seasonal requirements are low, thereby cutting away the deposited sediment above the dam; or by the provision of large flood gates which would pass the entire silt-laden flood flow, thereby preventing most of the deposition. The first procedure has not been effective generally, except in scouring out the deposits for short distances above the dam. Although used with "considerable success" on the Hambra and Hamiz reservoirs in Algeria, it has had little success with deposited silt in Bhatgurk Reservoir in India, and Zuni Reservoir in the United States (8). The second procedure eliminates the flood control value of the reservoir and merely passes the flood and silt problem to downstream areas. However, it has been found practicable in the irrigation reservoirs of Egypt, where the population of lower areas desires the fertilizing silt brought down from the Upper Nile River.

Use of density flows, previously described, may be considered a possible remedy analogous to sluicing, but the silt carried by such currents must be voided, before the density current comes to rest. Mr. Bell (25) suggests some interesting uses that might be made of density flows, which not only would result in voiding some sediment from the storage cavity, but would permit operating a large reservoir to provide silty water for the repair of leaky canals and the control of vegetation in channels. Knowledge of density flows in reservoirs is insufficient at present to indicate the extent to which they may be made to serve a useful purpose, but further study is warranted in determining remedies for reservoir silting.

Erosion Prevention.—Prevention of erosion, by checking sediment production at the source, appears to be the best remedy for minimizing the silting of a reservoir. It has been estimated that if all possible erosion-control measures were applied to the Colorado River watershed, a possible reduction of 15% to 20% could be made in the present silt load of the river, thereby adding 100 to 200 years to the life of the reservoir system (31).

Erosion-control measures are correctly termed "upstream engineering," as distinguished from "downstream engineering," which involves large dams and reservoirs and channel projects. "Upstream engineering" consists of reforestation, halting of gully growth by check dams and planting, contour plowing, regulation of crop and grazing practices, proper treatment of high embankments and cuts, and stabilization of stream banks.

One phase of reforestation that may also be applied near the reservoir is the planting of proper vegetation screens and the construction of earth barriers on the flats at the head of a reservoir and above the mouths of large tributaries. Such screens reduce the velocity of silt-laden inflows and cause valley deposition before the silt reaches the main cavity of the reservoir. The accidental introduction of tamarisk above Lake McMillan on the Pecos River in New Mexico in 1912 produced a dense screen over the entire upper end of the reservoir and for some 200 miles upstream The annual rate of sedimentation in the lake dropped from 13.30 acre-ft per 100 sq miles of drainage area in the period 1910–1915 to 0.98 acre-ft per 100 sq miles in 1925–1932 (1).

Desilting Works.—The desilting works of the All-American Canal at Imperial Dam were designed to desilt 15,000 cu ft per sec of water. The silted water is passed through circular stilling basins, with a maximum velocity of 0.24 ft per sec, and a detention period of 14 min. Only material larger than 300-mesh is removed. The deposited sludge has a water content of about 90%, and is removed at the center of the basins by means of circular scrapers and effluent conduits. Desilting removes an estimated five sixths of the silt load, and saves about $1,000,000 annually in canal maintenance costs (32). The use of desilting works of this type does not seem applicable to the prevention of reservoir silting itself, and appears practicable only when reservoir sedimentation is not sufficient for the purpose. It seems probable that "desilting" on a large scale may be secured more economically by vegetation screens previously mentioned.

Therefore it appears that the most certain means of maintaining reservoir capacity is to prevent sediment from forming, or, after formation, to prevent its deposition in the lake.

Henry M. Eakin and Carl B. Brown (1) state that:

> "Main reliance for material and permanent conservation of reservoir resources must rest upon control of sediment production at primary sources through more widespread and effective application of established methods of erosion control."

SUMMARY

To a great extent, evaluation of the sediment problem on a particular watershed remains a qualitative one, when the accuracy of available methods of analysis is compared with that of the more rigidly established branches of hydrology. The general aspects of the principal phases of reservoir sedimentation have been reviewed, perhaps too briefly, in an attempt to summarize the present status of knowledge and investigation. Recent developments attempt, with some success, to combine the empirical and rational procedures; their present complexity warrants retaining those empirical procedures which have been used successfully in the past.

Additional data should indicate the possibility of developing accurate "regional indexes" that may be applied to proposed reservoirs. Certainly, it would be desirable that a fund of data be accumulated in this field as in others involving natural phenomena. Although present methods of collecting data give a reasonable accuracy considering the highly variable factors involved, it is doubtful that engineers will be satisfied until the most practical and accurate methods of measurement and analysis are evolved. The required research and the collection of data are necessarily expensive and slow, but the return that may be reasonably expected should justify the expense. It is doubtful that total research costs to date could exceed a small percentage of the value of irreplaceable reservoir storage capacity already destroyed.

Knowledge of the physical quantities involved must lead to decisions concerning whether to provide additional storage space in a reservoir to insure its returning the investment costs and charges during its lifetime, or to undertake such other remedies as may be possible. The former course, if physically possible at a given site, is strictly an economic problem and usually can be evaluated easily. The latter course usually entails considerable additional expenditures, but it is also a sociological problem which can scarcely be neglected by an enlightened and progressive engineering profession.

The literature on the subject is extensive, and the Bibliography in Appendix II barely indicates the work accomplished or in progress. Yet unified data are meager, or often unavailable when the practicing engineer is suddenly faced with a problem on reservoir sedimentation. Often, then, he must make use of such approximate methods of analysis as readily present themselves, or, if he has sufficient time and funds in a unique case, make an independent investigation.

CONCLUSION

The present methods of studying sediment transportation and reservoir sedimentation are laying the foundations and accumulating the basic data required for a better understanding of the problem. Continued study should accelerate progress. Available data and methods, and known remedies, must suffice for immediate problems. It has been the writer's intention to review the problems involved and some of the solutions for them.

ACKNOWLEDGMENTS

The writer wishes to express his appreciation to all those listed in the Bibliography, and to those not listed, whose thoughts or ideas he may have assimilated and appropriated in a rather extensive reading of literature on the subject. He is further indebted to Lt.-Col. Harland C. Woods, M. Am. Soc. C. E., U. S. Engineer Office, Buffalo, N. Y., for his critical review of this paper, which was originally prepared early in 1942 for use within the U. S. Engineer Department. Revision for publication has involved practically complete rewriting, and some additional data and comments. The opinions expressed herein are the writer's and do not necessarily reflect the attitude of the U. S. Engineer Department.

APPENDIX I

NOTATION

The following letter symbols, used in the paper, conform essentially to American Standard Letter Symbols for Hydraulics,[3] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942:

---

[3] ASA—Z10.2-1942.

b = mean width of a stream; as a subscript it denotes "bed load";

C = general symbol for coefficients:

C_b = a constant in Eq. 5b, depending on the specific gravity and mechanical composition of the bed material;

C_k = an empirical coefficient in Eq. 1, depending on the kind of silt;

C_s = an empirical coefficient in a suspended sediment-rating curve;

C_T = "trap efficiency" coefficient for the reservoir;

c = velocity of a falling particle of sediment; as a subscript, c denotes "critical";

D = diameter: D_g = grain diameter;

d = a subscript denoting "total depth";

E = annual rate of erosion, or sediment production, on a watershed;

e = base of Napierian logarithms = 2.718;

G = rate of sediment movement, subscripts, b and s denoting "bed load" and "suspended load";

g = acceleration of gravity; as a subscript, g denotes sediment grain;

I = "regional index," an empirical coefficient in Eq. 6;

i = a subscript denoting "instantaneous";

N = sediment concentration, by weight, at any point in a vertical, at a distance y above the bottom: N_a = measured sediment concentration, by weight, at a sampling point in a vertical, distant y_a above the bottom;

n = Manning's roughness coefficient;

o = a subscript denoting the state at which bed-load movement begins;

P = ratio of mean sediment concentration in a vertical to sediment concentration at the bottom;

Q = total rate of water discharge: Q_i = total instantaneous discharge;

q = rate of water discharge per unit width of stream: q_o = value of q at which bed-load movement begins;

R = a subscript denoting "reservoir";

S = slope of the energy gradient of the stream at the time of measurement;

S_R = storage capacity of a reservoir: ΔS_R = annual rate of reservoir sedimentation;

s = a subscript denoting "suspended sediment";

T = a subscript indicative of the "sediment trap efficiency" of a reservoir;

t = dimensionless parameter in Eqs. 2 and 3;

V = velocity, subscripts m and c denoting "mean" and "critical," respectively;

W = total weight of sediment within a given size range in a unit width of stream;

x = a general symbol for exponent, defined in each case;

y = distance of any point in a vertical above the stream bed, definite points being further defined by subscripts;

z = relative depth of a point above the bottom = $\dfrac{y}{y_d}$;

Δ = annual rate; see ΔS_R.

DISCUSSION

Joe W. Johnson,[4] Assoc. M. Am. Soc. C. E.—An excellent discussion of the origin, transportation, and deposition of the sediments in reservoirs has been presented in this paper. Of interest to the writer is the section of the paper concerning the transportation of sediment to the reservoir. Some of the phases of this problem well may be extended in the light of recent investigations.

For practical considerations the total sediment load of a stream consists of three parts—the wash load (6), the coarse material in suspension, and the coarse material rolling or sliding along the bed. The equipment and method of calculation used in estimating these loads differ greatly. The wash load may be estimated very simply by continuous and frequent sampling during stream rises. In some instances, the use of distribution graphs of suspended-matter concentration (33) or turbidity data (34) may greatly simplify the labor of determining the load of wash material. The wash load is composed of relatively fine material and constitutes much the greater part of the material in a suspended-load sample. It may be regarded as sediment in relatively permanent suspension. The settling velocity of the wash material is very small, and, once the material is washed into a stream, it is transported completely through the stream system, by even the most feeble velocities, to the point of deposition. It is the wash material which probably constitutes the bulk of sediment that passes through reservoirs in muddy underflows. The quantity of wash material transported in a stream bears no relation to the discharge because the conditions of supply, which vary from year to year and season to season, are independent of flow conditions.

The author states (see heading, "Transportation of Sediment to the Reservoir: Bed Load") that "bed load, unlike suspended load, is directly related to the discharge at all times, because the sediment supply for the bed-load forces is nearly always available * * *." This statement which infers that no direct relationship exists between suspended load and discharge is true only when total suspended load is considered, but needs qualification when the loads of sediment of various size classifications are considered separately. The suspended load, including both fine and coarse material, is not directly related to the discharge because of the variability of the wash load. The coarse material in suspension, however, is related to the discharge because the supply of this material is always available, except, as stated by the author (see same heading), "on debris-clear rock-lined channels." An excellent illustration, showing how the coarser grades of sediment are related to discharge, is given by the extensive measurements of C. P. Vetter, M. Am. Soc. C. E. (35).

The author suggests the use of "silt-rating curves" in estimating the suspended load of streams. In such a practice, of course, it is assumed that the suspended load is directly related to discharge. The curves given by the author, along with the data of Messrs. Campbell and Bauder (16), indicate that an approximate relationship may be developed between instantaneous values of discharge and suspended load, presumably including both fine and coarse material. In these instances, the period of observation has extended over only two or three years when conditions of supply may have been approximately constant. In connection with the extensive sediment investigations on the Missouri River and its tributaries by the U. S. Engineer Office, silt rating curves were plotted for twenty-two stations (36). Except for the curve of the Kansas City station on the Missouri River, which has been published elsewhere (37), the curves for the various stations have not been published. These curves may be examined, however, in the office of the Chief of Engineers in Washington, D. C. Some of these curves show a usable relationship, as found for the Kansas City station, whereas other plots show such a large scattering of data that their use is of questionable value. As additional data to the information given in Table 4, the equation of the Kansas City curve reported by L. G. Straub, M. Am. Soc. C. E. (37), is

---

[4] Asst. Prof., Dept. of Mech. Eng., Univ. of California, Berkeley, Calif.

$$G_s = 30.42 \times 10^{-11} Q^{2.16} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

The minimum discharge was 20,000 cu ft per sec and the maximum discharge was approximately 187,000 cu ft per sec.

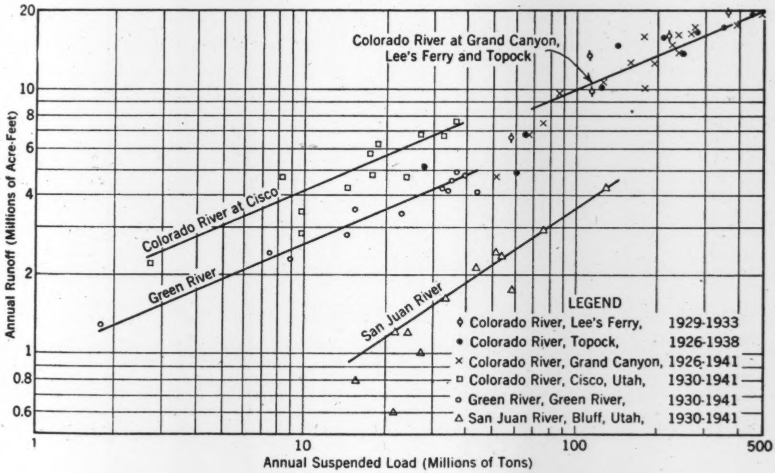

Fig. 4

For streams on which observations, extending over a period of several years, are available, a silt rating curve based on annual rates of runoff and sediment load shows some scattering of points but appears to give a more simple relationship for estimating the average annual suspended load. For example, Fig. 4 shows a plot of annual runoff and suspended load for the Colorado River and its tributaries as observed by the U. S. Geological Survey (38). These data were obtained for periods from twelve to sixteen years.

With the average annual runoff being estimated from long-term discharge records from the various streams, these curves can be entered directly to obtain the approximate average annual suspended load.

Although an estimate of the average annual contribution of suspended load of a stream requires considerable field and office work, an estimate of the average annual contribution of bed load can be made accurately and conveniently from the application of a suitable bed-load formula and a flow-duration curve. The author has suggested the Schoklitsch and the M.I.T. bed-load formulas, neither one of which has had the extent of verification in natural streams that the $(\phi-\psi)$-relationship (21) has had. The formulas expressed by Eqs. 5*a* and 5*b* include a "critical" discharge to describe the condition when movement of the bed material begins. "Unfortunately, this is a condition that does not exist in nature" (21*a*). In many instances, the magnitude of the critical discharge is negligible in comparison with the discharge under consideration and might just as well be discarded.

The author states (paragraph preceding heading, "The Action of Sediment in Reservoirs") that the Einstein functions "are quite complex, and do not readily permit estimates of bed load for the varied conditions met in the field." Admittedly, the functions are quite formidable in appearance on first examination. However, further consideration will show that many of the terms are constants, and calculations of the rate of bed-load transportation in a particular reach of a stream can be made quickly and conveniently from a few simply observed field data.

In the Einstein formula the intensity of transportation is given by the expression

$$\phi = \frac{q_b}{F(s_s - s_f)\,\gamma}\sqrt{\frac{s_f}{s_s - s_f}}\,\frac{1}{g^{0.5}\,D^{1.5}} \ldots\ldots\ldots\ldots\ldots (9a)$$

and is related to the hydraulic variable,

$$\psi = \frac{s_s - s_f}{s_f}\,\frac{D}{S_e\,R} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9b)$$

in which q_b is the rate of bed-load transportation in weight under water per unit width per second; F is a dimensionless factor in the Ruby equation for settling velocity and is a function of the representative grain diameter D; g is the acceleration of gravity; s_s and s_f are the specific gravity of the solid and fluid, respectively; γ is the unit weight of the fluid; S_e is the slope of the energy grade line; and R is the hydraulic radius of the bed.

For very wide channels—that is, where the energy dissipated along the banks is negligible compared to the energy dissipated along the bed—the ϕ-terms and ψ-terms can be used as follows to construct a set of curves or to prepare tables that show the rate of bed-load transportation per unit width as a function of either discharge or depth for various slopes and bed material. Thus, if $s_s = 2.65$, $s_f = 1$, and $\gamma = 62.3$ lb per cu ft, the ϕ-terms and ψ-terms may be written as follows:

$$\phi = \frac{q_b}{F\,D^{1.5}\,(1.65)^{1.5}\,(62.3)\,(32.2)^{0.5}} = \frac{q_b}{750\,F\,D^{1.5}} \ldots\ldots\ldots (10a)$$

and

$$\psi = \frac{1.65\, D}{S_e\, d} \qquad (10b)$$

in which d is the depth of flow. For a certain representative grain diameter (that is, the grain size at which 35% of the mixture is finer) and channel slope, values of ψ can be computed for various assumed depths of flow. From the Einstein curve showing the relation between ϕ and ψ, the value of ϕ corresponding to the computed value of ψ is obtained and the value of q_b is then computed. The total load, G_b, is $q_b\, B$ in which B is the channel width. A curve showing the relationship between G_b and depth of flow (or Q) may then be constructed. In the event that the friction along the side-walls cannot be neglected, the hydraulic radius of the bed should be used in place of the depth in the equation for ψ.

Field measurements by Mr. Einstein in 1941–1942 (39)(40) made on the rates of bed-load transportation in Mountain Creek near Greenville, S. C., and West Goose Creek near Oxford, Miss., using a portable measuring apparatus, have verified the $(\phi - \psi)$-relation previously developed from flume studies and have extended the range of application to $\phi = 10$. This range of application includes small streams and canals with fine sediment or large streams with coarse sediment.

A determination of the average annual volume of bed load transported by a stream may be obtained by using the relationship between discharge and rate of transportation in conjunction with the flow-duration curve of the stream (41). A table showing the frequency of occurrence of various discharges is prepared from the duration curve—that is, the total range in discharge is divided into a convenient number of parts and the percentage of time that the mean discharge in each part prevails is determined and tabulated. The number of seconds that each discharge prevails per year is computed. The amount of bed load that is transported per second for each discharge may be determined from the previously established relationship between discharge and rate of transportation. The rate of transportation for each discharge, multiplied by the total number of seconds that the particular discharge prevails per year, gives the annual amount of bed load for that discharge. The sum of the amounts of bed load for the various discharges gives the average annual weight of sediment transported as bed load. This annual load on a weight basis can be converted to volume by merely multiplying by the weight per cubic foot of the material.

On streams where discharge records are not available for the construction of a flow-duration curve, the duration curve for a neighboring stream (corrected for size of drainage basin) may be used because investigations have shown that the flow-duration curves are similar for various streams in a locality where topography, climate, and vegetation are similar.

JOHN W. STANLEY,[5] ESQ.—Studying the subject of reservoir silting and compiling data required much labor and time. Mr. Witzig is to be commended for his work in attempting to develop a method for predicting the sedimentation rate. It seems quite certain that any energy, time, and money spent in further study of the problem would be many times repaid by more efficient operation and longer life of reservoirs.

---

[5] Asst. Engr., Bureau of Reclamation, Denver, Colo.

Engineers and geologists have given much thought to the relationships among the many factors affecting the transportation and deposition of sediment, with the result that considerable progress has been made. Some facts have been established fairly well, and some promising theories have been advanced. In the process, however, a few conclusions, ideas, and suggestions have been submitted which later were found to be undesirable. Any investigator, in attempting to cover the subject by a perusal of pertinent literature, indeed would accomplish the impossible if he were able to weed out all the unacceptable statements. It is with this thought in mind, and with no intention of detracting from the value of Mr. Witzig's paper, that the writer wishes to call attention to the second paragraph under "Origin and Nature of Silt: Definition of Silt."

The statement in this paragraph that "When the vertical components of turbulence are sufficiently strong, no settling takes place" is somewhat misleading. The author undoubtedly intended the statement to mean that no sediment accumulates on the bottom. The present general belief, as pointed out by William E. Dobbins, Jun. Am. Soc. C. E. (42), and emphasized by Thomas R. Camp, M. Am. Soc. C. E. (42*a*), is that, except for possibly the very finest particles, there is a constant interchange between particles in suspension and those on the stream bed and that this will be true as long as there is any turbulence. It does not seem proper, therefore, to assume that no actual settlement occurs even when the vertical components of turbulence are very strong, although it is true that there might be no accumulation.

In the next sentence of the same paragraph Mr. Witzig refers to Mr. Einstein and to Alvin G. Anderson and Joe W. Johnson, Assoc. Members, Am. Soc. C. E., for this definition of bed load (6*a*): "* * * that part of the total sediment-load composed of all particles greater than a limiting size * * * whether moving on the bed or in suspension, and includes all bed-material in movement." Later in his paper, however, the author refers to bed load as the material moved by rolling along the bed, as distinguished from the material moving in suspension. The meaning actually used by the author is preferable. Bed load has been defined by a special committee of the Society (43) as "The silt, sand, gravel, or other detritus rolled along the bed of a stream," and long usage rather has fixed this meaning for the term. Although it is true that only material coarser than the "dividing grain size" is moved at a rate that is a function of the discharge, slope, etc., it is not necessarily feasible to ignore the fact that part of this material actually moves as suspended load and part as bed load. As someone has suggested, the natural term to use for material coarser than the "dividing grain size" would be bed-material load. By adopting this term and retaining the term bed load with its old meaning, much confusion may be avoided.

In the last sentence of the same paragraph Mr. Witzig refers to Table 2 for "the rate of settlement (7) of a particle in still water at 50° F." The rates in

Table 2 are questionable because those given for all particles except the 1-mm and 0.20-mm sizes are greater than the rates generally found for spheres with a specific gravity of 2.65. The rates are essentially the same as those given in a more extensive list by the late Allen Hazen, M. Am. Soc. C. E. (44). Mr. Hazen gave a table of "hydraulic values" for irregular grains (specific gravity approximately 2.65) of which "the diameters are taken as the diameters of spheres of equal volume." He determined these rates by actual experiment for particles from 1.0-mm to 0.10-mm diameter, by the Wiley formula from 0.02 mm to 0.0001 mm, and by interpolation from a connecting curve for particles between these two grades. His rates computed from the Wiley formula are approximately 200% of the rates given by the Stokes formula for spheres; those for particles 0.02 mm to 0.25 mm are greater, by varying amounts, than the rates for spheres (45); and those for 0.30 mm to 1.0 mm are lower than for spheres. Actually, any irregular particle should settle more slowly than a sphere of equal volume and specific gravity, because the irregular particle presents a greater surface area and hence has a greater resistance to motion than the sphere. In fact, if settling rates are to be used for denoting any apparent dimensions of irregular particles, extreme care must be exercised in selecting the rates for a particular type of material. A few workers besides Mr. Hazen have attempted to determine settling rates for irregular particles, and the results have varied widely.

Arthur Holmes (46) performed some experiments, in which he separated quartz grains by means of rising currents of water. The rates he determined are compared with the corresponding rates for quartz spheres in Table 6. A. Atterberg (47) determined rates for "fine sands" (Si O_2). He gave rates as the time required for particles to settle 10 cm in water and indicated that decantation or another elutriation process was used in making the determinations. He did not state the water temperature, but experiments on capillarity described in the same paper were performed at an approximate temperature of 17° C. The rates as indicated by his data, with corresponding rates for spheres, are shown in Table 6.

TABLE 6.—COMPARISON OF COMPUTED AND OBSERVED SETTLING RATES

(Units Are Millimeters per Second)

[a] Holmes rates determined at 15° C and Atterberg rates at approximately 17° C. [b] See reference (45) in Bibliography. [c] Stokes' formula.

E. C. J. Mohr (48) gives results of his own determinations and those of four other investigators, including Mr. Atterberg, for particles 0.06-mm diameter and smaller. All values are widely different except those of Messrs. Mohr and Atterberg, whose rates for particles 0.02-mm diameter and smaller are very close. No temperatures are given, however, and the apparent agreement therefore might be better or worse if temperatures were known.

C. K. Wentworth (49) desired to extend his sieve analysis curves into the sedimentation range and for this purpose chose certain "hydraulic values." He commented that his scale "has no precise theoretical justification," but that it approximates "the mean of several published tables by hydraulic values." Since he did not indicate at what temperature the values were to apply, it is impossible to compare them with other data. W. C. Krumbein (50) gives a brief résumé of the work of H. Wadell on settling velocities of nonspherical particles.

The writer has done some investigating on the subject and has found values for particles from about 0.03-mm diameter to 0.12-mm diameter. His values are somewhat lower than those of Messrs. Holmes and Atterberg. In the process of investigating the subject, a method was found which apparently permits reliable determination of values for any given material.

The chart, equation, and table developed by Mr. Witzig for use in estimating the rate of reservoir sedimentation are interesting and should be useful, especially if further refinements can be made as more data become available. Perhaps it would be desirable to change the method of designating the "envelopes." For example, it seems probable that, by classifying drainage areas according to average annual rainfall and average susceptibility to erosion, the envelopes might be narrowed and the "regional indexes" possibly changed to indexes according to rainfall and erosion characteristics.

That phase of engineering termed "upstream engineering" by Mr. Witzig is one that has been neglected much too often in the past. The engineer should not be relieved of the guilt of failing to take steps, where possible, to prolong the life of a reservoir by means of erosion control, even though he may be able to prove that the cost of the reservoir will have been repaid by the time its useful life is ended by sediment accumulation. It is to be hoped that in the future the problem of erosion control, as related to reservoir life, will be given more nearly the amount of attention merited by its importance.

Stafford C. Happ,[6] Esq.—Sedimentation in reservoirs is a complex problem, and, in his attempt to cover the subject in a single brief paper, Mr. Witzig appears to have given some citations which require further clarification. One such reference concerns the findings of the Soil Conservation Service (SCS) reported (3) in May, 1940.

Mr. Witzig (see heading, "Origin and Nature of Silt: Origin of Sediment") appears to contrast the estimate by Mr. Horton that "of the total erosion in the evolution of a humid drainage basin, probably 1% was initially bank erosion, and 99%, sheet erosion (2)" with the SCS studies which Mr. Witzig states "suggest that existing deposits within the flood plain of a stream are now often more important as immediate sources of sediment than concurrent sheet erosion, * * *." These two estimates apply to different conditions, but the second citation appears to be based on a misunderstanding of the actual findings.

---

[6] U. S. Engr. Office, Ocala, Fla. (formerly Geologist, SCS, Washington, D. C.).

The findings of the SCS originally were based on studies in northern Mississippi, but they have since been tested and confirmed in many places from the southeastern Piedmont to the Great Plains, and in the Ohio and upper Mississippi basins. In all these areas, as a general rule, concurrent sheet erosion is the principal source of reservoir sediment, and stream-bank erosion is of minor importance. As an average for the Central States and Southern States, where present information is most complete, the studies of the SCS would not support an estimate of more than 10% for the proportion of reservoir sediment derived from stream-bank erosion.

The relative importance of bank erosion may be greater in forested or mountainous areas, which have not been studied extensively by the SCS, but only in the Southwestern States (where enlargement of arroyos or ephemeral channels is very active) has bank erosion been found to be a principal source of reservoir sedimentation. This latter region is in arid or semi-arid country and on that account cannot be compared directly with Mr. Horton's estimates.

The SCS research did indicate that stream-bank erosion and gullying were major sources of the relatively coarse alluvial deposits which often cause damage to farm lands on the flood plain, but these sands and gravels seldom form any large part of reservoir deposits in the humid region because there are much greater quantities of silt and clay contributed to the reservoirs from sheet erosion on agricultural lands.

THOMAS H. MEANS,[7] M. AM. SOC. C. E.—The results of much recent research on sedimentation are brought together in concise form by the author. All the references in Appendix II, except (7) (9) (17) and (19), were published in 1933 or thereafter—the period of greatest reservoir building in the United States. It is no wonder the two activities have coincided because many problems of sedimentation are created by reservoirs, and it will be many years before all of them are solved.

One lack in recent studies of sedimentation rates, as illustrated in Fig. 3 and Table 5, is the scarcity of information as to the quantity of sediment deposited above the reservoir level. Deltas of noticeable size have been built upstream from some reservoirs, and certainly the change in stream grade which is created by the reservoir will affect other streams. Bridges and towns and occupied valleys along channels upstream from reservoirs will be affected, and it is to be hoped records will be kept so that the extent of changes can be determined. The writer has examined a number of reservoirs constructed recently where bridges will be menaced in a few years if the to-be-expected sequence of events follows. Owners of these bridges may be able to establish the cause of the increased menace if records are collected.

There seems to be a growing tendency to summarize all investigations in one formula. This may be helpful in understanding general relations but too often, when such a formula is used, the underlying data are not considered.

---

[7] Cons. Engr., San Francisco, Calif.

In the present state of knowledge several of the formulas presented by Mr. Witzig should be used with extreme caution or not at all. For example, Eqs. 2 and 3 are suggested as a short cut to sampling to determine the volume of sediment carried by a stream. A few samples run through this mathematical "mill" might produce results but not such as to inspire much confidence in an engineer who has observed silt-bearing streams in action.

Another example is the "silt-rating curve," also designed as a short cut to long sampling periods. The original paper in which this method was described (17) gives the following values of G_s for two periods on the Red River near Gainesville and the Washita River near Durwood:

Year	Red River near Gainesville	Washita River near Durwood
1936–1937	$1.04 \times 10^{-8} Q^2$	$9.2 \times 10^{-8} Q^2$
1938–1939	$3.85 \times 10^{-8} Q^2$	$2.7 \times 10^{-7} Q^2$

The differences between these two years (about 1 to 3) are too large to give one much confidence in this method of determining the flow of silt. One of the first things learned by an engineer, studying silt, is that the silt percentage does not always change as the flow changes.

The distinction between suspended silt and bed load still seems to be a matter of controversy. No phase of sedimentation has received more study, and today no phase seems to be in a greater state of uncertainty. There are many bed-load formulas but none seems to be valuable for all conditions. The writer was present many times when G. K. Gilbert was conducting his classic experiments at the University of California at Berkeley, and ever since has lived in hopes that someone would produce a usable method of determining the movement of sediment along the stream or canal bed. So far no such method has come to his attention. Bed load becomes very important in any study of sedimentation in reservoirs. For example, the Arkansas River is a great carrier of sand, as the manager of any canal diverting from it knows. What will be the result of Caddoa Reservoir on the movement of this sand and how will the bridges across the stream and the town of Lamar, Colo., be affected? There is an opportunity to collect much usable data from these new reservoirs, and it is to be hoped the Army Engineers will collect information systematically on changes in the bed upstream from reservoirs and of the delta formations that will build up at the point where the flow is checked.

The stream downstream from reservoirs, cleared of sediment, also will create new conditions. The Bureau of Reclamation is making very careful surveys of the Colorado River below Boulder Dam, as revealed by its Eighth Annual Report.

Carl B. Brown,[8] Esq.—The control of reservoir silting will constitute one of our most important problems of conservation in the postwar period. Construction of impounding reservoirs during the decade 1933–1943 has been a major item of public works. Reservoirs under construction in the United

---

[8] Head of Sedimentation Section, SCS, U.S.D.A., Washington, D. C.

States in 1941 will have cost, when completed, more than $1,000,000,000, compared to a total investment in reservoir storage during the past hundred years of about $5,000,000,000, not including the dependent developments in filtration plants, power transmission lines, irrigation canals, etc. There is every reason to believe that reservoir construction will be accelerated beyond any previous levels as soon as the Nation can return to peaceful pursuits. For these reasons Mr. Witzig's paper is of timely interest.

The direct annual loss in investment from reservoir silting is not less than $10,000,000 and is more likely several times that amount. Therefore, a more widespread understanding of the silting problem is obviously needed. Control of silting begins when the dam design takes shape on the drawing board. Many reservoirs built in recent years have suffered rapid loss because their storage capacity, although adequate to meet water needs, was much too small to accommodate the sediment load of the inflowing stream—even until the project was amortized. Furthermore, the increasing knowledge of sediment-laden density currents and of other silting phenomena indicates that properly designed and operated outlets in many dams would reduce the rate of silting substantially. The design of future dams and reservoir projects should include a thorough study, so often lacking in the past, of the effects of silting. No less attention should be given to methods of conserving the reservoir storage already developed.

Of the topics which Mr. Witzig discusses, "Estimating the Rate of Reservoir Sedimentation" is, perhaps, of the most practical importance to the designing engineer. Unfortunately, Eq. 6 and the envelope curves shown in Fig. 3 are misleading. They imply that the annual rate of sedimentation, in acre-feet per 100 sq miles of drainage area, ΔS_R, is a function of the original storage capacity, in acre-feet per square mile, S_R, and increases with it. If this were so, the rate of sedimentation at a given site would increase indefinitely with the size of the reservoir. Obviously this is not possible since the upper limit of sedimentation depends on the amount of sediment brought in by the streams, which is independent of the size of the reservoir.

If a reservoir with $S_R = 100$ traps 90% of the incoming load and $\Delta S_R = 47$, as shown by median curve IV in Fig. 3, a reservoir at the same location with $S_R = 500$ could have a value of ΔS_R not greater than 52.2, which would represent 100% deposition of all the stream load. Curve IV would appear to indicate, however, that, where $S_R = 500$, $\Delta S_R = 175$. Actually, ΔS_R is a function of several independent or partly interdependent variables; for example:

$$\Delta S_R = f(E_n, S_R, S_h, S_c, Q_c, O_R, \cdots \text{etc.}) \qquad (11)$$

in which: ΔS_R = annual rate of sedimentation; E_n = annual net watershed erosion, or sediment inflow to reservoir; S_R = reservoir storage; S_h = shape of reservoir; S_c = sediment characteristics, including textural composition and behavior under influence of dissolved load, temperature, etc., in forming density currents; Q_c = discharge characteristics of inflowing stream; and O_R = manner of operation of the reservoir. The symbols ΔS_R, E_n, and S_R are expressed in the same volume units per unit of drainage area (such as acre-feet per square mile).

The trap efficiency coefficient of a reservoir is best defined simply as the percentage of incoming sediment trapped:

$$C_T = 100\left(\frac{\Delta S_R}{E_n}\right) \qquad (12)$$

in which case C_T cannot exceed 100. From this relationship it is apparent that:

$$C_T = f\left(\frac{S_R, S_h, S_c, Q_c, O_R, \cdots \text{etc.}}{E_n}\right) \qquad (13)$$

Of the factors in the numerator only S_R can be assigned a definite value from data generally available. Furthermore, few and none too reliable data have been collected on actual values of C_T as defined in Eq. 12. The data that are available to the writer have been plotted in Fig. 5.

It is apparent from general considerations that any curves defining trap efficiency must pass through the origin and approach $C_T = 100$ asymptotically. Envelope curves enclosing the data in Fig. 5 may be defined by an equation of the form:

$$C_T = 100\left(1 - \frac{1}{1 + dS_R}\right) \qquad (14)$$

The spread of the curves is due to the effect of the variables, other than S_R, on which C_T depends. Therefore, the sum of effects of these variables is expressed in the range in value of the coefficient d, from 0.046 for the lower curve to 1.00 for the upper curve. Existing information indicates that the middle curve should represent a satisfactory approximation of the average relationship of C_T and R_S for reservoirs other than those used solely for flood detention. This average, or design, curve has the equation:

$$C_T = 100\left(1 - \frac{1}{1 + 0.1\,S_R}\right) \qquad (15)$$

Values of d tend to lie near the upper curve for: (*a*) Reservoirs in regions of smaller and more variable runoff; (*b*) reservoirs whose length and shape tend to reduce the time of flow through them; (*c*) reservoirs on watersheds which produce mainly coarse or highly coagulated sediments; and (*d*) reservoirs which are so operated as to release little water from the bottom of the dam or to hold back and store flood flows. Where $S_R > 100$, such a large proportion of the sediment is trapped that this factor generally may be ignored.

Substituting the value of C_T from Eq. 12 in Eq. 15, and transposing, it is found that, for an average reservoir:

$$\Delta S_R = \left(1 - \frac{1}{1 + 0.1\,S_R}\right) E_n \qquad (16)$$

The difference between Eq. 16 and Eq. 7 is that the latter is based on data from a paper by Messrs. Brune and Allen (4). Their letter symbol E does not denote the sediment load entering the reservoir, but is an estimate of gross erosion based on conservation surveys made by the Soil Conservation Service (SCS). These surveys are not intended to measure net watershed erosion volumetrically, but rather to show, among other things, the degree of soil loss from the land surface as this affects land use for agriculture and other purposes. These surveys do not ordinarily show stream-bank erosion, road erosion, or fan, colluvial, and flood-plain deposition in a form by which the quantity so eroded or deposited can be calculated. However, a rough volumetric approximation of soil loss from the land surface can be made from these surveys, and this is a fair measure of gross erosion, E_g, in most areas. The relation of E_n to E_g, as estimated from conservation surveys, varies within wide limits. Strictly, E_g should be a measure of the volume of all soil moved from place within the watershed per unit area, per unit time, regardless of where the resulting sediment is deposited. In drainage areas where sheet and gully erosion are slight and most of the sediment comes from stream-channel erosion, E_n may equal or exceed $2\,E_g$. In most watersheds, however, E_n is much less than E_g. In some of the watersheds used by Messrs. Brune and Allen, $E_n < 0.2\,E_g$. In general terms:

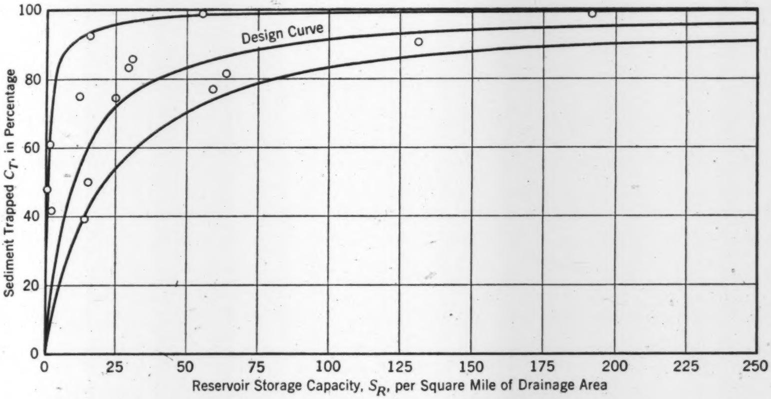

FIG. 5.—RELATION OF RESERVOIR TRAP EFFICIENCY, C_T, TO RESERVOIR STORAGE CAPACITY, S_R

$$E_n = C\,E_g \qquad (17)$$

In Eq. 7, therefore, C_T is not a true "trap efficiency" coefficient for the reservoir; it is a coefficient that depends on two independent variables—the true trap efficiency of the reservoir, defined by Eq. 14, and the coefficient C in Eq. 17. The relation between gross erosion on a watershed and rate of reservoir sedimentation may be defined by

$$\Delta S_R = \left(1 - \frac{1}{1 + dS_R}\right) C\,E_g \qquad (18)$$

but careful watershed surveys will be required to determine the value of the coefficient *C*.

It will be apparent from this discussion that there is no simple exponential relationship, as in Eq. 7, between ΔS_R and S_R. Regional envelope curves plotted on logarithmic paper would not be straight lines, as in Fig. 3, but curved lines approaching asymptotically some limiting value of ΔS_R with increase in S_R.

Someday, perhaps, data will be sufficient to develop an equation relating ΔS_R to all of the variables on which it depends. For the present, however, it seems desirable to plot ΔS_R against some one easily determinable variable, such as size of drainage area, A_D, for each geographic region of essentially similar soils, slopes, climate, and land use. The resulting spread of data represents the influence of other variables, but the spread is not too wide to preclude use for practical design purposes. In other words, there is a limit to the range of debris production per unit of drainage area.

In Fig. 6 is shown a logarithmic plotting of ΔS_R, in acre-feet per square mile per year, against A_D in square miles. Values for all the reliable data on reservoir sedimentation and suspended loads from the Southern Piedmont and immediately adjacent parts of bordering physiographic provinces have been plotted, except that reservoirs where $S_R < 15$ have been omitted to minimize the effect of C_T, for which no corrections have been made. Suspended-load data were converted to acre-feet by assuming a specific weight of 50 lb per cu ft. Envelope curves have been drawn to bound the data, and a median curve has been drawn "by eye." The single point outside the upper limiting curve represents Greenbelt Lake, Greenbelt, Md., where abnormal sediment production from an 0.83-sq-mile drainage area resulted from construction of a housing project (51). The envelope curves may be spread by future data, of course, but probably not much. The mean curve probably will not be changed appreciably by more

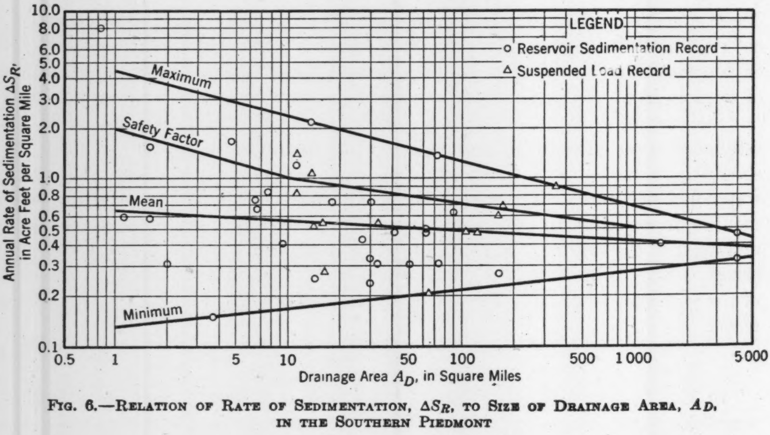

FIG. 6.—RELATION OF RATE OF SEDIMENTATION, ΔS_R, TO SIZE OF DRAINAGE AREA, A_D, IN THE SOUTHERN PIEDMONT

data. These data appear to show that, in the Piedmont, the larger the watershed, the more limited is the range of ΔS_R, and that the mean rate decreases somewhat with size of watershed.

It should be recognized that use of the mean curve in a design problem allows no "safety factor." An erosion and sedimentation reconnaissance of the particular watershed, comparison of observed watershed characteristics with those of watersheds from which sediment data are available, careful study of the methods of water release and waste, and other factors influencing trap efficiency of the proposed reservoir should indicate whether a value above or below the mean should be chosen. Lacking such a study, the writer would recommend use of the reasonable "safety factor" curve.

Once regional charts, such as Fig. 6, are compiled, the annual rate of storage loss can be estimated by substituting values for ΔS_R in the equation:

$$\Delta S_L = 100 \left[\frac{\Delta S_R \, (A_D)}{S} \right] \qquad (19)$$

in which: ΔS_L = annual percentage rate of storage loss; A_D = drainage area, in square miles; ΔS_R = annual rate of sedimentation, in acre-feet per square mile of drainage area; and S = storage capacity of reservoir, in acre-feet.

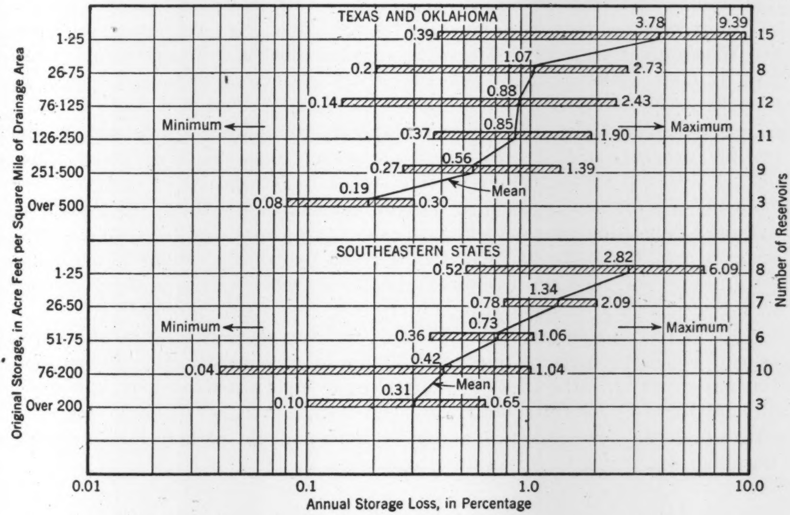

FIG. 7.—RELATION OF RESERVOIR STORAGE CAPACITY, S_R, TO RATE OF STORAGE LOSS, S_L

Except for flood detention basins and reservoirs where $S_R < 15$, there is generally no justification, in the light of present data, to consider trap efficiency separately. Its effect is well within the spread of the envelope curves, and it is taken into account in the "safety factor" curve.

In Fig. 7 is shown the relationship of the storage-watershed ratio, S_R, to the annual silting rate ΔS_L for two regions where most data are now available. This illustration reveals the range and mean values of annual storage depletion of representative reservoirs grouped according to values of S_R.

Mr. Witzig makes the statement (see heading, "Estimating the Rate of Reservoir Sedimentation: 'Regional Indexes'") "that reservoirs surveyed thus far are more typical of severe rather than of average conditions." Actually, the reservoirs that furnished the data used in Fig. 3 are a representative cross section of important reservoirs in the regions they represent. More than 150 detailed and 250 reconnaissance reservoir surveys have been made by the SCS since 1934 for the purpose of obtaining a representative sampling of silting conditions and developing the factual basis necessary for planning silting-control measures. The average regional conditions shown are conservative because the sampling did not give sufficient weight to the hundreds of smaller reservoirs with low values of S_R that are now more than 50% filled with sediment, where it is too late or uneconomic to undertake silting-control measures. However, only a few surveys, or none, have been made in New England, the Great Lakes region, the Northern Great Plains, and certain parts of the Rocky Mountains and Great Basin. With the exception of these areas, the existing reservoir data fairly represent silting conditions in the economically important impounding reservoirs of the United States.

Many methods have been tried for the control of reservoir silting, of which Mr. Witzig describes a few. The writer (52) has classified all methods of control into six major categories: (1) Selection of the reservoir site to avoid areas of excessive sediment production wherever possible; (2) design of the reservoir, which includes proper adjustment of capacity to watershed area and, where feasible, provision of outlets for sediment release; (3) control of sediment inflow by (*a*) settling basins, (*b*) vegetative screens, (*c*) location of reservoir off-channel, and (*d*) construction of by-pass canals and conduits; (4) control of sediment deposition by (*a*) venting density currents, and (*b*) control of waste water release; (5) removal of sediment deposits by (*a*) excavation, (*b*) dredging, (*c*) draining and flushing, (*d*) sluicing with controlled water, and (*e*) sluicing with hydraulic and mechanical agitation; and (6) watershed erosion control.

Mr. Witzig's paper is a valuable addition to the growing literature on various aspects of the problem of reservoir silting and its control. It is hoped that this paper will have the effect of stimulating interest among owners, operators, and designers of reservoirs, both in ascertaining the extent of silting in reservoirs with which they are concerned, and in studying possible methods for controlling the ill effects of this too often unrecognized menace.

C. S. JARVIS,[9] M. AM. SOC. C. E.—During more than two decades following the publication of the paper and discussions dealing with an irrigation reservoir that had lost 60.7% of its capacity in 12½ years (53), much progress has been made in the study of sedimentation phenomena and of the most promising means for their control or prevention in some degree. In spite of the notable progress accomplished by both federal and local agencies in the fields of soil conservation, channel stabilization, runoff regulation, and other activities designed to insure the utmost beneficial use of water resources along with adequate protection from the increasing flood menace, most of the required work yet lies ahead.

---

[9] Cons. Engr., Washington, D. C.

The paper under discussion affords a brief review of the situation and reflects diligent research and mature mental processes, along with an earnest effort to improve the outlook for the maintenance of reservoir capacities. Both Fig. 3 and Table 5 are forward steps in summarizing the findings of the Soil Conservation Service for various regions of the United States, indicating that the regional indexes are not so diverse as might have been expected in view of the wide range in climatic, rainfall, and runoff factors.

The alert irrigation farmer applying from 4 in. to 6 in. of turbid flood water on his field realizes that much fertility may be added thereby. If the thickness of the new sedimentary deposit happens to be ¼ in., he knows that from 4% to 6% by volume was carried by the irrigation lateral, in spite of all the deposits in the main canal system. Each farm is potentially a kind of hydraulic laboratory, if accurate and adequate records are kept.

Likewise with the stockwatering pond, especially if it is founded on gypsum-bearing or other highly permeable formation, the initial fillings may rapidly disappear through infiltration. The obvious corrective measure is to provide some kind of waterproof lining, such as clay or sand-clay mixture, preferably water-borne and deposited. Small reservoirs adequately lined in this manner have proved to be as retentive as if they had been waterproofed by much more expensive methods. Furthermore, the losses in the distribution canal system may be greatly reduced by the sedimentation processes. Where the need is great enough, it may be advisable to dump clay into a canal section for conveyance and puddling along the permeable reaches.

Wherever an irrigation supply has been deprived of its normal silt and sediment burden, either through intervening storage reservoirs or through the attainment of the ideal of effective erosion control or virtual prevention, the problem of restoring some of those elements for the aforementioned benefits is worthy of consideration. Some means of agitating the finest of the sediments within a storage reservoir, and delivering them to the irrigation canals serving lands that would be benefited by the addition of such sediment, might be devised with due regard to such regulations as the Biological Survey would necessarily impose.

In some locations, the gravel and sand deposits at the head of a reservoir might be used as a source of construction material; and the excavation resulting from such activity would serve as a trap for the next season's bed load, in the same manner as is intended for debris basins.

Now that fertile topsoil is becoming appreciated at somewhere near its true value, justifying its removal and storage in huge mounds, awaiting replacement as the final operation of some grading projects, it would appear that the finest sedimentary deposits in large storage reservoirs may have some commercial value within the range of cheap transportation, especially if waterways are available.

Hugh Stevens Bell,[10] Esq.—Under the heading, "The Action of Sediment in Reservoirs: Density Flows in Lake Mead," Mr. Witzig attributes to the writer (25) an estimate that "silt-laden density flows in Lake Mead carry about 24% of all sediment deposited in the lake." For the sake of accuracy it seems desirable to quote directly from the passage cited by Mr. Witzig (25), omitting any parts not pertinent to the present discussion:

> "Density currents * * * were transporting fine sediments into lower Lake Mead at the rate of 875,000 tons per week during the 61 months immediately following the closing of the (diversion) tunnel on May 1, 1936. * * * If it is assumed that these sediments will eventually compact to 60 pounds per cubic foot, the density currents are transporting material sufficient to occupy 1 percent of the original spillway-crest capacity each 8.2 years.* * *
>
> "To see what this might mean in terms of the total life of Lake Mead, assume that, under present conditions, the reservoir will become completely filled with sediments in 200 years. According to the estimates above, material transported by density currents will occupy approximately 24 percent of the original storage space at that time, provided that none is discharged, and the average concentration has become 60 pounds per cubic foot."

The 24% figure, then, is based upon two assumptions—(1) that density current deposits will contain 60 lb per cu ft of sediment and (2) that Lake Mead will be completely silted up in 200 years. These assumptions were not estimates based upon ample data. They were values chosen because they were convenient and conservative. Therefore, the 24% should not be used, as Mr. Witzig has used it, as a measure of the sediment carried by density currents in terms of the total sediment load brought to Lake Mead. The pertinent value is 875,000 tons per week, or, roughly, 45,000,000 tons per year. In 1928 Messrs. Fortier and Blaney estimated that a reservoir at Boulder Canyon would receive 253,628,000 tons of sediment per year (9). On this widely accepted estimate, the 45,000,000 tons transported annually by density currents would represent, roughly, 18% of the total.

Actually, there is no reason to expect that the fine sediment in lower Lake Mead will attain a mean specific weight that even approaches 60 lb per cu ft during the lifetime of the Boulder Dam project. The several hundred samples taken by the Bureau of Reclamation indicate that a value of 30 to 35 lb is a much more probable one (54).

Before the importance of density currents in the sedimentation of Lake Mead can be evaluated, a reasonable estimate must be had for the mean specific weight of all sediment deposited there. In 1930 Mr. Blaney stated that differences in opinion on this point had resulted in estimates ranging from 80,000 acre-ft to more than 250,000 acre-ft for the average annual volume of sediment that would be deposited. Although a value of 85 lb per cu ft had gained wide acceptance in engineering circles, Mr. Blaney expressed the opinion that 62.5 lb would prove to be approximately correct (55).

At 85 lb per cu ft the estimated annual sediment load of 253,628,000 tons would occupy 137,000 acre-ft. At 30 lb per cu ft, the 45,000,000 tons of this material that is carried into the lower part of the reservoir by density currents will occupy about 70,000 acre-ft, or more than half of the total. Therefore, the sediments not carried by density currents would occupy only 67,000 acre-ft, and would have a specific weight of 143 lb per cu ft. This is an absurd value.

---

[10] Associate Soil Conservationist, U. S. Dept. of Agriculture, SCS, California Inst. of Technology, Pasadena, Calif.

At 62.5 lb per cu ft the total sediment load would occupy about 186,000 acre-ft, of which the 70,000 acre-ft of density current deposits would constitute 37.6%. Sediments not carried by density currents would occupy the remaining 116,000 acre-ft, and would have a mean specific weight of slightly less than 83 lb per cu ft. Although the future may show that even this value is somewhat high, it seems to be a reasonable one.

It may be estimated with some confidence, then, that density currents are transporting not 24% of all sediment at Lake Mead, but from 35% to 40% of it in terms of the volume after deposition.

Not only do density currents transport those sediments that form deposits with specific weights that are very low, but also, by sorting and carrying away the fine particles that would fill a part of the interstices in the sediments left behind, they decrease the specific weight of even the coarser deposits. The economic importance of density currents, therefore, is tremendous. If it were possible to operate the reservoir so that 50% of the sediment carried by density currents could be vented, rather than stored, the life of the project would be increased by approximately 25%. The seemingly insurmountable obstacles that prevent this from being accomplished are human, not physical ones.

Mr. Witzig states (heading, "The Action of Sediment in Reservoirs: Formation and Dispersion"), "The loss of energy as the stream enters the reservoir is not generally sufficient to prevent the formation of a density current." This statement is correct, but may give a false idea as to the type of energy that produces density currents. It is kinetic energy that a river loses or releases upon entering a reservoir. Since this type of energy causes mixing between the river water and the reservoir water, the more of it there is available the less chance there is for a river to become a density current. If there is enough kinetic energy to make a homogeneous mixture of the river water and all the water stored in the reservoir, there can be no density current because there will not be two adjacent fluid masses of approximately equal density. On the other hand, if the kinetic energy is not sufficient to produce such a mixture, the river water may still possess great potential energy because, although it has been diluted by entrance mixing, it has a density that differs from that of the unmixed reservoir water. It is this potential energy, rather than any residual kinetic energy, that makes density currents possible.

HARRY F. BLANEY,[11] M. AM. SOC. C. E.—For many years engineers have recognized the need for more definite information concerning the silting of reservoirs under varying conditions. The author has raised this question again and his paper indicates the need for further research in the prevention of sedimentation in reservoirs. The writer believes, however, since determinations of silt content of river water usually are made on a weight basis, that the presentation of more data on the relation of volume and weight of silt would add to the value of the paper. Such information is needed to convert the results of silt samplings on a weight basis to volume, as the engineer is more interested in the volume of sediment than its weight.

---

[11] Senior Irrig. Engr., Div. of Irrig., SCS, U. S. Dept. of Agriculture, Los Angeles, Calif.

Under "Origin and Nature of Silt: Definition of Silt," the author states that Mr. Fortier and the writer "recommend for the Lower Colorado a specific weight of 62.5 lb per cu ft for suspended silt, and 85 lb per cu ft for deposits in reservoirs." These estimates were made in 1926. Since then additional information has been collected by various agencies. In 1929 the writer called attention to the fact that differences in opinion as to the weight of 1 cu ft of silt have resulted in estimates of the average volume of suspended silt that would be deposited annually in reservoirs on the Colorado River ranging from 80,000 to more than 250,000 acre-ft per yr (55). At that time the writer was of the opinion that the specific weight of sediment deposited in the bottom of a reservoir created by a high dam at Boulder Canyon would be approximately 62.5 lb per cu ft, provided the deposits were not given an opportunity to dry out and thus destroy their colloidal condition.

The quantity of material deposited in a reservoir that will be affected by alternate drying and wetting is difficult to estimate. When the water level of a reservoir is lowered, material deposited in the upper part of the reservoir will be uncovered, and, upon drying, undoubtedly will shrink in volume. Mr. Faris reported (22) that, in Texas, material deposited under reservoir conditions, and remaining submerged, contained 30 lb or less of dry materials per cubic foot of deposit, whereas material similarly deposited and then subjected to shrinkage through exposure contained in excess of 80 lb of dry material per cubic foot of deposit. These silt load studies have been continued by Dean W. Bloodgood of the Division of Irrigation, SCS, in cooperation with the Texas Board of Water Engineers. In a progress report (56) Mr. Bloodgood states that

> "* * * the average weight of the dry material in silt deposits which are continuously submerged approaches 30 pounds per cubic foot. In those deposits which are occasionally exposed, the average dry weight approaches 70 pounds per cubic foot. In deposits where reservoirs are used exclusively for flood control, the average weight ultimately approaches 90 pounds per cubic foot. After a careful consideration of the volume-weight ratios of silt samples in different degrees of consolidation together with the fact that an indeterminable volume of vegetable matter in the form of logs and brush deposited in reservoirs becomes water-logged and lasts indefinitely, seventy (70) pounds was selected as the average ultimate weight of the dry material per cubic foot of deposit in reservoirs where the deposits are subjected to alternate wetting and drying."

The studies of stratified flow in reservoirs by Mr. Bell, mentioned by the author (25), illustrate the need for further research on the sedimentation in reservoirs. Investigations of density flows may provide the means of prolonging the life of large reservoirs.

Since the author's paper was published, the SCS has issued a new publication (52), in which all the known methods of silting control, as described in a rather voluminous but widely scattered literature, and as recorded in the sedimentation studies of the SCS, have been analyzed and classified. This bulletin includes references to some 138 reports. A review of this publication is recommended to those interested in information on methods of controlling or reducing excessive silting in impounding reservoirs.

A. L. Sonderegger,[12] M. Am. Soc. C. E.—The accelerated rate of reservoir construction in the United States since about 1910, together with the marked loss of storage space within a comparatively short period in many of these structures, has focused the attention of engineers on the problem of reservoir sedimentation. Two thirds of the thirty-two papers in the Bibliography of this paper were published since 1938. Kindred subjects were discussed at the July, 1943, meeting of the Society in Los Angeles, Calif., by the U. S. Geological Survey (57),[12b] and in recent special reports issued by the Soil Conservation Service.

The origin and nature of sediments have been described in this paper and in other papers, and records of the rate of debris deposition are available for a large number of representative watersheds. Hence, it is possible to forecast with some degree of probability the rate of sedimentation which may take place in structures, directly intercepting flood waters. However, a reconnaissance of physiographical and geological conditions and of the effect of the invasion of the watershed will be required.

Under the heading, "Remedies for Reservoir Silting," the author correctly states that authorities generally agree that redemption of lost reservoir capacity is practically impossible. In this connection, he mentions the removal of debris in Southern California by mechanical excavation, a process feasible with relatively shallow reservoirs in open terrain; the removal of silt deposits by sluicing which has been practiced with partial success; and last, but not least, the utilization of density flows. Since full redemption of lost capacity is not feasible, the question then arises as to what extent sedimentation may be prevented or controlled.

The basic causes of debris production are the disintegration and decomposition of rocks. These processes are as old as the hills, and nothing can prevent them; nor can the removal of debris by periodically occurring storms and concomitant runoff be stopped. Production of debris and erosion are at a minimum when a watershed is protected by its natural vegetal cover. Under such conditions a natural physiographic balance is maintained, and probably attempts by man to improve on these conditions would not be successful. Nature apparently is operating under the principle of self-conservation which automatically adjusts itself to varying conditions, climatic and physiographic (58).

Invasion of the watershed; effects of deforestation, overgrazing, cultivation, unstable slopes in road cuts; and other methods have generally tended to upset nature's balance and to increase sediment production and removal. The writer is impressed with the benefits that ultimately will result from the recent practice of erosion control initiated by the Soil Conservation Service to correct the destructive effects of land abuse. Many of the methods designed to restore the vegetal cover will become fully effective only after persistent efforts over periods of years. However, the long-range results should fully justify the expenditure.

---

[12] Cons. Engr., Los Angeles, Calif.

The author concludes (see "Remedies for Reservoir Silting") that "the most certain means of maintaining reservoir capacity is to prevent sediment from forming, or, after formation, to prevent its deposition in the lake." Although this theory is unquestionably correct, generally, it is not practicable. In this connection, the author has quoted Messrs. Eakin and Brown (1) as follows:

> "Main reliance for material and permanent conservation of reservoir resources must rest upon control of sediment production at primary sources through more widespread and effective application of established methods of erosion control."

This statement may apply to the disturbed watershed, but hardly to natural conditions. Since debris production cannot be reduced below its natural minimum, the preservation of water storage must rely mainly on the creation of separate space for sediment storage.

In many storage reservoirs, debris space has been created by raising the height of dams. On the other hand, storage and detention projects in large numbers have been constructed on silt-carrying streams without any provision whatever for preserving the integrity of the hydraulic function. The results have been little short of disastrous in many cases, not only because of the loss of the investment, but also because of the scarcity of reservoir sites.

In any storage project where sedimentation is a factor, provision for the long-time disposal of debris should be made part of the original project and should be included in estimates of costs and in budgets. The plans may contemplate additional height of dam, "upstream engineering" by the construction of a series of permanent debris barriers, provision for deposit grounds for sediments eventually to be removed, or other methods.

The author states (see heading, "Introduction") that "Studies by the Soil Conservation Service (SCS) of the U. S. Department of Agriculture (1) show that, in the silt-carrying streams of the United States, the probable life expectancy of existing reservoirs is dangerously short" and "* * * that about 64% of all reservoirs have useful lives of less than 100 years, * * *." Thus, a reduction of 80% in the capacity of a reservoir is assumed to terminate its useful life.

On the basis of these findings, the broad rule might be established that, in order to safeguard the storage supply of a community in the semiarid regions for 100 years or more, debris storage must be provided in volume equal to, or exceeding, the water storage. This is a "large order" and may be hard to fill; but it epitomizes the seriousness of the problem.

Although such provisions are not remedies, they tend to postpone the day of reckoning. Acting in accordance with the best available knowledge, engineers at least will escape the condemnation that was heaped on Louis XV when he shrugged his shoulder, saying "After us the deluge." It might be well to recall the fate that befell his grandson barely 35 years later during the French Revolution. The wise man has said that history repeats itself.

Coming generations may see more clearly and deeply into the true nature of things and find the solution that will save them from the fate suffered by some of the older civilizations in the semiarid regions.

The author is to be commended for the presentation of an excellent and condensed review of a complex problem.

L. STANDISH HALL,[13] M. AM. SOC. C. E.—By assembling the available data bearing on all phases of the subject of reservoir sedimentation, Mr. Witzig has rendered a valuable service to the profession.

Under the heading, "Origin and Nature of Silt," Mr. Witzig describes sheet and bank erosion as the principal sources of reservoir silting. The relative importance of these two factors on any watershed depends largely on the gradient of the main channel, although in some instances other effects may govern. In streams having a flat slope, the sediment carried by the tributaries will be dropped in the main channel resulting in aggradation. Then, reservoir sedimentation is caused by a reworking of these sediments in the stream channel. When the slope of the main channel is steep, the sediment fed into it by the tributaries will be carried along by the velocity of the current and the dynamic action of the water will cause excessive bank and bed erosion by abrasive action. In such cases, the erosion effect of the sediment is cumulative, increasing as the water proceeds downstream until a saturation of the sediment load is reached.

Other sources of erosion not mentioned by the author, but quite prominent in the Coast Range of California, are landslides and earth flow, particularly when these occur along stream channels. The toe of a slide which encroaches on the waterway is eroded by the flowing water causing a progressive movement of the slide into the channel. When landslides are not cut by water courses, the erosion of the slide may be negligible. In such cases, the landslip merely results in the mass movement of the soil from a higher to a lower level (59).[13b]

Erosion from highway construction is also an important factor. Much of the current highway practice of discharging water from small culverts with a free drop to the downstream end, or of failing to provide a basin at the outlet end of large culverts in which to dissipate the energy of the high velocity discharge through the culvert, has added many tons of sediment to stream channels.

Under the side heading, "Definition of Silt," the author cites a weight of 85 lb per cu ft for deposits in reservoirs. This value appears to be rather high unless the sediment in the reservoirs has been reworked and subjected to exposure and drying. Tests, by the writer, of samples of silty sand deposited by stream channels on their flood plains indicated a percentage of voids averaging 53% and a weight of the dry material of 77 lb per cu ft. For silty clay, the percentage of voids was 60% and the weight of the dry material 66 lb per cu ft. The weight of the dry material comprising the silt deposits in reservoirs, when not subjected to drying, is undoubtedly much less than that of material found in deposits on the overflow areas of stream channels. The void content of saturated sediments from reservoirs has been found by the writer to be as high as 80%, which corresponds to a dry weight of 33 lb per cu ft. The dry weight of deltaic deposits near the head of a reservoir, of course, would be greater and could equal the foregoing weight of the river bottom deposits, or in some instances it might be even greater.

---

[13] Hydr. Engr., East Bay Municipal Utility Dist., Oakland, Calif.

Under the heading, "Transportation of Sediment to the Reservoir," the difference between the method of transportation of suspended sediment and of bed load is indicated by a comparison of Eqs. 1 and 5*a*. In the Kennedy formula, V_c varies directly as a power of the depth, whereas, in the Schoklitsch formula, since $V_c = \frac{0.00532\, D_g}{y_d\, S^{4/3}}$, it varies inversely with the depth. Hence, it may be inferred that, to keep fine sediment in suspension, the velocity must increase with the depth of the water. On the other hand, the movement of bed load, by which erosion the stream bed continually deepens the channel and makes the bank slopes steeper, is the result of drag. This drag, in accordance with the du Boys theory, is proportional to the depth of water and to the slope or gradient of the channel (60). The movement of fine sediment depends on the supply available, which is variable, and this movement in a large measure is independent of the volume of flow. Approximate curves may be developed, but the actual proportion of sediment is normally greater on a rising than on a falling stage and, in addition, varies greatly between individual storms for the same drainage area (61). On the other hand, the movement of bed load is directly related to the volume of flow and for a given stream channel can be predicted with greater accuracy.

TABLE 7.—GENERAL CHARACTERISTICS, RESERVOIRS NEAR OAKLAND, CALIF.

Reservoir	Runoff, 1886–1887 to 1935–1936 (acre-ft per sq mile)	Drainage area (sq miles)	ORIGINAL STORAGE	
			Acre-ft	Acre-ft per sq mile, S_R
Chabot	409	42.05	15,860	377
Upper San Leandro	477	30.3	41,398	1,370
San Pablo	387	32.2	43,149	1,340
Temescal	409	2.75	656	238

Under the heading, "The Action of Sediment in Reservoirs," the author quotes Mr. Faris as follows: "* * * No suspended silt is carried through the reservoir and over the spillway until all of the clear water has been discharged." Observations of the writer indicate that this is not necessarily true in all instances. At the Pardee Dam on the Mokelumne River in California, the inflowing water is not of high turbidity at any time and during much of the year it is very clear. The maximum turbidity rarely exceeds 250 ppm. On one occasion in June, 1935, the sluice valves at the base of the dam had been opened and were discharging water of a turbidity of 20 to 30 ppm, while the river flow was between 3,000 and 5,000 cu ft per sec. These sluices were closed for a period of about a week. In a few days, turbid water was observed to rise through the reservoir near the spillway and to pass over the weir lip. By opening the sluice valves again to reduce the spillway discharge to a very small quantity, the release of the turbid water was transferred back to the sluice valves. The density currents in the reservoir at the time were such that the discharge of the turbid water could be transferred from the sluice valves at the base of the dam to the spillway, a vertical height of 327 ft, depending on the point at which the maximum volume of water was discharging.

TABLE 8.—SUMMARY OF SEDIMENTATION OF RESERVOIRS NEAR OAKLAND, CALIF.

Period	Interval, in years	Mean annual runoff (acre-ft per sq mile)	ANNUAL RATE OF SILTING			
			Mean annual (acre-ft)	Cu ft per acre	Total runoff (%)	Acre-ft per 100 sq miles
(*a*) CHABOT RESERVOIR						
1875–1900	25	447	60.4	98	0.32	144
1900–1910	10	526	131.0	212	0.59	312
1910–1923	13	303	37.5	61	0.23	89
1923–1942	19	232	17.3	28	0.18	41
1875–1942	67	387	54.2	88	0.33	129

(*d*) TEMESCAL RESERVOIR						
1869–1907	38	438	4.8	118	0.40	175

In connection with the section of the paper on "Estimating the Rate of Reservoir Sedimentation," the writer can add results on sedimentation obtained from surveys of storage reservoirs of the East Bay Municipal Utility District near Oakland, Calif. Surveys of sediment deposits in one of these reservoirs have continued over a period of 67 years (62). Additional surveys of the silt deposits have been made during the last few years and the results of these and previous surveys are summarized in Tables 7 and 8. The runoff per square mile from these drainage areas is relatively small and, on the other hand, the storage per square mile of drainage area is relatively large. Consequently, little runoff has been wasted over the spillways and the water that has been wasted was practically clear. Therefore, the deposits in the reservoirs represent all of the sediment produced on the watersheds during the periods recorded.

The relation between sediment deposited and the storage capacity per square mile of drainage area is plotted in Fig. 8 (in a manner similar to Fig. 3). The range in sediment deposits for the various periods between surveys is indicated. Based on the average deposit of sediment in the smaller reservoirs, Eq. 6 has been plotted using for *x* his value of 0.83. The application of this equation to the reservoirs listed in Tables 7 and 8 would require a much greater sediment deposit in the larger reservoirs than was actually recorded. The relation between the runoff by square miles of drainage area and the sediment deposits expressed as percentage of the volume of runoff has been plotted in Fig. 8(*b*). For these reservoirs, a straight-line relation appears to exist between these two factors. In the San Pablo Reservoir, the high deposits recorded between 1936 and 1938 were due to road construction and land subdivision above the reservoir during a period of heavy runoff. The subsequent survey in 1943 indicates that the rate of erosion from this watershed had returned to that indicated in Fig. 8(*b*).

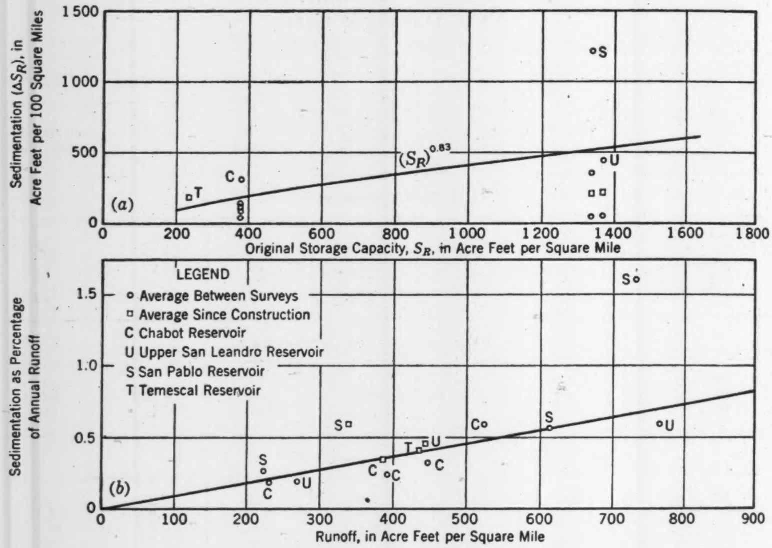

FIG. 8.—SEDIMENTATION OF RESERVOIRS NEAR OAKLAND

This relation between sediment deposits and volume of flow, if of general application, would be very useful in expanding short records of silting to indicate the true normal. Table 8 indicates that the rate of sediment deposits varies considerably during various runoff cycles. If the watershed erosion is proportional to the annual runoff, the mean rate of erosion could be determined from the ratio of the runoff during a period of sediment measurement to the long-time mean runoff from the watershed. Where appreciable quantities of sediment are discharged through sluiceways or over the spillways, this sediment should be combined with the quantity deposited in the reservoir to determine the entire watershed erosion.

Because of the relatively large size of the reservoirs of the East Bay Municipal Utility District near Oakland as compared with the discharge from the watershed, it has been estimated that their life will range from 500 to 800 years.

At Pardee Reservoir a record has been kept for several years of suspended sediment discharge through the sluiceways and turbines by taking samples of the river water immediately below the dam. The sediment discharge has been computed from these samples with a weight of 62.5 lb per cu ft for suspended material and a weight of 35 lb per cu ft for dry material if deposited in the reservoir. This light weight for deposited material has been used due to the fine colloidal nature of the sediment discharged through the sluiceways. The results of these measurements of the four years, 1940–1943, are as follows:

Year	Weight of discharge sediment, in tons	Equivalent volume, discharge in acre-feet
1940	4,806	6.3
1941	1,949	2.6
1942	6,951	9.2
1943	8,983	11.8

These quantities, added to the sediment deposits in the Pardee Reservoir, will give the total sediment load from the watershed. The drainage area above Pardee Reservoir is largely in granitic rock and the sediment load in streams is small. The mean annual runoff is 800,000 acre-ft from a drainage area of 575 sq miles, and the original storage capacity in the reservoir was 210,000 acre-ft. In the first ten years that the reservoir was in operation, the deposits were found to be approximately 1,000 acre-ft. Less than 10% of the total sediment was discharged through the sluice valves. The deposits consisted of about an equal proportion of delta deposits at the head reservoir, and of bottom-set beds of fine material in the main body of the reservoir. At this rate of sedimentation, the life of Pardee Reservoir will be longer than 2,000 years.

Eq. 7 expressing the relation between sediment deposits and the size of the reservoir appears to be defective in that it does not include the factor of runoff. A more suitable equation might be:

$$\frac{\Delta S_R}{E} = f\left(\frac{S_R}{Q_a}\right) \qquad (20)$$

in which, in addition to the notation of the paper, Q_a is the mean annual runoff. Other factors enter the problem which are not included in Eq. 20, but usually these are of secondary importance. These factors include: (1) The size gradation of the sediment; (2) the flow characteristics of the stream entering the reservoir; (3) the shape of the reservoir; and (4) the manner of operation of the reservoir, particularly the discharge of water through sluice gates or over the spillway.

Under "Remedies for Reservoir Silting," Mr. Witzig has presented four methods. Of these, sluicing of water through sluice gates and erosion control on the watershed above the reservoir appear to be the only practicable and economical means. The latter procedure offers the greatest possibilities as it controls the sediment at its source. The several types of "upstream engineering" listed by the author have been practiced by the East Bay Municipal Utility District on its local watersheds near Oakland. This work has been conducted since 1939 in cooperation with the U. S. Soil Conservation Service (62*a*)(63)(64).

Important causes of reservoir sedimentation on many watersheds, in addition to those mentioned by the author, are landslides or earth flow, particularly where the earth is carried into the stream channel. This condition is cured by draining the slide. However, in some instances where the toe of the slide has come to rest in a stream channel, the construction of a debris barrier below the slide will check the downstream movement of the sediment from the slide and result in its eventual stabilization.

To be more completely effective, debris barriers in stream channels must have a relatively narrow discharge weir with respect to the width of the channel at the dam. Otherwise, only the bed load will be trapped, since the velocity of the current will be only slightly reduced and the time of ponding will be so short that most of the suspended sediment will pass over the spillway. The discharge of a considerable portion of the suspended load is a fault naturally inherent in these small ponds. The growth of vegetation along the stream channel will increase the efficiency of the barrier by facilitating the deposit of fine material. If properly designed and maintained, a debris barrier will trap sediment greatly in excess of its normal water-holding capacity at the time of construction. This is made possible by the deposition of material well above the elevation of the spillway lip. An important function of debris barriers on main channels is the reduction of bank scouring by flattening the stream grade, and the reduction of erosion by localizing the drops at dams where the energy of the water can be dissipated in properly designed stilling pools.

An aid in the planning of the control of erosion on watershed lands is the taking of water samples from various tributaries entering the reservoir during storms. Channels carrying excessive sediment can thus be segregated and the source of erosion located later during more favorable weather. The erosion control work can then be planned to accomplish the maximum results with a minimum expenditure.

BERARD J. WITZIG,[14] ASSOC. M. AM. SOC. C. E.—The able engineers who discussed the paper have done much to clarify several aspects of the problem of sedimentation in reservoirs.

Messrs. Johnson and Stanley stress the confusion that exists in the lack of proper definitions and terms for material moving by the various modes of transportation. To eliminate this ambiguity in the paper, and to avoid confusion in the future, the writer suggests the following definitions:

---

[14] Engr. (Civ.), U. S. Engr. Office, Buffalo, N. Y.

(*a*) "Wash load" is the relatively fine material in near permanent suspension, which is transported entirely through a stream system without deposition.

(*b*) "Suspended load" is the coarser suspended material, derived from the stream bed, during changes in magnitude of the stream discharge.

(*c*) "Bed load" is the material derived from the stream bed, varying in size from silt to boulders, moved along the stream bed by rolling, sliding, or saltation.

(*d*) "Bed material" is the source of both the coarse suspended load and the bed load, and consists of the geologic formations and alluvial deposits through which the stream channel is cut.

The wash load, the greater part of which may be carried by the rising stages of the flood flow, bears no direct relation to discharge because of the seasonal variability of supply, affected by erosion, meteorologic, and hydrologic conditions on the watershed. However, because the coarse suspended load and the bed load are derived from an always available supply, relations between such loads and the water discharge exist, but may be different in different streams, or at different points on the same stream. Most total suspended-load measurements include the wash load. Hence, the lack of a relationship between the sediment loads so measured and the water discharge may mean only that the wash load constituted a preponderantly influential part of the total suspended load. Such measurements might be corrected, if the mechanical analyses of the sediment were known, and the boundary range of particle sizes were determined between the materials carried by the two modes of transportation.

No rigid natural distinction actually exists between the coarse material in suspension and the bed load. An arbitrary distinction is necessitated only by present limited knowledge of the phenomena of sediment transportation, and each condition must, therefore, be measured and evaluated by different methods. The writer believes that the so-called "dividing grain size" is only apparent, and may logically be expected to vary with change in stage or discharge at a given point on a stream, as well as with a change in location on the same stream or a shift to a different stream.

Mr. Stanley correctly interprets the writer's implication that no net settling occurs during sediment transportation in suspension. When the suspending forces are sufficiently strong, there is no accumulative deposition, but, because of the very nature of the modes of transportation, there must be an interchange of material between the load in suspension and that in movement or stationary on the bed.

Messrs. Johnson and Means add data on the so-called "silt rating curves." Their cautions in the use of such curves should be heeded, since these relations are not "rating curves" in the same sense as are stage-discharge relations above a real hydraulic control at a gaging station. They are inherently subject to the errors of including wash load, and to the approximations and errors unavoidable in measurement of suspended sediment. Moreover, they cannot include, intrinsically, any factor for bed load.

The writer believes that laboratory analysis of suspended-load samples could be refined to distinguish between wash load and suspended bed-material load, and, therefore, a relatively more accurate estimate could be made of the relation between the temporary suspended load and the water discharge. The breakdown might be made by comparison of suspended load samples with fresh bottom deposits sampled immediately after flood flows. However, there is a possibility that the wash load, varying independently of the discharge, may act either as a flux or, conversely, as a retardant, on the carrying capacity of a given discharge for the bed-material load. Only experimentation could settle this question.

With reference to the use of the silt rating curves, the writer reiterates his opinion that such relations are best interpreted not as actual physical relations but rather as statistical correlations, which may be validly used in estimating the probable average suspended loads carried by given water discharges. Perhaps doubt as to their validity for this purpose would be lessened if the envelopes enclosing the measurements were also drawn, so that it could be seen at a glance that the selected curve represents the probable average in the range of probable concentrations. Thus, the silt rating curve cannot be used to state the sediment concentration in a flood for which no sediment measurements were made, without probability of considerable error, any more than a flood-frequency curve can be used to state that a flood of a given magnitude will occur in a certain period. Both are statistical relations and should be used only as such. They can be employed to determine average annual occurrences. Whether the silt rating curve is used with a discharge-duration curve, as suggested by Professor Johnson, or with a flood-frequency curve, as in the writer's example, is immaterial, and would depend only on the extent of data available. Professor Johnson's method would require a longer period of silt sampling than the writer's; the data on the Cuyahoga River in Ohio cover too short a period to enable a comparison to be made.

Mr. Means properly warns against the indiscriminating use of "general relations" or formulas. The writer does not suggest that any of the formulas or procedures be so used. There is no adequate substitute for carefully observed data, but frequently, in their absence, or because time and expense prevent more thorough investigations, the short cuts provided by general formulas may give results of sufficient accuracy. Mr. Means questions Eqs. 2 and 3. Although these equations are intended to express what may prove to be a general law, reference to the source papers (14)(15)(21) shows that appreciable deviations exist. If this is admitted, proper use of these and similar equations can be made as engineering tools.

Professor Johnson clarifies the (ϕ-ψ)-relationship for bed load, developed by Mr. Einstein (21). The relationship seems based on and verified by a large mass of observed data. Equal substantiation of other methods of evaluating bed load is not known to the writer. However, the (ϕ-ψ)-relationship also requires evaluation of "a certain representative grain diameter." Because of this necessity, and the fact that many observations have varied considerably from Mr. Einstein's adopted curve, quite as much error may result in its use as in application of the simpler Schoklitsch bed-load formula.

Mr. Stanley carefully expounds his reasons for questioning the data on silt settling rates in Table 2, which was intended principally to illustrate indirectly the magnitude of forces required to keep sediment grains of different sizes in suspension. The additional data in Table 6 are of interest. These data illustrate the variation from theory of results obtained by different workers, which probably is due to laboratory procedure and control, material observed, and personal error in observation or interpretation, as well as some imperfection in the basic theory or formula. Because of the great variety in nature, such differences always might properly be expected.

Mr. Stanley suggests that the determination of reservoir silting "indexes" be further refined by consideration of the average annual rainfall and the average susceptibility to erosion. Evaluation of these factors would undoubtedly aid in presenting a more clear-cut delineation of the indexes, inasmuch as those derived in the paper are based on large geographical regions having considerable variation in rainfall and erosion characteristics. The writer has not had the opportunity to carry the study to this extent, however, because of lack of data.

A relation between rainfall and suspended load, on small watersheds, has been demonstrated by Professor Johnson (65). Mass curves of the deviation of suspended load from the mean closely parallel the mass curves of deviation of rainfall. The correlation obtainable therefrom may permit computation of suspended load from rainfall records for a period for which suspended load measurements are not available.

The writer does not know of any method of evaluating the average annual erosion from a watershed, except by surveys. As Mr. Brown states, the average annual erosion differs, depending on whether erosion is considered as the eroded material actually delivered to a reservoir or the material eroded from its source and deposited elsewhere on the watershed (colluvial and alluvial deposits). The former would be the factor to be evaluated in the present case. The magnitude of this factor can be stated in terms of annual accumulation of silt per square mile of drainage area, as shown by Mr. Brown in Fig. 6.

Mr. Happ clarifies the findings of the SCS relative to the influence of sheet and bank erosion. The writer was evidently in error in contrasting Mr. Horton's statement with the SCS conclusions. Identification of the principal source of erosion is of vital importance in attacking the problem. However, stream bank erosion is the principal culprit not only in the semiarid Southwest, but also in some humid basins in other parts of the United States. Thus, an SCS survey (52*a*) of the Buffalo Creek, New York, watershed, an area of 437 sq miles, indicates that stream bank erosion produces 80%, and land surface erosion, 20%, of the total sediment reaching lower Buffalo River. Buffalo Creek watershed can be called neither mountainous nor forested, although the headwaters are in the foothills of the Alleghenies. The annual rainfall on the watershed averages about 40 in., and is fairly well distributed throughout the year. A similar situation appears to hold for the Cuyahoga River. Although no erosion surveys of this watershed have been made, the writer's observations indicate that most of the eroded material carried to the lower Cuyahoga at Cleveland is produced from the stream banks and gullies in the lower half of the watershed. The river flats, the upland areas, and most of the headwaters area are of gentle slope, largely unwooded, and generally unaffected by sheet erosion.

Mr. Means pertinently draws attention to the important volume occupied by deposits above reservoir level. This was not emphasized sufficiently by the writer. Such deposits may be of serious consequence, if they should be eroded and again deposited in the reservoir cavity, or if the dam is later raised when they would detract from the added storage that might otherwise have been obtained. Use of vegetation screens, debris barriers, or desilting basins above the reservoir proper should therefore be planned with such future developments in mind. In this connection, Mr. Hall suggests several considerations for the design of debris barriers and vegetation screens. In addition, however, the designer should not disregard the possibility that resultant aggrading of channels and flattening of stream slopes upstream from such works may increase flood damages above the reservoir. If this damage cannot be prevented or avoided, then the damage, or its mitigation, should properly be included as a cost of the reservoir.

Mr. Brown epitomizes the problem when he states that "Control of silting begins when the dam design takes shape on the drawing board." Except for physical destruction of the dam itself, silting is the only force that can destroy the reservoir; the dam can be replaced, but loss of reservoir storage through silting has no completely efficient economical remedy. Mr. Brown properly questions the erroneous generalities that can be drawn from Fig. 3 and Eq. 6. Fig. 3, from which Eq. 6 was derived, represents an apparent correlation between rate of silting and reservoir capacity, and summarizes data that would otherwise be merely a mass of statistics. As evident from the plotted points, many of the smaller reservoirs have higher rates of sedimentation, when reduced to a common unit basis, than some of the larger. It was not intended to imply the existence of any natural law that the silting rate increases indefinitely with the size of the reservoir, but merely that, if a reservoir of a certain capacity per unit of drainage area were built, it might be expected to silt up at a rate similar to that of an existing reservoir in the same region. There must be a maximum limiting silting rate, regardless of the size of the reservoir, just as there is a limit to the rate of runoff from a watershed, regardless of the reservoir size that may be provided to store that runoff. If a reservoir of sufficient size to store the greater part of most floods from its drainage area silts at a certain rate, there probably would be but little increase in the rate of silting if greater storage had been provided at the same site.

Mr. Brown contributes a valuable discussion on sediment trap efficiencies. His distinction between net and gross erosion is important and should be kept in mind. Eq. 12 defines the trap efficiency coefficient in terms of silting and erosion rates only, which is simple and correct for a particular reservoir. Eq. 7, however, attempts to include the effect of reservoir size, so that known data on existing reservoirs may be applied to proposed reservoirs of different sizes. However, Eqs. 14 and 15, and Fig. 5, present the reservoir designer with a valuable tool for this purpose, and the writer especially appreciates Mr. Brown's contribution at this time.

Fig. 6 illustrates the relation between silting rates and drainage area. It seems reasonable to expect that, with an increase in drainage area, the unit silting rates on large drainage areas should decrease and become constant, since it would be unlikely that all parts of a large watershed would be eroding at the more intense rates found on certain of the small tributary areas. Use of Fig. 6, or of Fig. 3, should be based on thorough consideration of characteristics of and conditions on a basin. Neighboring watersheds often differ considerably; for example, Cayuga, Buffalo, and Cazenovia creeks in western New York, all join to flow into Buffalo Harbor. The three streams drain approximately equal areas, but Cayuga Creek with somewhat lower gradients contributes only about one tenth of the sediment deposited in lower Buffalo River, whereas the other two streams contribute the remainder.

In view of Mr. Brown's statement that SCS surveys have been made "for the purpose of obtaining a representative sampling of silting conditions * * *," the writer retracts his statement "that reservoirs surveyed thus far are more typical of severe rather than of average conditions." The latter statement was based on failure to find a specific utterance similar to Mr. Brown's in available reports of the SCS. Knowledge that SCS silting data constitute representative samples permits their study to proceed with some assurance that any results obtained are not influenced unduly by extreme conditions.

Mr. Brown has offered a valuable service to the profession in his paper (52) on the control of reservoir silting. It would be extraneous here to enlarge on control measures, and the writer seconds Mr. Blaney's suggestion that those interested review that publication.

Mr. Jarvis calls attention to some benefits resulting or obtainable from sedimentation in reservoirs and canals. However, some sediment deposits do not possess fertilizing value, especially those derived from bank erosion in areas of thin topsoil.

Mr. Bell objects to a misinterpretation of his paper (25) on density currents. Considering that both the original statement and the examples given by Mr. Bell in his discussion are only estimates based on assumed densities of silt in place, the magnitude of the quantities of material that apparently are carried through reservoirs by density currents is thereby illustrated. Whether density currents carry 24% or 35% to 40% of all sediment in Lake Mead, such currents evidently have considerable effect on the rate of sedimentation and may constitute an important factor in its control.

The writer does not agree entirely with Mr. Bell's statement that density currents decrease the specific density of the coarser deposits by removing the finer materials that would otherwise partly fill the interstices of sediments left behind. Density currents carry only the finer silts and clays. Curves given by E. W. Lane, M. Am. Soc. C. E., and Victor A. Koelzer, Jun. Am. Soc. C. E. (66*a*), indicate that the density of material deposited under water increases with an increase in the percentage of coarse material. Control of density flows for voiding silt from a reservoir before deposition might therefore result in final deposits of greater density and less volume. The deposits would also consolidate more rapidly because of the smaller silt or clay content.

Mr. Blaney emphasizes the importance of knowing the relation between silt volume and weight of deposited sediment. Messrs. Lane and Koelzer (66) have compiled all the available data on this subject, and have presented a procedure for estimating the density of deposits at any time after deposition, for various methods of reservoir operation.

Mr. Sonderegger distinguishes between the natural norm of erosion and that caused by man's activities, and states that erosion control can scarcely be expected to reduce sediment production to less than the undisturbed natural rate. The writer does not fully concur that nature cannot economically be improved on at times. When natural rates of erosion are due to the same causes as those accelerated by man, it does not seem an impossibility to modify them by proper remedial measures. Thus, burned-over areas can be reforested; eroding stream banks can be stabilized; and steep gully and stream slopes can be made more gentle by construction of dams and drop structures. The writer agrees, however, that sediment production, and transportation to reservoirs or navigable waters, cannot be prevented entirely at costs commensurate with the benefits.

Mr. Sonderegger properly emphasizes the necessity of providing adequate reservoir storage for silt loss to preserve the hydraulic functions of the reservoir. In many cases, it might be more economical to build a large dam immediately, rather than to raise the dam shortly after construction, but the decision to do so would necessarily rest on the engineering, financial, and natural conditions peculiar to a given project.

Mr. Hall discusses several special aspects of the erosion problem, and adds data on sedimentation rates in several reservoirs in California, as well as an example of the action of density currents in Pardee Reservoir. His comments on the effects of stream slopes seem to apply essentially to the reworking of flood plain and channel deposits. However, flat stream gradients do not necessarily imply that sheet erosion on the watershed outweighs bank erosion, for many streams of gentle slope flow through alluvial strata of low resistance to eroding forces, although the land surfaces themselves are amply protected by surface cover. A notable example is the Mississippi River below Cairo, Ill.

An interesting comparison is made between the Kennedy and the Schoklitsch formulas, with reference to the velocity and drag required, respectively, to maintain movement of sediment in suspension and along the bed. Although both these formulas are empirical in origin, the comparison would indicate that they are not unsound theoretically.

The extremely small concentration of sediment required to produce density flows is illustrated by Mr. Hall's description of the June, 1935, occurrence in Pardee Reservoir. This example also seems to demonstrate conclusively that density currents carrying silt can be controlled by proper manipulation of outlets. Neither laboratory research, nor large-scale experimentation with existing reservoirs, should be neglected until this presently speculative aspect of reservoir action is usefully applied.

With particular reference to Pardee Reservoir, the writer suggests that the current may have been of such density that it flowed along the top of a cold water layer of just slightly greater density. When the sluice-gates at the bottom of the dam were opened, the resulting hydraulic current drew the silty water to the outlet; when the gates were closed, the hydraulic current over the spillway drew the silty water to the top of the dam. Without further data, the writer would suggest that the concentration of silt in the spillway flow was somewhat less than that through the gates, inasmuch as the density current probably had to mix with a greater proportion of clear reservoir water in rising to the top of the dam, than in sinking to the bottom. Furthermore, the density flow must have been quite thick to have appeared so quickly over the spillway, or a considerable part of the stored water in the reservoir may have consisted of the silty suspension. The shape of the reservoir, and its relation to the location of the dam, as well as the shape of the back surface of the dam itself, may also have influenced the action of the current.

Mr. Hall suggests a method of correlating the rate of reservoir silting with the mean annual runoff from the tributary area. The linear relation illustrated in Fig. 8(*b*) between annual runoff volume per square mile and sedimentation as a percentage of annual runoff seems to fit the plotted data. The writer does not have the necessary information to test this correlation on the source data of Fig. 3. The method is worthy of further investigation, however, and may prove valuable in estimating sedimentation rates from runoff records. This tool may possibly be applicable to larger watersheds with more accuracy than is the correlation between mass deviation curves of rainfall and suspended load previously mentioned in this discussion. The latter method is unduly influenced by variable distribution of rainfall on large areas.

Eq. 20 is a particular statement of Eq. 11, but is more complete than Eq. 7. However, for practical use, it would require evaluation of a coefficient for the right-hand term. As Mr. Brown suggests in Eq. 12, however, the term E should be the net erosion, E_n, delivered to the reservoir. No practical method is apparent at this time which includes in a single quantitative equation the omitted factors mentioned by Mr. Hall. However, with reference to size gradation of sediment, few particles of the largest sizes are carried to the reservoir except in debris basins as in California, and most particles of the finest sizes are transported through the reservoir, except in the case of very large volumes which store the entire flood runoff for an appreciable period of time. The intermediate sizes, between "Cyclopean" sediment and colloidal silt, generally form the predominant components of reservoir deposits. The flow characteristics of the tributary stream are partly accounted for in the term, Q_a. Reservoir shape and manner of operation would seem to be qualitative factors.

By direct correspondence, C. S. Howard, Chemist of the U. S. Geological Survey, states that the greater part of the annual silt load in a stream may be carried in a relatively short time, with the stream flowing comparatively clear during the remainder of the year. This is illustrated in Fig. 1, where the quantity of 2.76 tons of silt per second was carried by a discharge of 27,800 cu ft per sec. A one-day flow of this magnitude would be equivalent to about 45% of the estimated average annual silt load of 532,000 tons. However, this concentration has about a 1.5% chance of occurrence, or may occur about once in 67 years. Thus, a flood of this magnitude and frequency would contribute over its period of recurrence only about 0.68% of the average annual silt load.

Mr. Howard also points out that the data in the basic paper on the efficiency of the desilting works for the All-American Canal were estimates before operation began. The writer has learned that up to August, 1943, the desilting works had not been put into operation, since it had been possible to obtain a comparatively silt-free diversion to the canal by reason of high reservoir levels and high sluiceway discharges.

The writer has found the discussions very instructive. Practically every topic in the basic paper has been discussed or commented upon, erroneous or doubtful points clarified, and interesting new data and suggestions added. Differences of opinion on theory and interpretation of natural phenomenon, of ourse, will continue. However, the travail common to the solution of all involved problems will undoubtedly produce valuable social and economic benefits, as the mechanism of sedimentation becomes better understood and practicable remedies are developed for reservoir silting.

In view of the historic fact that water resources are of utmost importance to a civilization and an economy, the present generation should exert every effort to use these resources wisely and to conserve them to the greatest degree for future generations.

THE HYDRAULIC JUMP IN SLOPING CHANNELS

By CARL E. KINDSVATER,[1] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JOE W. JOHNSON, KARL R. KENNISON, J. C. STEVENS, C. J. POSEY, JEROME FEE, FRANK S. BAILEY, G. H. HICKOX, AND CARL E. KINDSVATER.

SYNOPSIS

Common forms of the hydraulic jump in sloping channels have been classified into three general cases, and an analysis is presented which leads to a practical method of computing the dimensions of the jump. Satisfactory agreement between analysis and experiment was obtained from laboratory tests on a channel with a 1 on 6 sloping floor. Conclusions drawn from this investigation indicate that experiments on other slopes might eventually yield a satisfactory treatment for hydraulic jumps on any slope within the practical range.

INTRODUCTION

Historical Résumé.—The inability to predict the occurrence or to compute the essential dimensions of the hydraulic jump in sloping channels has been a source of difficulty in hydraulic design.[2] Sufficient verification data now exist to substantiate the application of the momentum principle, derived from Newton's second Law of Motion, to the hydraulic jump in open or enclosed horizontal conduits of any practical cross-sectional shape. To apply the same principle to an analysis of the hydraulic jump in sloping channels, however, it is necessary to obtain floor pressures and certain elements of the jump profile from laboratory experiment.

In their early work[3] on the hydraulic jump, Bidone, Bazin, Bélanger, and Boussinesq were unable to verify their analyses largely because they neglected components of pressure on the sloping floor. Others, more recently, have made the same error. In 1934, the late D. L. Yarnell, M. Am. Soc. C. E., of the U. S. Department of Agriculture, Division of Drainage, attempted an analysis in which floor pressures under the jump were evaluated from an assumed straight-

line profile from the beginning of the jump to the end of the roller. This approximation was not sufficiently accurate to give satisfactory results. In 1936, Mr. Yarnell resumed his investigation with a program of comprehensive laboratory tests, which were interrupted by his death on March 9, 1937.

In 1938, B. A. Bakhmeteff, M. Am. Soc. C. E., and A. E. Matzke, Assoc. M. Am. Soc. C. E., published[3] an analysis in which, by introducing a "form coefficient" based on profile measurements, they accounted for the effect of pressures on the sloping floor. Verification of their treatment was limited, however, to a single case of the jump in channels of very flat slope.

The present investigation, based on Mr. Yarnell's 1936 experiments, was undertaken by the Tennessee Valley Authority (TVA) in preliminary studies of spillway design for one of its dam projects.

Classification of the Hydraulic Jump.—The hydraulic jump occurs under many conditions in a great number of related forms. For facility of analysis it is desirable to classify into several general cases the most common forms of the jump in open rectangular conduits. Fig. 1 shows four basic cases selected for the present analysis, designated cases 1 to 4 in order of position relative to the sloping floor. Case 1, with the entire roller on the horizontal floor, is the hydraulic jump in horizontal channels. Cases 2, 3, and 4 are common forms of the jump in a sloping channel. Thus, in Case 2 the toe of the roller is on the slope and the end of the roller is on the horizontal floor; in Case 3 the toe of the roller is on the slope and the end is at the junction of the sloping and horizontal floors; in Case 4 the entire roller is on the slope. In each case, the water surface and channel bottom downstream from the jump, as well as the reference axis, are assumed to be horizontal. Messrs. Bakhmeteff and Matzke[3] investigated a fifth case, in which the water surface downstream from the jump was parallel to the slope. This case occurs in some natural channels and in long flumes of flat slope.

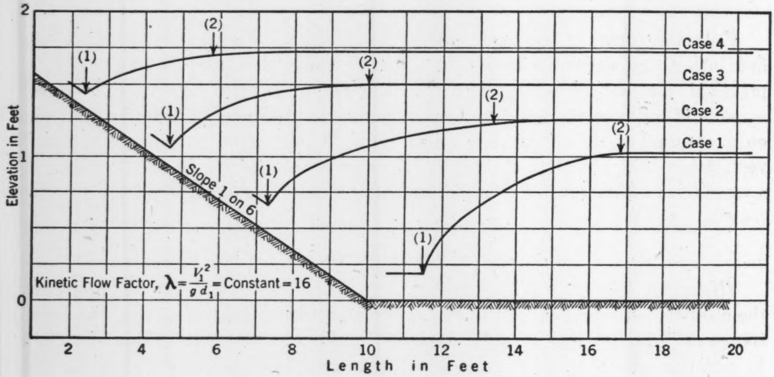

FIG. 1.—BASIC CASES OF THE HYDRAULIC JUMP IN SLOPING CHANNELS

NOTATION

The following letter symbols, selected for use in this paper, conform essentially to American Letter Symbols for Hydraulics, prepared by a Committee of American Standards Association, with Society representation, and approved by the Association in 1942:[4]

A = area of cross section, in square feet;
d = depth of flow, in feet, with appropriate subscripts to denote sections;
f = "function of";
g = acceleration due to gravity, in feet per second per second;
j = subscript denoting "hydraulic jump"; for example, "d_j = depth of hydraulic jump" and "L_j = length of hydraulic jump";
k = coefficient for Case 2 (dimensionless);
L = length along channel, in feet;
n = a subscript denoting "normal"; for example, p_n denotes "normal unit pressure";
P = total pressure, in pounds;
p = unit pressure, in pounds per square foot;
Q = total rate of discharge, in cubic feet per second;
r = radius; as a subscript, r denotes "roller"; for example, L_r = length of roller;
s = embankment or side slopes; as a subscript s denotes sloping floor; for example, L_s = length along a sloping channel floor;
V = average velocity of flow, in feet per second; $V = \frac{Q}{A}$;
y = vertical height of the pressure gradient above the floor, in feet; $\bar{y}$ = average height along a given length of channel;
α = slope angle ($\tan \alpha$ = slope of channel);
γ = unit weight of water, in pounds per cubic foot;
λ = kinetic flow factor, $\frac{(V_1)^2}{g\, d_1}$;
ϕ = pressure coefficient (dimensionless).

HYDRAULIC JUMP IN HORIZONTAL CHANNELS

The theory of the hydraulic jump in horizontal channels, Case 1, has been treated thoroughly by others,[5,6] and repetition is unnecessary except to review the important assumptions involved. Fig. 2 shows the hydraulic jump in a rectangular open channel with a horizontal floor. The body of the jump is delimited by section 1 at the toe of the jump and section 2 at the end of the jump. Since parallel lines of flow are assumed to exist at sections 1 and 2, pressure distribution in both sections is governed by hydrostatic principles. The vertical distances d_1 and d_2 are depths of flow at sections 1 and 2, respectively.

The momentum principle, from Newton's second Law of Motion, states that the time rate of change of momentum between any two sections in a steady flow is equal to the resultant of external forces applied on the mass of fluid between those two sections. Thus, taking the floor of the channel as reference axis, and neglecting the force of boundary friction, the momentum principle can be applied to Fig. 2:

$$P_2 - P_1 = \frac{Q\,\gamma}{g}\,(V_1 - V_2) \quad \ldots\ldots(1)$$

in which P_1 and P_2 are the horizontal forces due to hydrostatic pressure, and V_1 and V_2 are uniform velocities across sections 1 and 2. The pressure-momentum equality in Eq. 1 is illustrated by the superimposed pressure diagrams in Fig. 2.

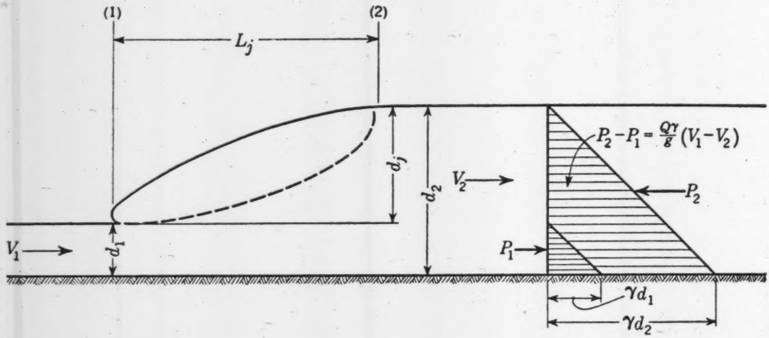

FIG. 2.—CASE 1; THE HYDRAULIC JUMP IN HORIZONTAL RECTANGULAR CHANNELS

Although Eq. 1 is an algebraic expression of the momentum principle, it is not in a form suitable for computation of the dimensions of the hydraulic jump. If the rate of change of momentum is evaluated on the assumption of uniform distribution of the average velocity, Eq. 1 can be written as an equation for d_2 in terms of V_1 and d_1:

$$d_2 = \frac{d_1}{2}\left[\sqrt{\frac{8\,(V_1)^2}{g\,d_1} + 1} - 1\right] \quad \ldots\ldots(2)$$

Messrs. Bakhmeteff and Matzke[6] have shown that the term $\frac{(V_1)^2}{g\,d_1}$, which they have called the kinetic flow factor, is the square of Froude's number, a criterion for dynamic similarity in fluid motion where forces of inertia and gravity predominate. Substituting λ for $\frac{(V_1)^2}{g\,d_1}$, Eq. 2 becomes

$$d_2 = \frac{d_1}{2}\left(\sqrt{8\,\lambda + 1} - 1\right) \quad \ldots\ldots(3)$$

THE HYDRAULIC JUMP IN SLOPING CHANNELS

Limitations to Analysis.—There are a number of practical limitations to the application of a generalized analysis of the hydraulic jump in sloping channels. The jump is commonly utilized as a means of dissipating energy below spillways and chutes, frequently as a supplement to impact devices in the stilling basin. Analysis of the latter case is not practical because of the difficulty in evaluating the impact forces on the auxiliary structures.

On very steep slopes on large structures, the problem is often complicated by the entrainment of air in the high-velocity stream before the jump or by the formation of traveling waves on the surface of the stream. In either case, it is practically impossible to compute accurately the momentum or the hydrostatic pressure in a cross section at the toe of the jump.

Hydraulic literature contains many references to differences between the level-floor jump and the jump in sloping channels, with the implication that similar analyses are not feasible for the two cases. In outward appearance, the hydraulic jump on flat slopes is quite similar to the jump in horizontal channels. On steeper slopes, however, the hydraulic jump has been dismissed as an imperfect form of the phenomenon, described as a "drowned nappe" and a "submerged jump." It is possible that these terms apply exclusively to jumps in the Case 2 classification.

Careful observations of several hundred jumps on slopes from 1 on 6 to 1 on 1 indicate that the sloping-floor jump is generally similar to the jump in horizontal channels. Fig. 3 is a mosaic of short-exposure photographs showing a Case 4 jump in a 1 on 6 sloping channel. Fig. 4 shows a Case 2 jump in a 1 on 3 channel. In both exhibits, when the high-velocity stream before the jump impinges on the tailwater, the impact produces a turbulent circulation of "white water" throughout the body of the jump. Immediately downstream from the toe of the jump, the high-velocity stream begins to expand, and the curve of expansion is apparently similar for all cases. However, as the slope of the channel increases, an increasing length of expansion is required before the curve of the upper boundary of the live stream changes from its initial negative slope to a positive slope, ascending to the tailwater surface. On the other hand, the difference in water-surface elevation between sections 1 and 2 decreases with increasing channel slopes.

Fig. 5.—Case 3; Hydraulic Jump in Sloping Channels, with the End of the Roller at the Junction of the Sloping and Horizontal Floors

Length of the Jump in Sloping Channels.—Although the length of the jump is not a factor in the analysis leading to Eq. 3 for the level-floor jump, it is a prerequisite to an analysis of the jump in sloping channels. If the channel slope is continuous, as in Case 4, some expansion may occur beyond the end of the jump. Thus, for analytical purposes, it is necessary to know the minimum length of expansion for which the depth of tailwater at section 2 is sufficient to insure the formation of the jump. It is possible to approximate the length of the jump with an assumed constant "safe length," but tailwater depths determined in this manner usually exceed the depth required to produce the jump.

In the present analysis, the length of the jump has been taken as the length of its surface roller. On the water surface, the end of the roller is marked as a narrow zone within which the downstream currents are divided from the upstream currents of the backroller. In the laboratory, the end of the roller was defined reasonably well as the point on the water surface from which confetti particles would float both upstream and downstream. Prolonged observations indicated that the end of the roller was the only point on the surface of the water near the end of the jump which could be determined conveniently and consistently by different observers. Experiments on a 1 on 6 slope showed that the depth of tailwater at the end of the roller was sufficient to produce a jump on the slope.

Since, as in Case 4 jumps, a slight expansion due to the recovery of velocity head may occur beyond the end of the roller, section 2 is not necessarily the point of maximum elevation on the water-surface profile. Nor is it necessarily true that the end of the roller marks a section of complete dissipation of destructive bottom velocities. However, experiments on a 1 on 6 slope showed a negligible error due to an assumption of uniform velocity distribution at section 2.

Generalized Analysis.—Case 3, with the end of the roller at the end of the slope, is obviously a primary form of the hydraulic jump in sloping channels, since the depth of flow at section 2 is definitely limited to the depth of tailwater. It is convenient for analysis to derive a general treatment from this case. Fig. 5 shows Case 3 in a channel with slope angle α, in which $V_1 \cos \alpha$ is the horizontal component of the average velocity in section 1 at the toe of the jump, and V_2 is the average velocity in section 2 at the end of the jump. The pressures P_1 and P_2 shown on the pressure diagram in Fig. 5(*a*) are the horizontal forces due to pressure on sections 1 and 2, respectively; and P_s is the horizontal component of the total pressure on the sloping floor between sections 1 and 2.

Neglecting boundary friction, the momentum principle applied to Fig. 5 gives

$$P_2 - P_1 - P_s = \frac{Q\,\gamma}{g}\,(V_1 \cos \alpha - V_2) \ldots\ldots\ldots\ldots\ldots (4)$$

The right-hand side of Eq. 4 is equivalent to the rate of change of the horizontal component of momentum between sections 1 and 2. If the velocity at section 2 is evaluated on an assumption of uniform velocity distribution, $V_2 = \frac{Q}{A_2}$, then for a channel of unit width,

$$V_2 = \frac{V_1\,d_1}{d_2} = \left[\frac{V_1 \cos \alpha \dfrac{d_1}{\cos \alpha}}{d_2}\right] \ldots\ldots\ldots\ldots\ldots (5)$$

Substituting this expression for V_2 in Eq. 4, the rate of change of momentum becomes

$$\frac{Q\,\gamma}{g}\,(V_1 \cos \alpha - V_2) = \frac{\gamma\,(V_1)^2\,d_1 \cos \alpha}{g\,d_2}\left(d_2 - \frac{d_1}{\cos \alpha}\right) \ldots\ldots (6)$$

If the pressure distribution in section 2 is assumed to follow hydrostatic principles, then P_2 in Eq. 4 becomes, for a channel of unit width,

$$P_2 = \frac{\gamma\,(d_2)^2}{2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

Referring to Fig. 5(*b*), the equation of equilibrium[7] for section 1 gives

$$P_1 = \left(\frac{d_1}{\cos \alpha}\,\frac{\gamma\,d_1 \cos \alpha}{2}\right) = \frac{\gamma\,(d_1)^2}{2} \ldots\ldots\ldots\ldots\ldots (8)$$

but it is convenient for the present analysis to substitute for Eq. 8 an approximation,

$$P_1 = \frac{\gamma\,(d_1)^2}{2 \cos^2 \alpha} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

---

[7] "Applied Fluid Mechanics," by Morrough P. O'Brien and George H. Hickox, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1937, p. 293.

As far as the final equation for the hydraulic jump is concerned, the difference between Eqs. 8 and 9 is negligible for slopes as steep as 1 on 2.

The term P_s in Eq. 4 must be evaluated from empirical relations established by laboratory measurements of floor pressures. Since experiments indicate that pressure on the sloping floor is proportional to the weight of the fluid body on the slope, P_s is a function of the dimensions and shape of the jump. In this analysis, it is convenient to express P_s in terms of a dimensionless parameter, ϕ, selected to facilitate algebraic operations:

$$P_s = \phi \left[\gamma\, (d_2)^2 - \frac{\gamma\, (d_1)^2}{\cos^2 \alpha} \right] \tan \alpha \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

As shown subsequently, ϕ is an experimental coefficient, distinct for each value of the kinetic flow factor and each channel slope.

Eq. 4 may now be evaluated in terms of Eqs. 6, 7, 9, and 10:

$$\frac{\gamma\, (d_2)^2}{2} - \frac{\gamma\, (d_1)^2}{2 \cos^2 \alpha} - \phi \left[\gamma\, (d_2)^2 - \frac{\gamma\, (d_1)^2}{\cos^2 \alpha} \right] \tan \alpha$$
$$= \frac{\gamma\, (V_1)^2\, d_1 \cos \alpha}{g\, d_2} \left[d_2 - \frac{d_1}{\cos \alpha} \right] \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

Eq. 11 is a complete equation for the hydraulic jump in sloping rectangular channels.

For practical use it is desirable to have an equation for the depth of tailwater, d_2. Eq. 11 can be simplified by dividing both sides of the expression by $\frac{\gamma}{2} \left[d_2 - \frac{d_1}{\cos \alpha} \right]$, giving

$$\left(d_2 + \frac{d_1}{\cos \alpha} \right) - 2\, \phi \left(d_2 + \frac{d_1}{\cos \alpha} \right) \tan \alpha = \frac{2\, (V_1)^2\, d_1 \cos \alpha}{g\, d_2} \ldots (12)$$

and Eq. 12 can be solved for d_2:

$$d_2 = \frac{d_1}{2 \cos \alpha} \left[\sqrt{\frac{8\, (V_1)^2 \cos^3 \alpha}{g\, d_1\, (1 - 2\, \phi \tan \alpha)} + 1} - 1 \right] \ldots\ldots\ldots (13)$$

Letting the quantity $\frac{(V_1)^2}{g\, d_1} = \lambda =$ the kinetic flow factor, Eq. 13 can be written in another convenient form:

$$d_2 = \frac{d_1}{2 \cos \alpha} \left(\sqrt{\frac{8\, \lambda \cos^3 \alpha}{1 - 2\, \phi \tan \alpha} + 1} - 1 \right) \ldots\ldots\ldots\ldots (14)$$

Eq. 14 is a general equation for d_2, the depth of flow at section 2, for either Case 3 or Case 4 of the hydraulic jump in sloping channels. For Case 3, the depth at section 2 is equivalent to the tailwater depth.

Case 2, shown in Fig. 1, is a transition between cases 1 and 3, and neither Eq. 14 nor Eq. 3 for the level-floor jump can be applied directly to that case. As shown subsequently, however, experimental coefficients can be used to relate Eqs. 14 and 3 in a solution for Case 2.

LABORATORY INVESTIGATION OF HYDRAULIC JUMP IN SLOPING CHANNELS

Scope of Tests.—An intensive study of the hydraulic jump in sloping channels was begun in August, 1936, by Mr. Yarnell, in cooperation with the Iowa Institute of Hydraulic Research, State University of Iowa, Iowa City, Iowa. Six hundred tests, on slopes of 1 on 6, 1 on 3, 1 on 2, and 1 on 1, were completed, and an analysis of the data had been started before Mr. Yarnell's death in March, 1937. The data from this investigation were loaned to the TVA in April, 1939.

Unfortunately, because of limitations in the apparatus, jumps tested on slopes greater than 1 on 6 were largely in the Case 2 classification shown in Fig. 1. Since it is basic to the present analysis to derive experimental coefficients from jumps in the Case 3 or Case 4 classification, data on the steeper slopes were insufficient to develop the necessary empirical relations.

Laboratory Setup.—The laboratory setup consisted of a glass-walled flume, 30 in. wide, 3 ft deep, and 30 ft long, with a large head-tank at the upper end. The sloping floor was built of wood, carefully treated and reinforced to produce a smooth, flat surface. The upstream end of the slope was fastened to a watertight bulkhead in the head-tank. An adjustable, sharp-edged, vertical slide-gate was used to regulate flow from the head-tank to the flume. Water depths in the flume were regulated at the lower end by a steel gate hinged at the bottom. Discharges were measured by means of a sharp-edged, suppressed, rectangular weir which emptied into the head-tank. Water-surface elevations in the flume were measured with a point gage on a sliding carriage. Point-gage readings were "zeroed" by readings on the floor after every observation. Three rows of piezometers were located on 6-in. centers over the entire length of the flume. Piezometers in the level steel floor consisted of $\frac{3}{8}$-in. pipe nipples, threaded into the floor and ground flush with the bottom of the flume. Piezometers in the wooden apron were made of $\frac{1}{4}$-in. brass tubing. Each piezometer was connected by means of rubber tubing to a manometer board.

VERIFICATION OF ANALYSIS FROM TESTS ON 1 ON 6 SLOPE

The Kinetic Flow Factor, λ.—In the foregoing analysis, the quantity $\frac{(V_1)^2}{g\,d_1} = \lambda$ has been referred to as the kinetic flow factor, a dimensionless criterion for dynamic similarity which is the square of Froude's number.[8] In problems of open-channel flow Froude's number is applicable when forces of inertia and gravity predominate. As applied to the hydraulic jump in channels of unit width, dynamic similarity implies geometric similarity of all common vertical and longitudinal dimensions. Since the kinetic flow factor is a dimensionless index of similarity, independent of the units of measurement or absolute size of the phenomena, it can be used to correlate experimental data obtained under many different test conditions.

The Pressure Coefficient, ϕ.—In the derivation of Eq. 11 the horizontal component of pressures on the sloping floor was expressed in terms of an experimental coefficient, ϕ (see Eq. 10). In this investigation, normal pressures on the sloping floor were measured by means of piezometers. An interesting fact observed by Messrs. Bakhmeteff and Matzke[3] and verified by the Yarnell tests was that the pressure profile of the hydraulic jump on a slope is very closely approximated by the point-gage profile. It would seem possible, therefore, to derive reasonably accurate pressure coefficients without the use of piezometric observations.

---

[8] "The Analytical Approach to Experimental Hydraulics," by Hunter Rouse, *Civil Engineering*, November, 1934, p. 563.

If p_n is the normal pressure at any point on the slope, then

$$p_n = \gamma\, y \qquad (15)$$

in which y is the vertical height of the pressure gradient above the floor. Thus, if $\bar{y}$ is the average height of the pressure gradient over a slope of length $\frac{L_r}{\cos\alpha}$, the total normal pressure on a unit width of channel is

$$P_n = \frac{\gamma\, \bar{y}\, L_r}{\cos\alpha} \qquad (16)$$

The quantity ($\bar{y}\, L_r$) in Eq. 16 is the area of the pressure diagram, shown by experiment to be proportional to the area of the jump body. The horizontal component of the total normal pressure is P_s, or

$$P_s = P_n \sin\alpha = \gamma\, \bar{y}\, L_r \tan\alpha \qquad (17)$$

Thus, from Eqs. 10 and 17,

$$\phi = \frac{\bar{y}\, L_r}{(d_2)^2 - \dfrac{(d_1)^2}{\cos^2\alpha}} \qquad (18)$$

Fig. 6(*a*) shows a plot of experimental data from tests on a 1 on 6 slope, indicating that ϕ is a function of the kinetic flow factor, or

$$\phi = f_1(\lambda) \qquad (19a)$$

An average curve is quite well defined for values of λ from 5 to 50. Future tests may extend the curve to higher values of the kinetic flow factor, unless a maximum of $\lambda = 50$ can be accepted as a practical limit. The curve in Fig. 6(*a*) has the straight-line equation,

$$\phi = 2.58 - 0.021\,\lambda \qquad (19b)$$

Length of the Roller, L_r.—It is convenient to express the length of the jump roller in terms of a dimensionless ratio. In treatments of the level-floor hydraulic jump, the length is commonly expressed in the ratio $\frac{L}{d_j}$, in which d_j is the difference in water-surface elevation at sections 1 and 2. For the case of the jump on a slope, however, d_j is not a suitable parameter since, as shown in Fig. 1, it varies with the jump's position on the slope. Experiments indicate that the length of the roller of the hydraulic jump in sloping channels is best defined by the ratio $\frac{L_r}{d_2}$ as a function of the kinetic flow factor, or

$$\frac{L_r}{d_2} = f_2(\lambda) \qquad (20)$$

Fig. 6(*b*) is a plot of Eq. 20 from experiments on the 1 on 6 sloping channel. An average curve is reasonably well defined.

Verification of Eq. 14, Cases 3 and 4.—To confirm the applicability of Eq. 14, all tests for which the nominal slope of the channel was 1 on 6 were classified as shown in Fig. 1. For each test classified in Case 3 or 4, the depth d_2 was computed from Eq. 14, using measured values of slope, discharge, and initial depth, with values of ϕ taken from Fig. 6(*a*). Actual slope of the channel varied from 0.170 to 0.176 for different installations. The depth at section 1, d_1, was taken as the average of a series of point-gage measurements made at the toe of the roller. Since the depth d_1 is not only difficult to measure accurately but is important to the evaluation of Eq. 14, it is frequently a source of inaccuracy in the computations. The depth at section 2, d_2, was taken for Case 3 jumps as the depth of tailwater and for Case 4 jumps as the depth at the end of the roller.

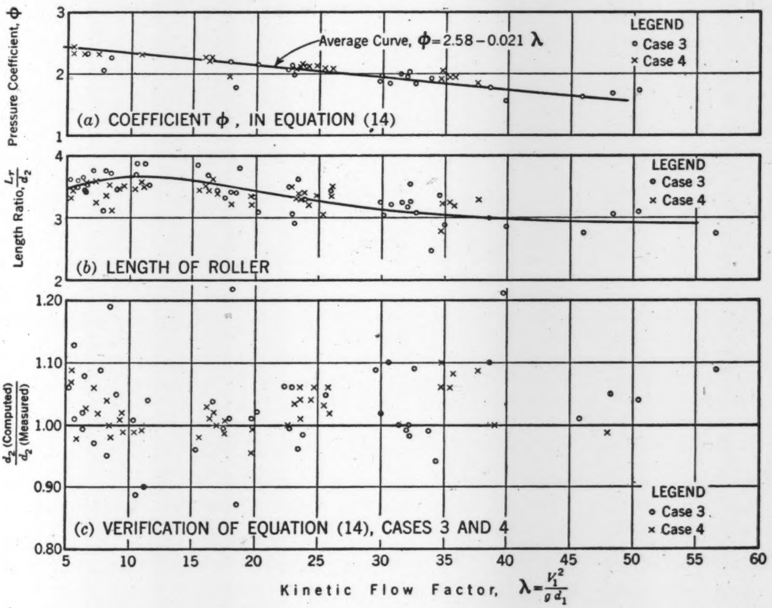

Fig. 6.—Dimensionless Relationships Derived from Experiment (Slope of Channel, 1 on 6) Eq. 14, Cases 3 and 4

A comparison for verification of Eq. 14 is shown in Fig. 6(*c*), in which the ratio of d_2-computed to d_2-measured is plotted against the kinetic flow factor. It is believed that deviations from an exact agreement between measured and computed values reflect to some extent the difficulties of observation.

Verification of Eq. 14, Case 2.—Fig. 7 shows Case 2 of the hydraulic jump which, being partly on the slope and partly on the level floor, is intermediate between cases 1 and 3. Obviously, if given values of slope, discharge, and initial depth for a Case 2 jump are evaluated in Eq. 14, the result, always exceeding the depth of tailwater, d_2, for the given case, is a depth $(d_2)'$ for an imaginary Case 3 jump. Similarly, if the same data are evaluated in Eq. 3, the result is a depth $(d_2)''$, less than d_2, for an imaginary Case 1 jump.

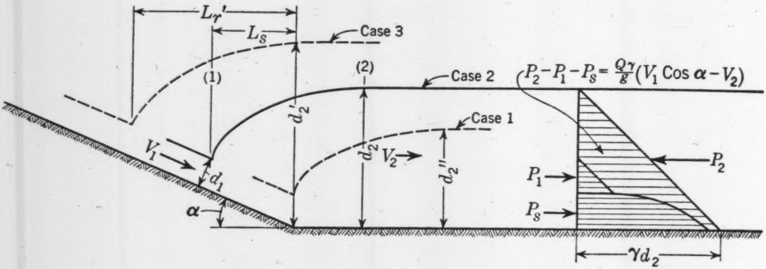

FIG. 7.—CASE 2; THE HYDRAULIC JUMP IN SLOPING CHANNELS, WITH THE TOE OF THE ROLLER ON THE SLOPE AND THE END OF THE ROLLER ON THE HORIZONTAL FLOOR

Experiments indicate that the depth of tailwater for any jump in the Case 2 classification can be expressed in an empirical relation,

$$d_2 = (d_2)' - k\left[(d_2)' - (d_2)''\right] \dots\dots\dots\dots\dots\dots (21)$$

in which k is an experimental coefficient, a function of λ and the ratio $\frac{L_s}{(L_r)'}$. The symbol L_s denotes the horizontal length from the toe of the jump to the lower end of the slope, and $(L_r)'$ is the length of the roller of the imaginary Case 3 jump from Eq. 20. Thus,

$$k = f_3\left[\frac{L_s}{(L_r)'}\right] \dots\dots\dots\dots\dots\dots\dots\dots (22)$$

Fig. 8 shows a plot of k against $\frac{L_s}{(L_r)'}$, from tests on the 1 on 6 slope. For all practical purposes, the average curve ($\lambda = 25$) is probably sufficient. Fig. 9 for Case 2 jumps in the 1 on 6 sloping channel shows a comparison of measured depths with depths computed from Eqs. 3, 14, and 21, using the average curve of Fig. 8.

Practical Application of the Analysis.—Frequently, when a large number of computations are required, solution for d_2 in Eq. 3, Case 1, can be simplified by writing the equation in dimensionless form,

$$\frac{d_2}{d_1} = \tfrac{1}{2}\left(\sqrt{8\,\lambda + 1} - 1\right) \dots\dots\dots\dots\dots\dots (23)$$

and the ratio $\frac{d_2}{d_1}$ can be plotted as a function of λ.

Similarly, for cases 3 and 4, when the slope of the channel is constant, Eq.

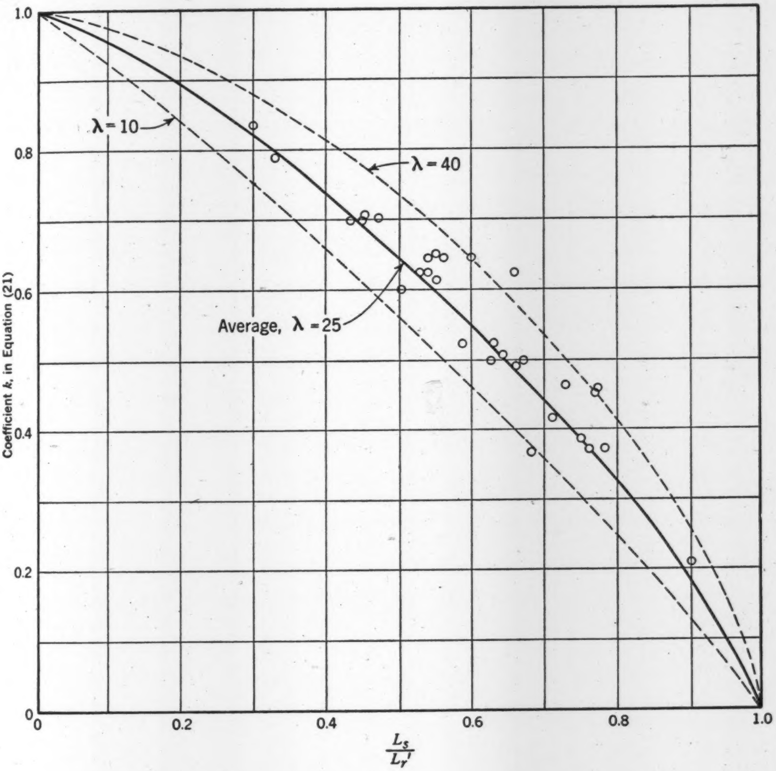

FIG. 8.—COEFFICIENT k IN EQ. 21, FOR A CASE 2 JUMP ON A 1 ON 6 SLOPE

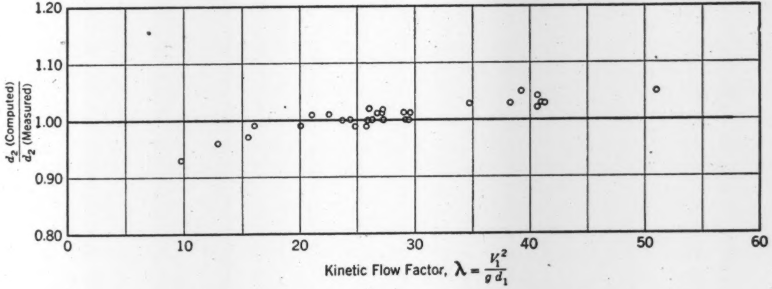

FIG. 9.—VERIFICATION OF EQ. 21, CASE 2, 1 ON 6 SLOPE

14 can be written,

$$\frac{d_2}{d_1} = \frac{1}{2 \cos \alpha} \left(\sqrt{\frac{8 \lambda \cos^3 \alpha}{1 - 2 \phi \tan \alpha} + 1} - 1 \right) \ldots\ldots\ldots\ldots (24)$$

and again, if the terms cos α and tan α are evaluated, the ratio $\frac{d_2}{d_1}$ can be plotted as a ratio of λ, using ϕ from Eq. 19*a*. Having curves of Eqs. 23 and 24 for cases 1 and 3, the solution of Eq. 21 for Case 2 is greatly facilitated.

In nearly every practical case, the location of section 1 at the toe of the jump must be assumed in first approximation for d_2, in order that d_1, λ, and ϕ can be evaluated from known conditions. If the jump falls in the Case 2 classification, the length L_s must also be assumed. Results obtained from the initial assumptions can readily be refined by successive approximations.

CONCLUSIONS

It is convenient to classify the most common forms of the hydraulic jump in open channels into several general cases based on the position of the jump in a sloping channel. Although the jump on a slope is similar in most respects to the level-floor jump, analysis of this case is dependent upon experimental coefficients to evaluate pressures on the sloping floor.

This paper presents a generalized analysis of the jump in sloping channels, leading to a practical method of computing the essential dimensions of the jump. The treatment was verified by application to experimental data on jumps in a 1 on 6 sloping channel. Dimensionless presentation of data on the 1 on 6 slope makes the results suitable for design use. It is hoped that further experimentation will make available similar data for use with steeper slopes.

ACKNOWLEDGMENTS

The analysis contained in this paper was made in the Hydraulic Laboratory Section of the Hydraulic Data Division, Tennessee Valley Authority. The work of the Hydraulic Laboratory is under the direction of A. S. Fry, M. Am. Soc. C. E., head hydraulic research engineer, and the direct supervision of G. H. Hickox, M. Am. Soc. C. E., senior hydraulic engineer.

As stated previously, the experimental data were obtained from the laboratory investigation made in 1936–1937 by Mr. Yarnell, whose notes and photographs were loaned to the TVA by the U. S. Department of Agriculture. The writer was employed as an assistant to Mr. Yarnell from August, 1936, until January, 1937.

Grateful acknowledgment is due Mr. Hickox and Sherman M. Woodward, Hon. M. Am. Soc. C. E., for consultation and advice. Many others have contributed with criticism and assistance in computations.

DISCUSSION

Joe W. Johnson,[9] Assoc. M. Am. Soc. C. E.—The problem of the hydraulic jump in a sloping channel is discussed in detail in this paper. The author has presented a formula which is applicable in most practical problems. The experimental coefficient in this formula has been determined over a fairly wide range of the kinetic flow factor.

From experiments in the hydraulic laboratory of the University of California, B. D. Rindlaub[10] developed a relationship for calculating the principal dimensions of a jump in sloping channels. The results of these experiments are of interest in connection with Mr. Kindsvater's paper.

The experiments were conducted in a glass-wall channel, 6 in. wide and 3 ft deep, in which a sloping bed could be set at various angles between 0° and 30°. The flume was equipped with an orifice for flow measurement, a forebay, a tail gate, and point gages for the determination of surface elevations. Most of the experiments were conducted with the bottom set at the angle $\alpha = 12°$; however, experiments also were made with slopes of 8°, 24°, and 30°.

In analyzing the experimental results, Mr. Rindlaub assumed the following equation to describe the jump in a sloping channel:

$$\frac{Q\,\gamma}{g}(V_1 \cos\alpha - V_2) = \frac{b\,\gamma}{2}(d^2{}_1 - d^2{}_2) + W \sin\alpha \cos\alpha \ldots\ldots\ldots (25)$$

in which W is the weight of the water in the jump. As in the case of the jump in a horizontal channel, the variables in this equation may be separated into dimensionless groups. If l represents the length along the floor from the toe of the jump to the point of change in grade $\left(l = \frac{L_s}{\cos\alpha} \text{ in Fig. 7 of the paper}\right)$, and d_1, d_2, α, and Q are as defined by the author, the following dimensionless groups may be written:

(a)..............α

(b)..............$\frac{d_2}{d_1}$

(c)..............$\lambda_1 = \frac{Q^2}{g\,d^3{}_1}$ and $\lambda_2 = \frac{Q^2}{g\,d^3{}_2}$

and

(d)..............$\frac{l}{d_1}$

The method of summarizing the experimental data by the use of these dimensionless groups is illustrated by Fig. 10. For the data taken with a bed slope of 12°, a plot of the ratio $\frac{d_2}{d_1}$ against the kinetic flow factor, λ_1, is shown for various values of $\frac{l}{d_1}$. The plotted points show a fairly consistent variation and, therefore, permit curves of constant $\frac{l}{d_1}$ to be constructed. For comparative purposes the relationship between $\frac{d_2}{d_1}$ and λ_1 for a jump in a horizontal channel also is shown in Fig. 10. Data taken on channels with slopes of 8°, 24°, and 30° gave curves similar to those in Fig. 10. In the experiments the value of l was varied between 0 and 4.11 ft, d_1 between 0.013 and 0.224 ft, d_2 between 0.25 and 1.18 ft, and Q between 0.056 and 0.670 cu ft per sec. All four of the author's classifications of the jump in sloping channels, consequently, were included in the experiments.

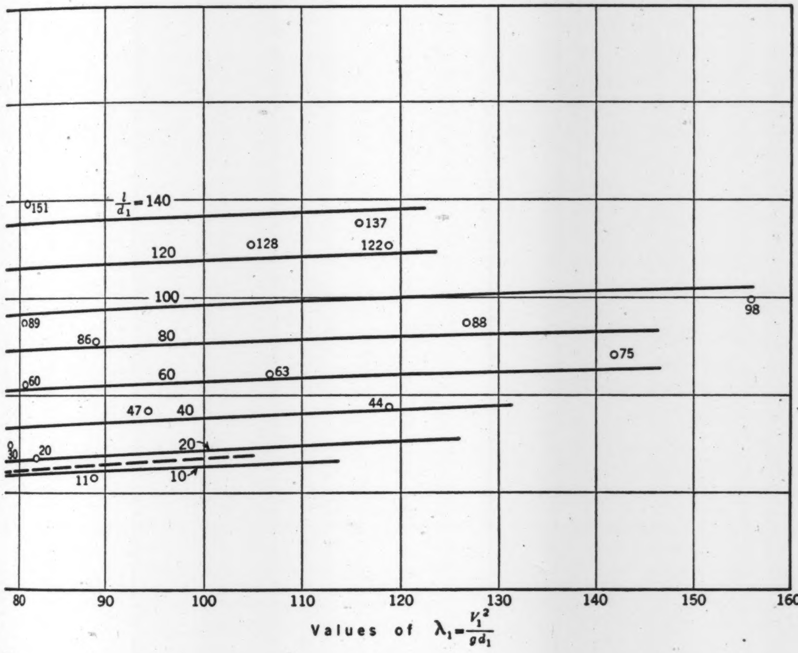
FIG.

The characteristics of a jump on a particular slope may be computed from plots similar to that illustrated in Fig. 10. Thus, by knowing the values of d_1 and Q, and by assuming a value of l, the values of $\frac{l}{d_1}$ and λ_1 can be computed. The plot of $\frac{d_2}{d_1}$ versus λ_1 for the particular slope can then be entered and the value of $\frac{d_2}{d_1}$ corresponding to the computed values of $\frac{l}{d_1}$ and λ_1 determined. Finally, the value of d_2 can be calculated from $\frac{d_2}{d_1}$.

This procedure is similar to the solution of Eq. 24 as described by the author. Mr. Kindsvater's generalized method of analysis, perhaps, is more practicable because curves of $\frac{d_2}{d_1}$ versus λ_1 (similar to Fig. 10) for the particular slope are not required. The author is to be complimented on his presentation of a simple and convenient method of computation that is suitable for most design problems.



10

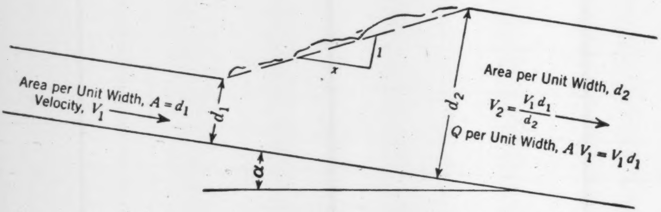
Karl R. Kennison,[11] M. Am. Soc. C. E.—The author has done an excellent job in summarizing the available data in usable form. The subject of the paper seems to be somewhat of a misnomer, since it does not deal with continuous sloping channels, referred to as "a fifth case," but rather with the extent to which a sloping jet striking a horizontal apron can be backed up the slope. The results are very much worth while, particularly because they contain empirical factors resulting from important experimental work.

---

[11] Chf. Engr., Met. Dist. Water Supply Comm., Commonwealth of Massachusetts, Boston, Mass.

The computations involved in the theoretical deductions of the formulas seem to be more complicated than warranted by the actual uncertainties in flows of this type. For example, these problems generally deal with a condition where the neglected friction loss is an important item. In the case of any formula for the jump in sloping channels, it should be borne in mind that this fact is certain to vitiate the results, particularly in the case of low Froude numbers.

The writer believes that the formula for the hydraulic jump in a sloping channel (made general to include the angle of slope, if any, of the channel bottom) can be simplified, both in the derivation and in the result, by equating the momenta before and after the jump, considering the forces parallel to the channel bottom, and by expressing the height of the jump as a function of its length. Referring to Fig. 11, the momentum equation is as follows, using the author's nomenclature:



Area per Unit Width, $A = d_1$
Velocity, V_1
d_1
α
1
x
d_2
Area per Unit Width, d_2
$V_2 = \frac{V_1 d_1}{d_2}$
Q per Unit Width, $A V_1 = V_1 d_1$

FIG. 11

$$\frac{Q \gamma V_1}{g} - \frac{Q \gamma V_2}{g} = \frac{\gamma d^2{}_2 \cos \alpha}{2} - \frac{\gamma d^2{}_1 \cos \alpha}{2}$$

$$- x (d_2 - d_1) \left(\frac{d_2 + d_1}{2}\right) \gamma \sin \alpha \ldots\ldots\ldots\ldots\ldots (26)$$

This becomes

$$d_2 = \frac{d_1}{2} \left(\sqrt{\frac{8 \lambda}{\cos \alpha - x \sin \alpha} + 1} - 1 \right) \ldots\ldots\ldots\ldots (27a)$$

Instead of expressing the depth after the jump as the height normal to the bottom of the slope, consider the author's case of impinging on a horizontal apron and take d_2 vertical; then Eq. 26 becomes

$$d_2 = \frac{d_1}{2 \cos \alpha} \left(\sqrt{\frac{8 \lambda}{\cos \alpha - x \sin \alpha} + 1} - 1 \right) \ldots\ldots\ldots (27b)$$

which is to be compared with Eq. 14.

It is sufficiently accurate for practical purposes to assume that the length of the jump is three times its height, or that $x = 3$. Actually this simpler formula with $x = 3$, will give the same result as the author's, for a kinetic flow factor, λ, in the vicinity of 50. The choice of the value to assign to the multiplier, x, makes surprisingly little difference in the result. Using $x = 2$ gives a resulting value of d_2 which is 97% of that using $x = 3$, for a slope of 0.05; and 93%, for a slope of 0.10.

J. C. **Stevens**,[12] M. Am. Soc. C. E.—This paper touches a phase of the hydraulic jump about which comparatively little is known, and the author deserves the thanks of the profession for presenting an analysis of the data obtained by Mr. Yarnell. This analysis brings out a few anomalies for which there is no ready explanation. Perhaps it would be well to agree on a definition of the hydraulic jump before speculating too much about it.

The beginning of the jump is definite and well defined, but the end is open to conjecture. On a horizontal bed the end of the jump has been taken very properly as the section where the water surface reaches its maximum height[13] —in other words, where all the kinetic energy that is susceptible of conversion to potential energy has been so converted and before the surface profile is affected by the friction gradient in the channel below the jump. This end of the jump is not the end of the roller, as the author has considered it.

To define the length of the roller as the length of the jump, even on a sloping bed, slurs over the dominant characteristic of the jump, which is to convert kinetic to potential energy by highly concentrated turbulence.

The author's four cases are purely arbitrary, and scarcely can be considered as basic. With fluctuating tailwater or variable flow, the jump will oscillate through all four cases. The first three are applicable only where a slope merges into a horizontal bed.

Madden Dam was designed with an apron inclined downward into tailwater at a slope of 1 on 4.[14] The apparent theory was that, as the high-velocity water flows down the slope, it will encounter the proper tailwater level to produce the jump, and thus prevent undue scouring of the river bed. Actual experience has not substantiated that theory even though model tests seemed to be favorable to it. On Madden Dam, the upward sloping continuous baffle at the end of the apron has counteracted the effect of the 1 on 4 slope.

Certain it is that the model tests of a downward sloping apron for Bonneville Dam indicated that such an apron would be the worst that could be built as far as scour is concerned.[15]

General Formulas for the Hydraulic Jump in Rectangular Channels.—Some tentative formulas are presented herein for the solution of the hydraulic jump on level beds and on beds sloping both downward (negative) and upward (positive) in the direction of flow. Fig. 12 shows the elements of an hydraulic jump (a) for a negative slope and (b) for a positive slope. In each case the momentum relationships for a rectangular channel or for a unit width of a wide channel are: For a negative slope (downward in the direction of flow)—

$$\frac{Q}{g} V_1 + \frac{d^2_1}{2} \cos \alpha + W \sin \alpha = \frac{Q}{g} V_2 + \frac{d^2_2}{2} \cos \alpha \ldots\ldots\ldots (28a)$$

and, for a positive slope—

$$\frac{Q}{g} V_1 + \frac{d^2_1}{2} \cos \alpha = \frac{Q}{g} V_2 + \frac{d^2_2}{2} \cos \alpha + W \sin \alpha \ldots\ldots\ldots (28b)$$

in which, in addition to the notation of the paper, W is the total weight of water in the jump prism between the two depths d_1 and d_2.

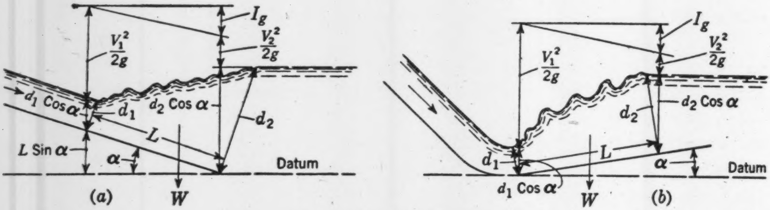

FIG. 12.—ELEMENTS OF AN HYDRAULIC JUMP

The length of the jump is quite arbitary except that it should not be assumed too short. The length should be chosen so that the energy conversion would be completed as indexed by the maximum height of the water surface. If a greater length is taken, the height of the jump is penalized by a slight drop due to friction. However, to include the force of friction for the relatively short length in which the jump develops is usually an unnecessary refinement.

The writer has adopted the length of jump given by Andréi Ivanchenko,[16] M. Am. Soc. C. E., in his discussion of the paper by Messrs. Bakhmeteff and Matzke. His formula, based on the lengths given in the paper for jumps on a level bed, is

$$L = 10.6\, \lambda^{-0.185} (d_2 - d_1) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

in which L = length of jump.

Weight of the Jump.—The weight of the jump prism has the force component $W \sin \alpha$ acting in the direction of flow for negative slopes and counter to the direction of flow for positive slopes. On a level bed this force disappears.

Any other than the simplest delineation of the jump boundaries seems an unwarranted refinement, therefore the body of the jump has been considered as a trapezoid bounded by the stream bed, a straight-line surface profile, and the two depths d_1 and d_2. Neglecting the curvature of the surface profile involves certain compensating consideration, such as

(1) The specific weight of the water is reduced by the entrained air;

(2) The water is being decelerated, which reduces the horizontal component of the weight on a negative slope and increases it on a positive slope;

(3) Deceleration of the vertical component tends to increase the weight on either slope; and

---

[16] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 668.

(4) In a strict sense, hydrostatic pressure within the jump does not exist although pressure measurements on the bed indicate that static pressures are closely approximated.

Considering all these factors, the effects of which are virtually unknown (or at best may be determined only by refined experimentation), to take into account the curvature of the surface profile seems hardly justified. However, if found to be desirable, the numerical factor in Eq. 29 may be increased to compensate completely for thus neglecting curvature.

The weight of the body of the jump for a unit width therefore becomes

$$W = 10.6\,\lambda^{-0.185}\,\tfrac{1}{2}\,(d^2_2 - d^2_1) \qquad (30)$$

Kineticity of the Jump.—There seems to be no particular virtue in tying the "kinetic flow factor" $\left(= \frac{V^2}{g\,d_1}\right)$ to the Froude number. The writer prefers to use half that factor, $k = \frac{V^2}{2\,g\,d_1}$, which has real physical meaning since it is the ratio of the kinetic to the potential energy at the beginning of the jump and therefore well may be called its "kineticity."

For any given bed slope, k is the only independent dimensionless parameter of the jump. It is measured easily and, once known, all other characteristics are derived readily from it. The jump characteristics on a level bed already have been outlined by the writer.[17] The kineticity k will be used in place of λ in what follows. Since its value is $\frac{\lambda}{2}$, Eq. 30 becomes

$$W = \frac{9.3}{k^{0.185}}\,\frac{d^2_2 - d^2_1}{2} \qquad (31)$$

Probably, the numerical factor in Eq. 31 should be increased for negative slopes and reduced for positive slopes. Only future experimentation can determine that. However, for this discussion, no change was made from that indicated for level beds.

General Formula.—Substituting Eq. 31 in Eqs. 28 and transposing,

$$\frac{Q}{g}\,(V_1 - V_2) = \tfrac{1}{2}\,(d^2_2 - d^2_1)\,(\cos\alpha \pm m \sin\alpha) \qquad (32)$$

in which for brevity m (a coefficient for the length of the jump) is written for $\frac{9.3}{k^{0.185}}$. In Eq. 32 the negative sign is for negative slopes (downward) and the positive sign for positive slopes (upward) in the direction of flow.

It will be simpler if each jump characteristic were to be put in dimensionless terms by expressing each as a ratio in which the denominator is the initial potential energy. Thus, let

$$k = \frac{V^2_1}{2\,g\,d_1 \cos\alpha} \qquad (33a)$$

and, the dimensionless height of the jump,

$$J = \frac{d_2}{d_1 \cos\alpha} \qquad (33b)$$

---

[17] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 660.

Substituting these in Eq. 32 and invoking the continuity relations $Q = V_1 d_1 = V_2 d_2$, Eq. 32 reduces to

$$J\,(J \cos \alpha + 1) = \frac{4\,k}{\cos \alpha \pm m \sin \alpha} \quad \text{.............. (34)}$$

For a level bed, Eq. 34 reduces to

$$J\,(J + 1) = 4\,k \quad \text{...................... (35a)}$$

and, from Eq. 34, the final depth is given by

$$J = \frac{1}{2 \cos \alpha}\left(-1 + \sqrt{\frac{16\,k}{1 \pm m \tan \alpha} + 1}\right) \quad \text{.......... (35b)}$$

which may be compared with Eq. 14.

Eq. 35*b* is a general formula for rectangular channels in which the negative sign is for negative slopes and the positive sign for positive slopes. When the slope is zero, it reduces to,

$$J = \tfrac{1}{2}\,(-1 + \sqrt{16\,k + 1}) \quad \text{.................. (35c)}$$

TABLE 1.—LIMITING VALUES FOR JUMPS ON SLOPING BEDS

No.	Description	TANGENT α					
		0.10	0.125	0.167	0.200	0.225	0.250
1	Final depth, J, is infinite when k =...........	0.85	2.25	10.96	28.5	54.2	98.9
2	Height of jump, J, is minimum when k =.....	1.70	5.59	26.7	70.6	134	219
3	Minimum height of jump, J =...............	6.14	11.6	26.1	43.3	60.5	80.5

Eq. 35*b* shows that the hydraulic jump on negative sloping beds has certain very definite limitations. The final depth becomes infinite for $m \tan \alpha = 1$. The values of k for which this occurs are found by substituting for m its value and solving for k (see Table 1, Item 1).

For larger values of k the depths diminish rapidly to some stable point. This point may be the minimum value of J, in either Eq. 34 or Eq. 35*b*, or an inflection point for a somewhat larger value of k. If either Eq. 34 or Eq. 35*b* is differentiated for negative slopes, the minimum values of J are found for

$$k = (11.0 \tan \alpha)^{5.4} \quad \text{...................... (36)}$$

and, for the foregoing negative slopes, the values given in Table 1, Items 2 and 3, apply.

The significance of Table 1 is that, for the slopes given, the jumps are wholly fictitious for values of k less than the limitations outlined therein. Fig. 13(*a*) shows graphs of Eq. 35*b* for both negative and positive slopes. Values of J were computed from assigned values of k. The minimum values of the curves for negative slopes are indicated by circles which have been connected by a curve.

It is likely that the zone of possible jumps on these curves is defined by the points of inflection rather than by the points of minimum values. A second line therefore has been drawn connecting the points of inflection (determined graphically). Between the two curves is a zone of doubt, but to the left of the minimum-values curve the jumps are fictitious.

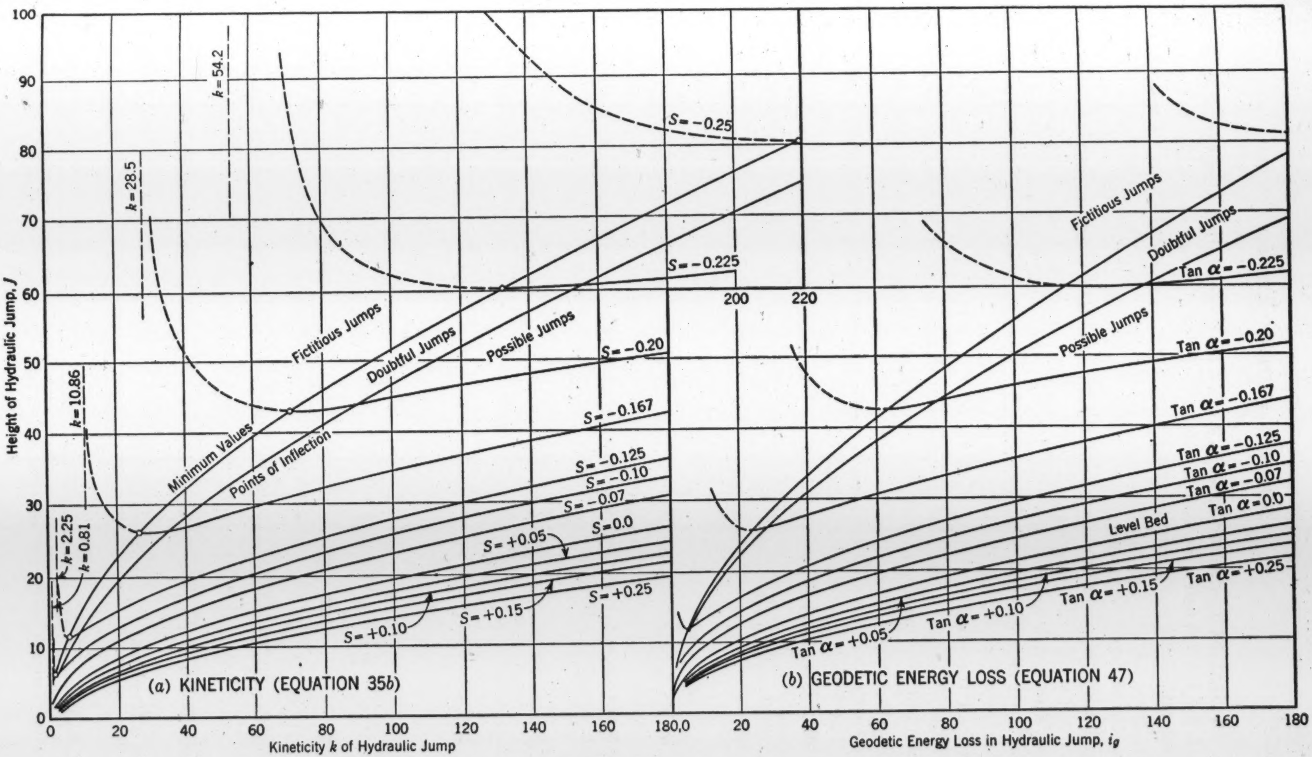

FIG. 13.—CURVES OF HYDRAULIC JUMP EQUATIONS

Analogous limitations exist in Eq. 14 from which it is seen that d_2 becomes infinite for $2\,\phi \tan \alpha = 1$ or for $(5.16 - 0.042\,\lambda) \tan \alpha = 1$ (Fig. 6(*a*)). This limitation will not apply to the 1 on 6 slope for which the author's formula is designed.

From the foregoing analysis it would appear that what have been called hydraulic jumps on inclined beds of 1 on 6 or steeper, projecting into tailwater, are not hydraulic jumps at all but a mere plunging of water into a pool. If a jet from a fire hose be directed into a pond, considerable turbulence results, but an hydraulic jump is not formed. This anomaly was noted by Messrs. Bakhmeteff and Matzke in their experiments.[3] The apparatus used by them limited the steepest slope to $S_0 = 0.07$, yet they state (speaking of steeper slopes), "The live jet 'plunges' into the tail water and within the steep section follows the slope downward with comparatively slow expansion and obviously relatively small losses."

Energy Losses.—There are two kinds of energy losses in hydraulic jumps on inclined beds: (1) Specific energy losses (that is, losses with reference to the stream bed); and (2) geodetic energy losses that are referenced to a horizontal datum.

The specific energy equation for either negative or positive slopes is

$$d_1 \cos \alpha + \frac{V^2_1}{2\,g} = d_2 \cos \alpha + \frac{V^2_2}{2\,g} + I_s \ldots\ldots\ldots\ldots (37)$$

in which I_s is the specific energy loss. (Coefficients,[18] strictly speaking, should be applied to the momentum flux and to the kinetic energy to obtain the mean momentum and energy of a unit weight of water. However, at this stage such refinements are hardly warranted.) Eq. 37 reduces to

$$\frac{V^2_1}{2\,g} = \frac{d^2_2}{d_2 + d_1} \cos \alpha + \frac{d^2_2}{d^2_2 - d^2_1} I_s \ldots\ldots\ldots\ldots (38)$$

The specific energy loss I_s is also to be put in terms of the initial potential energy—

$$i_s = \frac{I_s}{d_1 \cos \alpha} \ldots\ldots\ldots\ldots (39a)$$

Substituting Eqs. 33 and 39*a* in Eq. 38:

$$k = \frac{J^2 \cos^2 \alpha}{J \cos \alpha + 1} + i_s \frac{J^2 \cos^2 \alpha}{J^2 \cos^2 \alpha - 1} \ldots\ldots\ldots\ldots (39b)$$

The specific energy loss is then obtained by eliminating k between Eqs. 34 and 39*b* and solving for i_s:

$$i_s = \frac{(J \cos \alpha - 1)^3}{4\,J \cos \alpha} \pm \frac{(J^2 \cos^2 \alpha - 1)\,(J \cos \alpha + 1)}{4\,J \cos \alpha} \tan \alpha \ldots\ldots (40)$$

For a level bed this reduces to

$$i = \frac{(J - 1)^3}{4\,J} \ldots\ldots\ldots\ldots (41)$$

---

[18] "Applied Fluid Mechanics," by Morrough P. O'Brien and George H. Hickox, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1937.

—a formula developed by writer in 1925.[19,20] Eq. 40 gives the energy loss with reference to the stream bed. A more useful formula is one that gives the losses with reference to a horizontal datum plane which will be styled the "geodetic energy loss." Let the plane be one passing through the foot of d_2 for negative slopes and d_1 for positive slopes, as shown in Fig. 12. The geodetic energy equation then becomes, for negative slopes,

$$L \sin \alpha + d_1 \cos \alpha + \frac{V^2_1}{2\,g} = d_2 \cos \alpha + \frac{V^2_2}{2\,g} + I_g \tag{42a}$$

and, for positive slopes,

$$d_1 \cos \alpha + \frac{V^2_1}{2\,g} = d_2 \cos \alpha + \frac{V^2_2}{2\,g} + L \sin \alpha + I_g \tag{42b}$$

in which I_g = the geodetic energy loss. Eq. 29 in terms of k becomes

$$L = 9.3\,k^{-0.185}\,(d_2 - d_1) = m\,(d_2 - d_1) \tag{43}$$

and Eq. 39a for geodetic losses becomes

$$i_g = \frac{I_g}{d_1 \cos \alpha} \tag{44}$$

Substituting Eq. 43 in Eqs. 42:

$$\frac{1}{2\,g}\,(V^2_1 - V^2_2) = (d_2 - d_1) \cos \alpha \pm m\,(d_2 - d_1) \sin \alpha + I_g \tag{45a}$$

and

$$\frac{V^2_1}{2\,g} = \frac{d^2_2}{d_2 + d_1}\,(\cos \alpha \pm m \sin \alpha) + \frac{d^2_2}{d^2_2 - d^2_1}\,I_g \tag{45b}$$

Substitute Eqs. 33 and 44 in Eq. 45b and solve for k, thus:

$$k = \frac{J^2 \cos^2 \alpha}{J \cos \alpha + 1}\,(1 \pm m \tan \alpha) + i_g\,\frac{J^2 \cos^2 \alpha}{J^2 \cos^2 \alpha - 1} \tag{46}$$

The geodetic energy loss is then found by eliminating k between Eqs. 46 and 34 and solving for i_g, thus:

$$i_g = \frac{(J \cos \alpha - 1)^3}{4\,J \cos \alpha}\,(1 \pm m \tan \alpha) \tag{47}$$

For $\alpha = 0$, Eq. 47 reduces to Eq. 41.

Fig. 13(b) shows graphs of Eq. 47 in which the geodetic energy loss is plotted against values of J. The same zones of fictitious, doubtful, and possible jumps are evidenced in these graphs as in those of Fig. 13(a). For any given value of k, the height of jump J may be found from Fig. 13(a); then, entering Fig. 13(b) with this value of J, the geodetic energy loss as a multiple of the initial specific potential energy is readily found.

Perhaps a better picture of the energy losses in the hydraulic jump is obtained by expressing them as percentages of the initial energy. Only the percentage geodetic energy losses will be presented. From Fig. 12(a) for

---

[19] "Determining the Energy Lost in the Hydraulic Jump," by J. C. Stevens, *Engineering News-Record*, June 4, 1925, p. 929.

[20] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 661.

negative slopes,

$$\%\ \text{loss} = \frac{100\ I_g}{L \sin \alpha + d_1 \cos \alpha + \frac{V^2_1}{2\ g}} \quad \text{(48a)}$$

Substituting Eqs. 33*a* and 44,

$$\%\ \text{loss} = \frac{100\ i_g}{l \sin \alpha + k + 1} \quad \text{(48b)}$$

in which $l = \frac{L}{d_1 \cos \alpha}$, the length of the jump as a multiple of the initial specific potential energy.

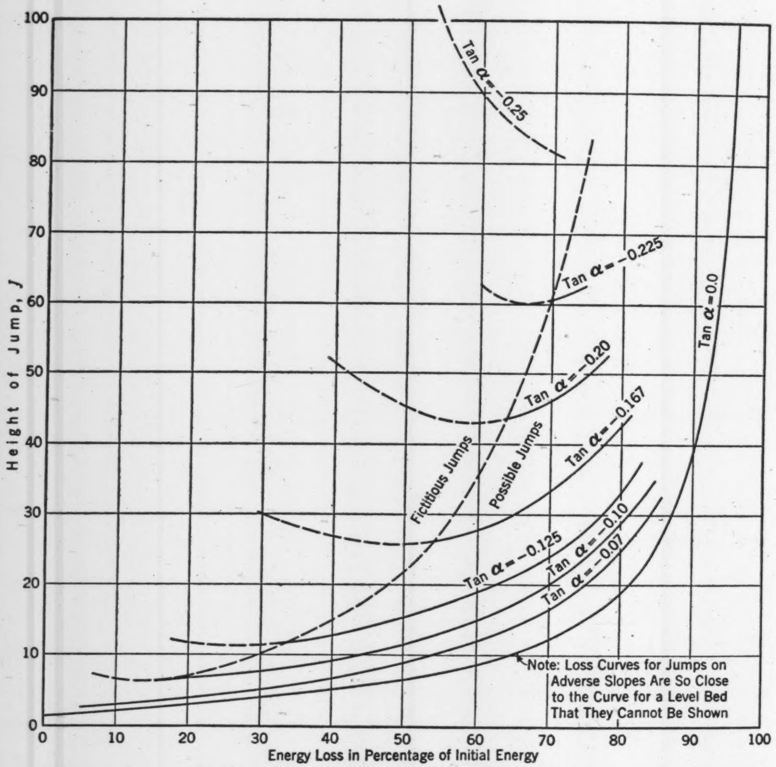

FIG. 14.—ENERGY LOSSES IN TERMS OF J (EQ. 48b)

Fig. 14 shows the losses computed from Eq. 48*b*, plotted to corresponding values of J. The loss curves for positive slopes are so near the curve for a level bed that they cannot be shown to the scale of this graph.

It is interesting to note that the percentage loss for any given height of jump increases as the negative slope diminishes; also that the zone of fictitious jumps is carried over from Fig. 13(*b*).

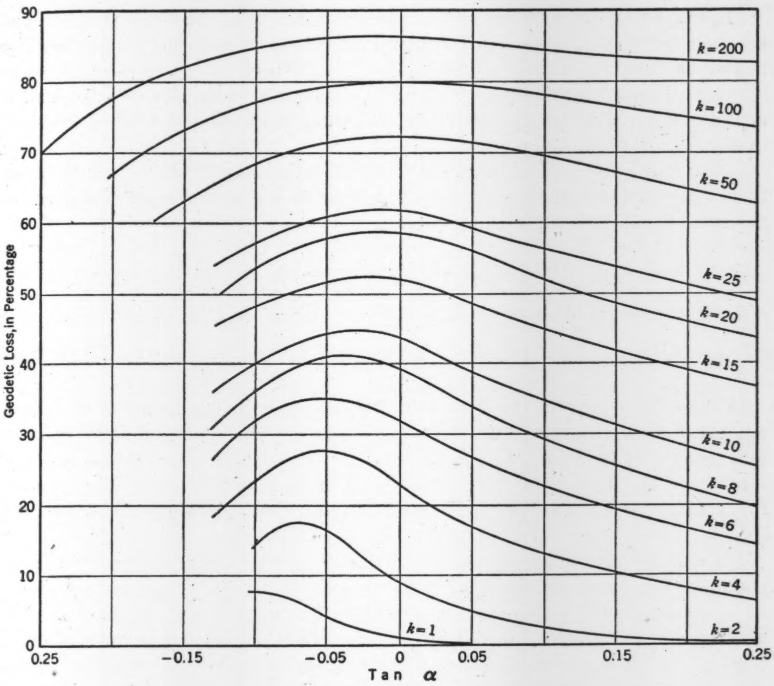

FIG. 15.—VARIATION OF LOSSES IN TERMS OF SLOPE AND KINETICITY

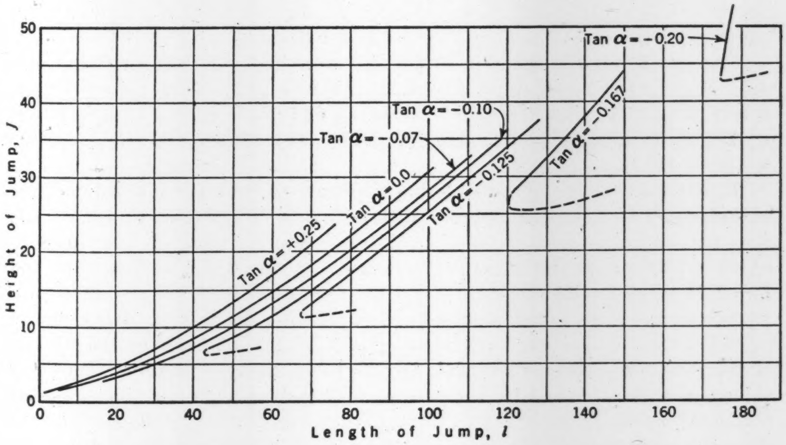

FIG. 16.—RELATION BETWEEN HEIGHT AND LENGTH OF JUMP

In order to show how the percentage loss varies with the slope and with the kineticity, Fig. 15 has been prepared. Loss (in percentages) is plotted against bed slope for given values of the kineticity k. Only values from the zone of "possible jumps" are plotted in Fig. 15. It appears from these curves that a negative slope of about 0.05 (1 on 20) is slightly more efficient than a level bed in dissipating the initial energy.

Length of Jump.—The length of the hydraulic jump for this discussion has been taken as indicated in Eq. 43. This may be put in dimensionless terms in the same manner as other jump characteristics. Thus, let

$$l = \frac{L}{d_1 \cos \alpha} \quad \text{(49a)}$$

Substituting Eqs. 33*b* and 49*a* in Eq. 43,

$$l = m \left(J - \frac{1}{\cos \alpha} \right) = 9.3\, k^{-0.185} \left(J - \frac{1}{\cos \alpha} \right) \quad \text{(49b)}$$

Curves for Eq. 49*b* are shown in Fig. 16 wherein the length l is plotted against J for various slopes. For negative slopes, the zone of fictitious jumps and lengths is evident. The lengths for positive slopes are so close to those for a level bed that only the curve for a 1 on 4 slope is shown. The lengths for a negative 1 on 4 slope could not be shown within the compass of the drawing.

Illustrative Examples.—In order to clarify the use of the curves presented, the following examples are offered:

Example 1.—On a level apron at the foot of a dam, the depth at the beginning of a jump is 1.25 ft and the velocity, 75 ft per sec. The velocity head is 87.0 ft; hence, from Eq. 33*a*, the kineticity $k = 69.5$. From Fig. 13(*a*), $J = 16.2$ and $d_2 = 16.2 \times 1.25 = 20.2$ ft. From Fig. 13(*b*), the energy loss $i_g = 54.5$; the head lost is $I_g = 1.25 \times 54.5 = 68.2$ ft; from Fig. 14, this loss is seen to be 77% of the initial geodetic energy. From Fig. 16, the dimensionless length of jump $l = 64.5$, whereas the actual length is $L = 1.25 \times 64.5 = 81$ ft.

Example 2.—If the apron in Example 1 were inclined downward into tailwater at a slope of 1 on 6, $d_1 \cos \alpha = 1.23$, and: $k = 70.5$; J (Fig. 13(*a*)) $= 31.1$; $d_2 = 1.23 \times 31.1 = 38.3$ ft; i_g (Fig. 13(*b*)) $= 62.0$; $I_g = 1.23 \times 62.0 = 76.4$ ft or 67% of the initial geodetic energy (Fig. 14); l (Fig. 16) $= 128$; and $L = 1.23 \times 128 = 157$ ft.

Example 3.—If the apron were inclined upward from the low point of the bucket on a 1 on 4 slope, $d_1 \cos \alpha = 1.21$; and: $k = 71.9$; J (Fig. 13(*a*)) $= 11.7$; $d_2 = 1.21 \times 11.7 = 14.3$ ft; i_g (Fig. 13(*b*)) $= 51$; $I_g = 1.21 \times 51 = 61.8$ ft, which is 69% of the initial geodetic energy (Fig. 14); l (Fig. 16) $= 45.5$; and $L = 1.21 \times 45.5 = 55$ ft.

Summary.—The writer would question (1) the conclusion of the author regarding the "convenience" afforded by his classification based on the position of the jump on a sloping channel, for the jump changes position with every change in kineticity; and (2) the statement that the jump on a slope is similar to the level-floor jump. The similarity only extends to mild slopes. As the slope steepens, the jump loses its identity entirely and becomes something else about which little is known. It is obvious from the author's four cases that he had in mind jumps at the toe of overflow dams, at which slopes obtain that are far steeper than any herein considered.

The writer's analysis is admittedly theoretical, but his formulas do have simplicity to recommend them. The existing experimental data apply to such mild slopes that the behavior of the jump on steep beds as outlined in this discussion is subject to experimental verification. As far as the writer knows, there are no experiments with jumps on adverse slopes.

The author's generalized formulas are based on experimental data obtained on only one slope. The data in the Yarnell experiments were not presented in usable form and the length of the jump used by the author, which is a vital factor on sloping beds, was greatly foreshortened. The soundness of the formulas may therefore be open to some question until verified by experiments on other and steeper slopes.

C. J. POSEY,[21] ASSOC. M. AM. SOC. C. E.—The mathematical analysis of the hydraulic jump on a sloping floor, presented in this paper, parallels logically the well-established momentum analysis of the jump on a horizontal floor. The final result is not obtained by purely analytical means, as is that for the jump on a horizontal floor, because of the effect of the unknown weight of the water in the jump itself, a major factor which cannot be eliminated from the momentum equation. The author's method of introducing this factor into the equation seems to be as rational as can be used and still permit a simple algebraic solution. Evaluation of the empirical function necessary is based on the large-scale experiments made by Mr. Yarnell.

The author's classification of the jump on a sloping floor into four cases is a convenience in studying the experimental data, but it should be noted that his subsequent analysis of the data shows that only three different classifications really may be necessary. For a floor with 1 on 6 slope, the data for Case 3 and Case 4 fit the same equation with no significant difference in average coefficients, as shown in Fig. 6. The points showing the maximum positive and negative deviations in Fig. 6(*c*) are all for Case 3, however, a fact which may indicate a slight difference between the two cases on the basis of variability. If further investigation shows no measurable differences, these two cases can be considered to be but one—a hydraulic jump on a sloping floor. Case 2 is a hydraulic jump forming across or "straddling" a change of grade from a steep slope to a horizontal or nearly horizontal slope. Case 1, as the author states, is the ordinary hydraulic jump on a level floor.

It seems likely that for the steeper slopes the phenomenon may change entirely, with the jet plunging under with little localized impact and continuing far downstream as a thread of high-velocity current. This happens to a jump below a sluice gate if the tailwater is raised so high that the jump is "drowned out." (Below a gate in a horizontal channel, an intermediate phenomenon known as the submerged jump can form; but it does not form over a very wide range of tailwater depths, and the sharply rising water surface over the submerged jump indicates considerable localized impact and energy loss.) A drowned-out jump cannot be classed as a true jump since it has lost its ability to lower velocities safely within a short distance along the stream. Therefore, it is important to know at what Froude number the jump on any given slope tends to plunge and become similar to a drowned-out jump. Both Froude number and slope evidently are involved because, if the slope is near zero, there seems to be no limit to the Froude number for which a true jump will form; whereas, if the slope is near infinity, the jet will plunge, no matter how low the Froude number. It may be that other factors also are involved, for air entrainment may play a vital part in the energy-destroying and velocity-evening capacity of the true jump. Certainly the change of grade which was a complicating feature of the Yarnell experiments would have an effect. Many investigators have observed that for particular setups there is an apron slope above which true jump action ceases. In the report on hydraulic tests referred to by the author, for example, occurs the statement, "The slope of 1 on 4 * * * is about the steepest that can be used and still obtain a satisfactory jump formation." [22]

---

[21] Associate Prof., Hydraulics and Structural Eng., State Univ. of Iowa, and Research Engr., Iowa Inst. of Hydr. Research, Iowa City, Iowa.

The Yarnell data include a large number of jumps straddling the change of grade. Although the author presents a method of computing the height of such jumps if the floor slope is 1 on 6, he gives no method for the steeper slopes because the data did not include enough jumps that were complete upstream from the change in grade for these steeper slopes. According to his method, coefficients for jumps complete on the slope must be determined before the heights of straddling jumps can be estimated. It may be possible to devise a more direct method of analysis that could be used to summarize Mr. Yarnell's data on straddling jumps. Such a method would have to make a clean break away from the type of analysis that has been successful with the jump on a level floor. For practical use in engineering design and construction, the final information desired is whether, in a given situation, the jump will form, and if it will form, where its location will be. For a nearly horizontal channel, this information can be obtained if, in addition to the upstream and downstream flow conditions, the height and length of the jump are known. For flat slopes, close to normal friction slopes, the height is the more important element, although J. W. Trahern, Assoc. M. Am. Soc. C. E., has shown that the length also must be considered in determining where the jump will form.[23] The importance of the height and the remarkably close agreement between theory and data, for jumps in channels that may be considered horizontal, naturally suggest that the height should be the first element for investigation in the case of the jump on a sloping floor. The steeper the slope, however, the less important is the height, for the more certain it is that the jump will form a short distance downstream from the intersection of the tailwater surface profile and the profile of the high-velocity flow on the slope. The information needed for design purposes is the location of the downstream end of the jump, where velocities have become sufficiently low to permit ending the apron. This point can be fixed by supplying its distance from the point of intersection of the upstream and downstream water-surface profiles, a distance that can be determined experimentally as a function of the Froude number and the profile of the channel bottom.

---

[22] "Hydraulic Tests on the Spillway of the Madden Dam," by Richard R. Randolph, Jr., *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 1090.

[23] "Location of the Hydraulic Jump," by J. W. Trahern, *Western Construction News and Highways Builder*, October 25, 1932, p. 608.

This method of attack would not be satisfactory for slopes so flat that the distance from the intersection of the headwater and tailwater profiles to the toe of the jump was large in comparison with the length of the jump but not flat enough to permit neglecting the horizontal component of the bottom pressure under the jump profile. The 1 on 6 slopes for which experimental coefficients are obtained by the author are apparently in this range. Even here, however, there may be an advantage in discarding the traditional "height-of-jump" approach. Using the author's coefficients for a 1 on 6 slope, Eq. 14 becomes

$$d_2 = \frac{d_1}{1.972}\left(\sqrt{\frac{7.67\,\lambda}{1 - \frac{\phi}{3}} + 1} - 1\right) \ldots\ldots\ldots\ldots\ldots (50)$$

The points determining the experimental coefficient ϕ, plotted in Fig. 6(*a*), seem to lie very close to the average curve. In the range $\lambda = 5$ to $\lambda = 10$, however, Fig. 6(*a*) shows a range of uncertainty of ϕ between 2.05 to 2.50. Substitution of the appropriate values in Eq. 50 shows that the corresponding uncertainty in the ratio $\frac{d_2}{d_1}$ is about 40%. Near $\lambda = 40$, ϕ may vary between 1.6 and 1.95, according to the data plotted in Fig. 6(*a*), giving a possible range of values for $\frac{d_2}{d_1}$ of from 12.5 to 14.5, a variation of about 16%. Moreover, the designer is not finished when he has found d_2 because d_2 is measured upward from a point on the steeply sloping bottom. The location of this point, at the downstream end of the jump, is also uncertain. According to the data in Fig. 6(*b*), $\frac{L_r}{d_2}$ may vary from 3.2 to 3.8 in the range $\lambda = 5$ to $\lambda = 10$, or from 2.4 to 3.4 near $\lambda = 40$. The corresponding uncertainty in water-surface elevation, from this source, is about 0.10 d_2 in the former case and about 0.16 d_2 in the latter. As far as can be ascertained from Figs. 6(*a*) and (*b*), these uncertainties are in addition to, and independent of, those due to possible variations in ϕ. In combination, they amount to a possible maximum of from 30% to 50% of d_2. Fig. 6(*c*) shows the actual total range for the data plotted to be about 36% of d_2. This uncertainty becomes especially significant when it is realized that, for a jump in a sloping flume, d_2 is the largest vertical dimension.

In view of the fact that the phenomenon has so much inherent variability, would it not be better to use a simpler method for representing the experimental results? The following relationships could be plotted so as to show the variation of the experimental values and give directly, without the necessity of substitution into intricate formulas, the information needed by the designer:

$$\frac{d_j}{d_1} = f_1\,(\lambda, \alpha) \ldots\ldots\ldots\ldots\ldots (51a)$$

and

$$\frac{L_r}{d_1} = f_2\,(\lambda, \alpha) \ldots\ldots\ldots\ldots\ldots (51b)$$

In these equations the variables are the same as those shown in Figs. 2 and 5.

It is suggested that the height and length of the jump be given in terms of d_1 rather than d_2 because d_2 is purely a dependent variable with little or no real utility in the case of the jump on a steeply sloping floor.

With regard to the author's use of λ, the "kinetic flow factor," it might be well to note that a factor of similar importance but of greater usefulness in practical hydraulic work is the ratio of the velocity head to the depth. It has much older standing in American literature than either the kinetic flow factor or the Froude number. Representing this ratio by ω, the equation of the hydraulic jump in a horizontal channel of rectangular cross section becomes

$$\frac{d_2}{d_1} = 2\sqrt{\omega + \frac{1}{16}} - \frac{1}{2} \qquad \text{(52)}$$

The factor ω could be used advantageously instead of λ in all of the equations, including Eqs. 51. Unfortunately, ω has no short convenient name. A state of confusion (apparent at least to the beginner) exists when hydraulic engineers refer to the Froude number and then plot charts in illustration showing values of λ, which is not numerically equal to the Froude number. Since ω is more convenient for practical work, why not use it, giving it some simple name such as "velocity-head ratio"? The writer knows of no other technical use of this phrase, and its meaning is at least as evident as is that of "kinetic flow factor" or "Froude number."

JEROME FEE,[24] ASSOC. M. AM. SOC. C. E.—Few investigations of any kind have been made of flow in open channels with steep slopes. Therefore, the author has performed a valuable service to the engineering profession by his study of the hydraulic jump in sloping channels. By further experiments the method easily can be extended to cover a wide range of conditions.

Fig. 6, showing the relation between the kinetic flow factor and several essential elements of the hydraulic jump, is particularly interesting. The pressure-coefficient curve is defined with surprising accuracy; and even the length of roller is more amenable to measurement than might be expected.

In view of the greater accuracy of the pressure-coefficient curve, it would appear desirable to obtain similar curves for other slopes by direct piezometric measurements, as was done in this case, rather than to derive values of the pressure coefficient from Eq. 18, which depends directly on the length of roller.

Although the momentum law is used instead of energy considerations to determine the dimensions of the hydraulic jump, the total loss of energy under various conditions is one of the most important features of this problem, particularly where the jump is used as a means of dissipating energy. The author's method can be applied directly to the determination of energy loss, and thus it will be possible to compare the efficiency, as energy dissipators, of the four classes of hydraulic jump described in this paper.

The writer has been interested particularly in the energy phase of flow in steeply sloping channels. The energy line in such cases is not the simple line with which the engineer is familiar under ordinary flat slope conditions. To borrow a term from modern physics, the energy line has a "fine structure" analogous to certain spectroscopic lines which were believed originally to be single lines and later each was found to consist of several lines, very close together, which could be separated under certain circumstances.

---

[24] Engr., Federal Power Commission, San Francisco, Calif.

This may be shown by the construction of Fig. 17. In Section A–A, normal to the bottom, particles indicated by the letters m, n, o, and p are all at the same energy level, Z–Z. For example, particle o has a pressure head equal to o–o′ and a velocity head equal to o′–o″, as determined by the velocity in the direction of flow, parallel to the slope. From an energy standpoint, particle o is in exactly the same condition as it would be at point o″. The same argument applies to Section B–B, also normal to the slope. Particle o at this section, of course, is not the same particle o as at Section A–A but a different particle at the same distance from the bottom. This particle is at energy level, X–X, being represented by point o″ on the horizontal line, X–X.

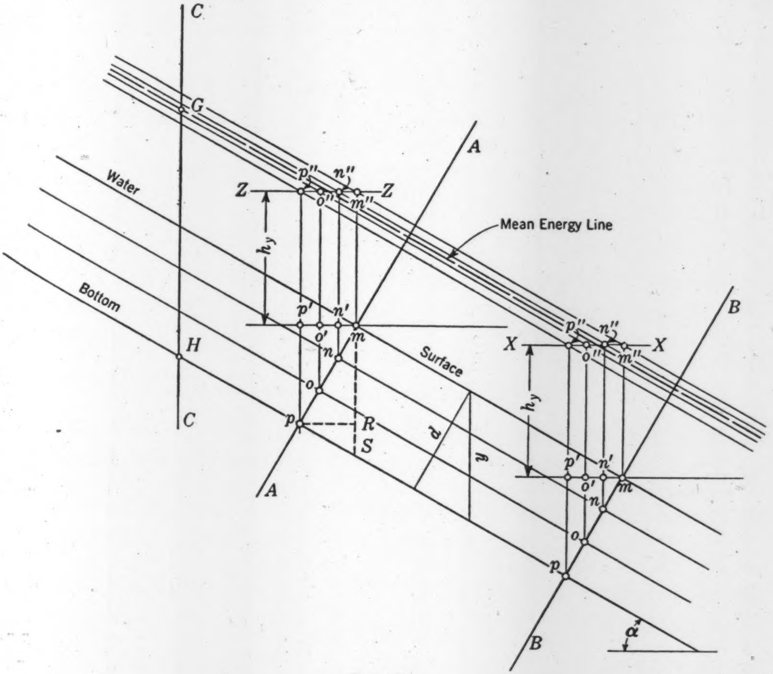

FIG. 17

The sloping line o″–o″, which for uniform flow is parallel to the water surface, is the energy line for all particles at the same distance above the bottom as particle o. Similarly, lines m″–m″, n″–n″, etc., are energy lines for particles at respective depths corresponding to points m, n, etc. Instead of a single energy line, there is a band of energy lines between m″–m″ and p″–p″.

The significance of these lines is apparent when one considers a vertical section, C–C. The point of intersection of line o″–o″ and Section C–C gives the energy level of the particle defined by the intersection of line o–o and C–C. Vertical sections, such as C–C, are the only practical means of defining the position of particles flowing in a conduit, and, to be of any value, energy lines must be correlated with vertical sections in the manner shown.

The average energy level of all particles in a vertical section is at the point of intersection of the "mean energy line" (shown in Fig. 17) with the section itself. The vertical distance from the bottom of the conduit to the mean energy line is readily determined as

$$\overline{HG} = y + \beta \frac{V^2}{2\,g} - \frac{d}{2} \sin \alpha \tan \alpha \qquad (53)$$

in which β is a constant greater than unity, introduced by inequalities in velocity across the section. The term $\frac{d}{2} \sin \alpha \tan \alpha$ is equal to one half of the distance RS, in Fig. 17.

In the foregoing analysis it is assumed that the reader is acquainted with the formula:

$$p = \gamma\, d \cos \alpha \qquad (54)$$

The author refers to the derivation of this equation[7] by Messrs. O'Brien and Hickox, who, in turn, ascribe the equation to Harald Lauffer. There is apparently some discrepancy in the text cited, since it contains the following erroneous equation:

$$(y - z) \cos \theta + z = y \cos \theta \qquad (55)$$

Eq. 55 leads to $z = z \cos \theta$, which is clearly incorrect.

The writer has not had an opportunity of learning the date and reference of Lauffer's work, which would doubtless be of interest to others. Possibly the author can supply this information.

The late John Hedberg,[25] Assoc. M. Am. Soc. C. E., presented an excellent proof of the equation, $p = \gamma\, d \cos \alpha$. Although he was evidently not the first, Mr. Hedberg gave a derivation that hardly could be improved upon—certainly not in point of brevity.

In developing Eq. 8 the author refers to "the equation of equilibrium for section 1" of Fig. 5(*b*). It would seem that Eq. 8 depends fundamentally on the equilibrium of the body of water between two sections; namely, section 1 and a section normal to the slope which intersects section 1 at the water surface. One section, alone, is not enough in this case to be the basis of an equilibrium equation.

It is a pleasure to find such a valuable contribution to the study of flow on steep slopes. The author is to be congratulated for successfully carrying out an investigation presenting unusual difficulties, both experimental and analytical.

Frank S. Bailey,[26] Assoc. M. Am. Soc. C. E.—Paraphrasing the Declaration of Independence, all men are endowed with certain rights, and among them are life, liberty, and the pursuit of knowledge.

The pursuit of knowledge often involves much labor and, when knowledge is attained by any one engaged in research and is presented for the consideration of other researchers, some advance in the understanding of the particular topic under consideration is almost certain to follow.

Many members of the engineering profession are engaged on work which must be pushed forward with as little delay as is consistent with reasonable accuracy. Thus, when a job is under way, they often must rely for basic information on the analyses and experimentation of others. The writer realizes the complexities and difficulties of the subject the author has undertaken to clarify and trusts that the paper will be of great value in its field.

G. H. Hickox,[27] M. Am. Soc. C. E.—The hydraulic jump as a means of dissipating energy has been known and studied for many years. The underlying theory is relatively simple, and has been stated clearly by Mr. Woodward.[5] A number of studies of its performance on a horizontal surface have been made, and the agreement of experiment with theory is gratifying, particularly with respect to the vertical dimensions. In many practical applications it is desirable, and sometimes necessary, to produce the jump on a sloping surface rather than on a horizontal one. The prediction of the final depth for this condition has not been entirely satisfactory heretofore. The phenomenon is governed by the same laws as when it occurs on a horizontal surface, but trouble has been experienced in applying them. The difficulty occurs in determining the horizontal component of pressure exerted on the mass of water within the jump proper by the sloping bottom.

Mr. Kindsvater presents an ingenious and rational method of accounting for the pressures on the sloping surface. The fact that his analysis includes an experimentally determined coefficient ϕ does not detract from its value. The paper was the outgrowth of studies, made at the Hydraulic Laboratory of the Tennessee Valley Authority under the direction of the writer, to establish the elements of the jump on sloping surfaces. The method of attack was suggested by an earlier paper by Messrs. Bakhmeteff and Matzke[28] in which it was shown that the horizontal and vertical elements of the jump could be expressed as functions of λ.

This discussion presents the results of later experiments made on a slope of 1 on 3 and shows that the author's analysis is applicable to any slope on which a satisfactory jump can be formed. The tests were made in a flume 3.5 ft wide with discharges varying from 0.760 to 3.966 cu ft per sec, initial velocities from 5.57 to 9.68 ft per sec, and initial depths from 0.028 to 0.179 ft. The values of λ ranged between 6.9 and 73.0. Fig. 18(*a*) shows values of ϕ as a function of λ for these tests.

[28] "The Hydraulic Jump in Terms of Dynamic Similarity," by B. A. Bakhmeteff and A. E. Matzke, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), pp. 630–647.

Fig. 18(*b*) has been prepared to show the relationship between ϕ and λ for slopes between the horizontal and 1 on 3. Data for the horizontal slope have been taken from the paper by Messrs. Bakhmeteff and Matzke.[29] The curve for $S = 0.336$ is the same as that in Fig. 18(*a*). The other curves have been interpolated using the Kindsvater data as a guide. With the value of ϕ given by Fig. 18, it is possible to calculate d_2 for any slope by means of Eq. 14.

Calculation of Depth d_2.—In calculating the depth d_2 the writer prefers to use Eq. 24 which is dimensionless and therefore directly applicable to a large range of variables. When the relationship between ϕ and λ is known for a given slope, $\frac{d_2}{d_1}$ can be expressed as a function of λ for that slope. It has been calculated for slopes between 0 and 0.336 for values of λ between 5 and 60 using the curves of Fig. 18(*b*), and the results are shown in Fig. 19. The experimental values of $\frac{d_2}{d_1}$ found for the 0.17 slope by Mr. Kindsvater and for the 0.336 slope by the writer also are shown in Fig. 19 for comparison.

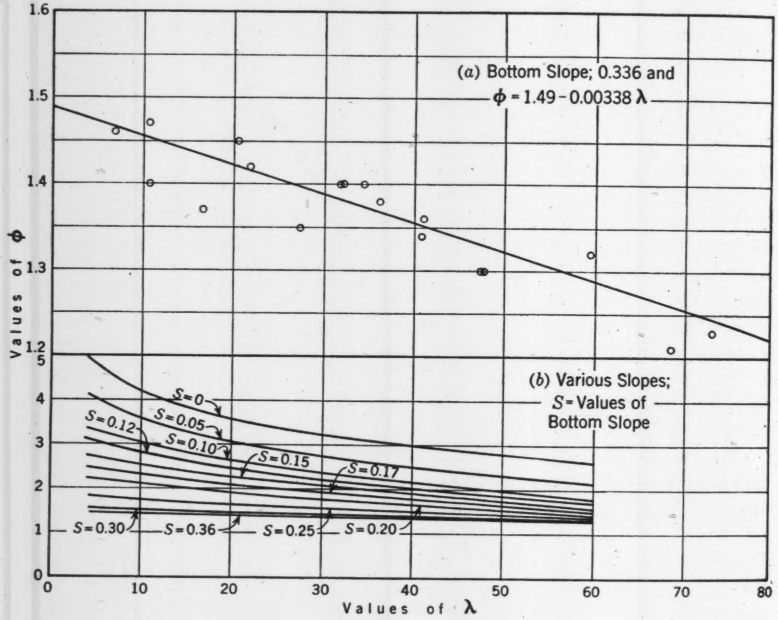

FIG. 18.—VALUES OF ϕ AS A FUNCTION OF λ

A paper by Messrs. Bakhmeteff and Matzke[3] includes data on four flat slopes, including the horizontal, from which the ratio $\frac{d_2}{d_1}$ can be calculated directly from experimental results. The points thus determined also are plotted in Fig. 19. In general, they agree reasonably well with the interpolated curves. It may be noted that the points for the horizontal surface fall slightly below the corresponding curve, indicating the possibility of experimental error. If the points for the other slopes are similarly in error, the agreement with the curves is improved accordingly. In general, the agreement between the calculated curves and the experimental results is good and it is believed that the curves are satisfactory for practical estimates of the jump height.

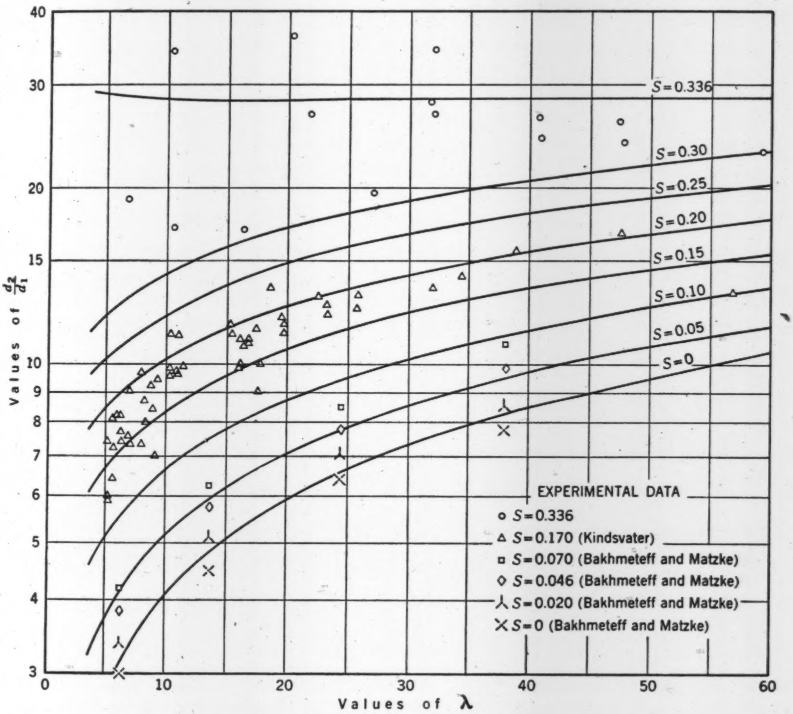

Fig. 19.—Relation Between λ and $\frac{d_2}{d_1}$

Location of End of Jump.—The location of the end of the jump is a matter on which there seems to be little agreement among investigators. The precise point to be chosen is open to question. Some authorities assert that the end of the jump is marked by the highest water-surface elevation. This is not true on a slope, however, since a part of the rise is not due to the jump itself but is caused by the conversion of kinetic to potential energy that occurs in any expanding channel. Hence, the highest elevation has no particular significance with respect to the jump. In addition, it is practically impossible to determine a corresponding point in observations of field installations because of the extreme surface turbulence and also because the recovery of velocity head varies considerably due to local variations in channel shape. Another criterion for determining the length of the jump is the distance to the point at which the bottom velocities are no longer dangerous to the bed. This distance is not a satisfactory measure as it depends on the resistance of the bed to erosion and has no absolute basis for determination. It also is extremely difficult to determine in a prototype structure. The location chosen by the author (the end of the roller) is one that can be determined with comparative ease both in the laboratory and in the field and is preferred by the writer for this reason. It is open to the objection that on steep slopes seriously high bottom velocities may exist beyond this point, and thus it does not necessarily indicate the length within which the high-velocity jet loses its destructive energy. On a horizontal surface the end of the roller is some distance from the end of the jump but on slopes as steep as 1 on 6 and steeper, the elevation at the end of the roller is practically equal to the highest water surface.

In practical applications of the hydraulic jump to the dissipation of energy, these differences in location of the end of the jump become unimportant. In most cases it is not economical to provide protective paving on the river bottom for the full length of the jump as defined by the highest water surface. It is frequently much cheaper and equally satisfactory to stop the apron at a point some distance upstream and to terminate it with a low sill having a sloping upstream face. Such a sill deflects upward from the river bed any high-velocity flows that still might exist. It also extends the range of depths over which a satisfactory jump will occur by maintaining a sufficient depth to produce the jump if for some reason the tailwater should fall below its expected elevation. An extended discussion as to exactly what constitutes the end of the jump is thus largely academic. The length of paving below a spillway is subject to economic considerations and seldom is determined finally by the theoretical length of the jump. Further discussion of this subject properly belongs to a study of stilling-basin design.

In the preparation of Figs. 18(*b*) and 19 two definitions of the end of the jump have been used. Values of ϕ for $S = 0$ in Fig. 18(*b*) are from data by Messrs. Bakhmeteff and Matzke[28] for which the end of the jump was taken at the highest tailwater elevation. For the Kindsvater data on the 0.17 slope and the writer's data on the 0.336 slope, the end of the jump was taken at the end of the roller. As stated, for slopes steeper than 1 on 6, the two elevations are practically identical. For the level floor, the highest elevation of the water surface is preferable since the elevation at the end of the roller is somewhat lower. It is believed that interpolation between the values used for the level floor and the 0.17 slope will give satisfactory results.

Calculation of Bottom Elevation.—The calculation of the depth d_2 at the end of the jump on a sloping surface has no meaning unless the depth can be measured at a known point along the slope. Messrs. Bakhmeteff and Matzke[28] have shown that the ratio $\frac{L}{d_2}$ is a function of λ for a jump on a horizontal surface.

The curve for $S = 0$ in Fig. 20 is taken from their data. The curve for $S = 0.17$ is reproduced from Fig. 6(*b*), and the curve for $S = 0.336$ is based on the experimental data on the 1 on 3 slope. Messrs. Bakhmeteff and Matzke considered the length L to be the distance to the highest water surface and the curve for $S = 0$ is constructed accordingly. Mr. Kindsvater, on the other hand, measured L to the end of the roller. The curves are thus inconsistent in this respect. However, for a 1 on 6 slope, the end of the roller and the highest water surface are practically at the same elevation. The broken lines of Fig. 20 represent an attempt to interpolate tentative curves that may be useful for design purposes. The plotted points represent the results of experiments by Messrs. Bakhmeteff and Matzke on relatively flat slopes. The agreement is not perfect but indicates that the curves are approximately correct. Fig. 20 is sufficiently accurate for practical design purposes.

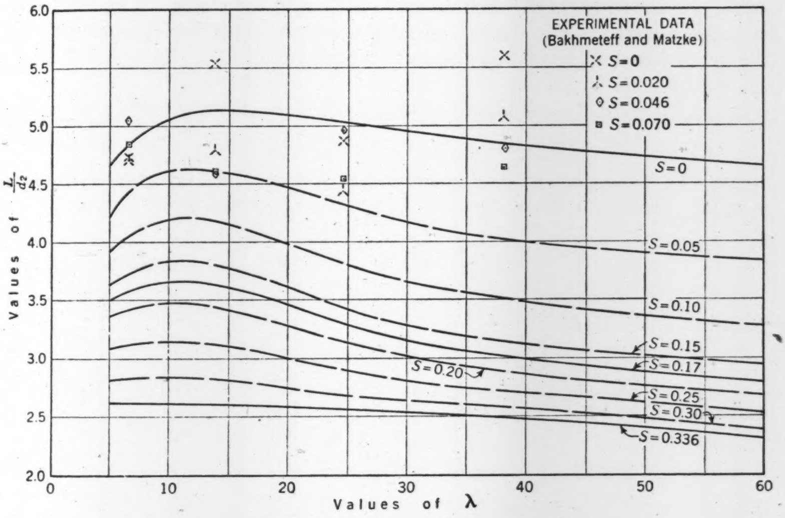

FIG. 20.—RELATION BETWEEN λ AND $\frac{L}{d_2}$

It is frequently necessary to determine the required bottom elevation to insure the formation of the jump with a given discharge and tailwater elevation. This can be done by assuming an elevation slightly below tailwater as the point of beginning of the jump. Having determined d_1 and λ for this point, the depth d_2 and the length L are determined in that order with the aid of Figs. 19 and 20, respectively. The elevation of the bottom at distance L from the beginning then is found by multiplying L by the slope (tan α) and subtracting the result from the bottom elevation at the assumed point of beginning. The difference between tailwater elevation and the bottom elevation thus calculated should be equal to d_2. If the difference is smaller than d_2, another trial must be made assuming a lower point of beginning. Only a very few trials are needed to determine the necessary dimensions with sufficient accuracy.

Case 2 Jump.—Data on the 0.336 slope for the Case 2 jump were not obtained. It was not possible, therefore, to supply a curve similar to Fig. 8 for other slopes.

Effect of Approximate Initial Pressure on Final Depth.—The effect of the approximation to the initial pressure (Eq. 9) on the final depth may be determined to a first approximation by assuming that the neglected difference in initial pressures affects the final depth so little that the change in final velocity may be neglected. The error in initial pressure, ΔP_1, is the difference between the approximate pressure and the correct pressure, or

$$\Delta P_1 = \frac{w\,(d_1)^2}{2\cos^2\alpha} - \frac{w\,(d_1)^2}{2} = \frac{w\,(d_1)^2}{2}\left(\frac{1}{\cos^2\alpha} - 1\right) = \frac{w\,(d_1)^2}{2}\tan^2\alpha \,.\,.\,(56)$$

Neglecting corrections to the momentum at section 2, the error in pressure P_2 is equal to the error in pressure P_1. The error at section 2 is

$$\Delta P_2 = \frac{w\,(d_2 + \Delta d_2)^2}{2} - \frac{w\,(d_2)^2}{2} = \frac{w}{2}\left[2\,d_2\,\Delta d_2 + \Delta(d_2)^2\right] \ldots\ldots (57)$$

Neglecting the square of Δd_2,

$$\Delta P_2 = w\,d_2\,\Delta d_2 \ldots\ldots\ldots\ldots\ldots\ldots (58)$$

Equating 56 and 58, $\frac{w\,(d_1)^2}{2}\tan^2\alpha = w\,d_2\,\Delta d_2$; from which

$$\Delta d_2 = \frac{(d_1)^2}{2\,d_2}\tan^2\alpha \ldots\ldots\ldots\ldots\ldots\ldots (59)$$

It is more convenient to write the ratio of the error in final depth to the depth:

$$\frac{\Delta d_2}{d_2} = \left(\frac{d_1}{d_2}\right)^2 \frac{\tan^2\alpha}{2} \ldots\ldots\ldots\ldots\ldots\ldots (60)$$

The error for a slope of 1 on 3 and a depth ratio of 0.4 is 0.9%. For smaller depth ratios and flatter slopes the error is less. For practical purposes it may be neglected.

The actual pressure at section 1 seems to be rather uncertain. The pressures on both sides of a vertical plane at that point should be equal. Approaching the section from upstream, the pressure on the section for uniform parallel flow is given by Eq. 8. On the downstream side of the section, experiment shows that the bottom pressure is $\frac{w\,d_1}{\cos\alpha}$. Since the vertical depth is $\frac{d_1}{\cos\alpha}$, the total pressure on the section is $\frac{w\,(d_1)^2}{2\cos^2\alpha}$ which is Eq. 9. This indicates a discontinuity of pressure at section 1 or, more probably, a rapid change in the type of flow. The use of Eq. 9 thus may be justified on other grounds than expediency.

Carl E. Kindsvater,[29] Jun. Am. Soc. C. E.—Observers apparently do not agree on a definition for the true hydraulic jump. Mr. Stevens discards the jump on a slope, because it is "a mere plunging of water into a pool," and because,

> "As the slope steepens, the jump loses its identity entirely and becomes something else about which little is known."

He quotes Messrs. Bakhmeteff and Matzke[3] to support his opinion:

> "The live jet 'plunges' into the tail water and within the steep section follows the slope downward with comparatively slow expansion and obviously relatively small losses."

A typical opinion, in which the jump below steep slopes is qualified as a "drowned-out" jump, was expressed by Professor Posey,

> "A drowned-out jump cannot be classed as a true jump since it has lost its ability to lower velocities safely within a short distance along the stream."

Thus, the criterion for a true jump would be its ability to destroy energy, and the reason for disqualifying the hydraulic jump in sloping channels is an opinion concerning its suitability as a stilling basin device. The disqualification is not based on proof that a similar manner of analysis will not apply to all jumps, free or "drowned out," in sloping or horizontal channels.

It is hazardous to attempt a general definition of a phenomenon having so many variations of form as the hydraulic jump in open channels of any slope. Fundamentally, the hydraulic jump is marked by an abrupt increase in the depth of flow. It is created when a stream of water flowing at less than critical depth is retarded by a stream of water flowing at a depth greater than critical. To form a stable jump in horizontal channels, the depth of flow at the downstream section must be exactly equal to the upper conjugate depth. When a jump is formed on a slope, the depth of water at the end of the slope may exceed the upper conjugate depth, but the stream will continue to expand beyond the end of the jump because of the increasing depth and the resulting transformation of energy. For any given conditions of initial depth and discharge, there is only one corresponding conjugate depth, and any change of slope beyond the point where this depth occurs will have negligible effect on the location of the beginning of the jump, its length, or its form. Thus, the selection of economic stilling basin dimensions might depend on the upper conjugate depth. This paper did not intend to propose the hydraulic jump in sloping channels as a stilling basin device. It has been used for that purpose, however, and apparently with some success. Therefore, regardless of a difference in opinion concerning the name of the phenomenon, computation of its essential dimensions is frequently desirable. The analysis proposed by the writer appears to serve this purpose. The length of the roller, as defined by the writer, is a fair approximation of the length from the toe of the jump to the section of upper conjugate depth. In addition, the agreement between measured and computed depths for jumps occurring on a 1 on 6 slope is adequate proof of the practical value of the analysis.

(b) SLOPE 1 ON 6
(c) SLOPE 1 ON 3
(d) SLOPE 1 ON 2

FIG. 21.—VIEWS OF THE HYDRAULIC JUMP

The method described for determining the end of the roller might possibly yield unreliable results for very steep slopes. Mr. Hickox' discussion indicates, however, that this limit must be beyond a slope of 1 on 3. The writer's treatment of Case 2 jumps on 1 on 6 slopes may prove invalid for other slopes. Obviously, other limitations might be imposed by the form of the structure on which the jump must occur. For those cases where the path of the water under the jump is materially influenced by the shape of the structure, or where it is obstructed by impact devices (baffle piers, sills, etc.), the proposed analysis of the simple phenomena certainly is not a substitute for model studies.

In the foregoing quotations, the hydraulic jump which forms on slopes greater than about 1 on 10 is described as an occurrence in which the live jet plunges under the roller in a manner distinct from the behavior of the jump in horizontal channels. Under the heading, "The Hydraulic Jump in Sloping Channels: Limitations to Analysis," the writer expressed the opinion that the jump on a slope is generally similar to the jump in horizontal channels. In support of this opinion he submitted two large photographs which lost some of their effectiveness in reproduction (see Figs. 3 and 4). In another attempt for this closing discussion, he devised a miniature laboratory in his family bathroom and produced the four views in Fig. 21. The test flume was approximately 2 in. wide and 24 in. long. The photographs were taken with an exposure of 1/100 sec. The kinetic flow factor for all photographs was estimated to be approximately 35. In these short exposures, action is revealed which is not apparent to the naked eye. "White water" becomes a pattern of air bubbles and water. Slowly moving bubbles are caught as if motionless; rapidly moving bubbles make a visible streak, the length of which is a measure of local velocity components. Because the flume was so unusually narrow, the number of air bubbles involved in the photographs is comparatively small. The pictures illustrate instantaneous typical sections rather than average conditions. The four views in Fig. 21 show clearly a general confusion of path lines and a wide range of velocities throughout the jump. Fig. 21(*c*), for a 1 on 3 slope, shows a remarkable dispersion of high-velocity currents. Fig. 21(*a*), for the horizontal floor, is not a good photograph because it shows a temporary splash of bubbles near the toe. The distribution of velocities in Fig. 21(*a*) does not appear widely different from that for the other views. Any evidence of the distinctive plunging action described by some observers is difficult to find in these photographs.

Length of the Hydraulic Jump.—Argument concerning the definition of the downstream limit of the jump is made confusing by the tendency of some writers to think of the jump only in its relation to stilling basin design. As defined by the writer, the length of the jump is the horizontal length of the top roller. This definition was adopted after careful investigations showed that the end of the roller was the only section near the end of the rapid expansion which could be easily defined and readily observed, giving consistent results when recorded by different observers. For Case 3 jumps, the observed end of roller usually occurs near the point where the water surface first reaches its maximum height. Actually, this "point" is a fluctuating "zone," and argument concerning its exact definition is superfluous.

An important assumption in the writer's analysis, as well as in the classic analysis of Case 1, is that the velocity distribution at section 2 is reasonably uniform, in order that (*a*) the average velocity, $V_2 = Q/A_2$, will yield a satisfactory evaluation of the momentum in that section, and (*b*) the pressure distribution may be assumed to be hydrostatic. The agreement between computed and measured depths for both Case 3 and Case 4 is sufficient proof that the assumption is valid for practical use. As a matter of fact, velocity measurements at section 2 show that the distribution of velocities is not uniform at the end of the roller. Sporadic concentrations of higher-velocity currents prevail considerably beyond the end of the roller. Throughout the long series of tests described by the writer, repeated attempts were made to define a section where destructive bottom velocities ceased. The paths of entrained air bubbles were carefully observed to determine a section where the bottom velocities were no longer sufficient to carry the bubbles along the floor of the flume. Several hundred observations served only to prove that two observers could not agree on the location of that section, usually disagreeing by several feet. Attempts to analyze the observations were fruitless. The presence of local concentrations of erosive velocities beyond the end of the roller is a characteristic of the jump on a level floor as well as of the jump on a slope. Neither the end of the roller nor the highest point on the water-surface profile should be accepted as a zone marking the complete dissipation of erosive velocities.

There is no law of mechanics which requires that the end of the jump, the end of the roller, or any other section be taken as section 2 for the mathematical analysis of the hydraulic jump. The length of the jump is necessarily made as short as possible in order that the boundary losses may be neglected. This does not signify that the pressure-momentum equality could not be verified at any section between the beginning and end of the jump. Quite to the contrary, Kazimierz Woycicki,[30] working with the discharge of water below rectangular sluice gates, has shown that for both the free and the "covered" jump, the fundamental pressure-momentum equality can be verified for any intermediate section, as long as the direction and magnitude of the component velocities and pressures are properly considered. Any successful mathematical solution for the hydraulic jump in sloping channels hinges not only upon the analytical evaluation of forces and velocities at the end sections but also upon the experimental evaluation of forces on the sloping floor under the body of the jump.

Mr. Stevens' comments concerning the length of the jump appear to be somewhat contradictory. For example, he states that "The length of the jump is quite arbitrary except that it should not be assumed too short." Then, recognizing that the length varies with the kinetic flow factor, he adopts for his general analysis the involved formula proposed by Professor Ivanchenko for jumps on a level floor. If the quotation cited is correct, would it not be better to assume that the length ratio might be taken as a "safe" constant? Such was the assumption made by Messrs. Bakhmeteff and Matzke,[3] as well as by Mr. Kennison. However, as demonstrated by the experimental data—

---

[30] "The Hydraulic Jump and Its Top Roll and the Discharge of Sluice Gates," by Kazimierz Woycicki, translation by I. B. Hosig, *Technical Memorandum No. 435*, U. S. Bureau of Reclamation, Denver, Colo., Chapters III and IV.

both Mr. Yarnell's and Mr. Hickox'—the length of the jump on a slope is dependent on the degree of slope as well as on the kinetic flow factor. Curves of L_R/d_2 derived from the experiments are quite well defined for a practical range of λ-values, making unnecessary the use of an arbitrary "safe" length, which to be safe must be excessive. Regardless of the definition for section 2, the slope of the apron is obviously an important factor governing the length of the principal expansion within the jump.

Fig. 16, based on an algebraic extension of Mr. Stevens' generalized analysis, does not show a true variation of length as a function of slope, since Eq. 43, taken from Eq. 29, assumes the length of the jump to be primarily a function of the kinetic flow factor.

Classifications of the Hydraulic Jump.—Mr. Kennison questions the title of the paper on the grounds that the "fifth case," in which the water surface downstream from the jump is parallel to the slope of the floor, has been omitted. Although the limits imposed on the length of descriptive titles often lead to ambiguous expressions, the writer believes that the scope of the paper is adequately described by the title. Cases 3 and 4 are concerned with jumps entirely on the sloping floor. Case 1 is necessarily included as a basic case. Case 2 is a practical intermediate classification. The fifth case, as defined by Mr. Kennison, occurs only infrequently and only on mild slopes, where d_2 is ordinarily the normal depth of flow. For practical purposes, any analysis which leads to a satisfactory solution of Case 4 will also yield a satisfactory solution for the fifth case. In the summation of pressure and momentum at section 2, the effect of substituting $V_2 \cos \alpha$ for V_2 would, because of the relatively small magnitude of $\frac{Q \gamma V_2}{g}$ compared to P_2, be negligible. Thus, the value of d_2 computed from Eq. 14 may be expected to agree satisfactorily with measured vertical depths at the end of a jump in a continuously sloping channel. All of the cases defined by the writer are basic to the extent that they include the four principal forms of the jump within a full range of tailwater levels. As stated by Professor Posey, and, as defined by the writer, Case 3 is really the primary case of the hydraulic jump in sloping channels. The agreement between experimental coefficients for Case 3 and Case 4 demonstrates that the distribution of velocities in section 2 can be neglected, and further obviates the fifth case suggested by Mr. Kennison.

Verification of the Analysis by Application to Other Slopes.—Mr. Johnson suggests that all of the writer's four basic cases are contained in Colonel Rindlaub's data in Fig. 10. Not only is this true, but Case 3, in which $l = \frac{L_R}{\cos \alpha}$, can be defined in Fig. 10 with remarkable success by applying Mr. Hickox' interpolated curves, Figs. 19 and 20. Fig. 22 shows a section of Fig. 10, comparing Colonel Rindlaub's data with computed points based on the Hickox curves. This verification of Mr. Hickox' interpolated curves is simultaneously a gratifying verification of the writer's analysis, since it indicates that the end of the roller is a satisfactory criterion for the location of the section of minimum depth for d_2.

Mr. Hickox' experiments on a steeper slope, and his attempt to develop a complete family of characteristic curves by interpolation of experimental results, are valuable contributions to the paper. The results of his computations are generally satisfactory when compared to the existing experimental data.

FIG. 22.—COMPARISON OF B. D. RINDLAUB'S DATA ON FIG. 10 WITH INTERPOLATED CURVES BY G. H. HICKOX

There is a danger in writing an equation for ϕ such as Eq. 19*b* or Mr. Hickox' equation in Fig. 18(*a*),

$$\phi = 1.49 - 0.00338\,\lambda \qquad (61)$$

There appears to be no reason why the relation $\phi = f_1(\lambda_1)$, Eq. 19*a*, should define a straight line. Although a straight-line equation does fit the data within the limits tested, the curves so defined should not be extended indefinitely.

Simplified Analyses.—Mr. Kennison and Mr. Stevens propose simplified general analyses of the jump on sloping floors. Both suggest the assumption of a straight-line profile between sections 1 and 2 to evaluate the volume of the jump body. This idea was explored by Mr. Yarnell in 1934 and by the writer in 1939. In both cases, the results of the simplifications were disappointing when computed data were compared with experimental measurements over a full range of λ-values. The explanation is probably suggested by drawing a straight line from the surface at section 1 to the surface at section 2 on the measured profiles shown in Fig. 1. The discrepancy thus illustrated is considerably greater than that shown by Mr. Kennison in Fig. 11.

Mr. Kennison objects to the various manipulations involved in the derivation of Eq. 14. The derivation is not particularly complicated; in fact, the equations were expressly set up in a manner to facilitate algebraic solution, and the result is an equation for d_2 quite similar in structure to the formula for the level-floor jump. For a full range of values of λ, the results from Eq. 14 are much more accurate than those to be expected from Eq. 27*b*. Considering the nature of the phenomenon and the difficulties of observation, the range of observational errors, as computed by Professor Posey, is not excessive. Average curves drawn from the experimental data are believed to be of sufficient accuracy for practical use.

Mr. Stevens' generalized analysis is based not only on the assumption of a straight-line profile of the jump, but also on the aforementioned erroneous assumption concerning the length of the jump. Using Professor Ivanchenko's formula for the length of a jump on a level floor, Mr. Stevens derives an equation for the jump on floors of any slope, in which the length factor becomes quite important. Thus, using $m = \frac{9.3}{k^{0.185}}$, he discovered a zone of "fictitious" jumps which might have been considerably different had he used another arbitrary assumption for the length term. Following this conclusion, Mr. Stevens constructed several diagrams showing zones of fictitious, doubtful, and possible jumps. From Fig. 13(*a*), it appears that all of the jumps taken from Mr. Yarnell's experiments on the 1 on 6 slope are fictitious, since values of *k* in every case are less than 30. When these data are plotted on a curve similar to Fig. 14, however, only about half of the observed jumps appear to be fictitious. This comparison is shown on Fig. 23. The manner in which a fictitious jump differs from a real jump is not clearly shown. Really fictitious is Mr. Stevens' case of a hydraulic jump on adverse slopes. A stable jump cannot exist on an adverse slope except, possibly, when the slope is relatively close to zero.[31]

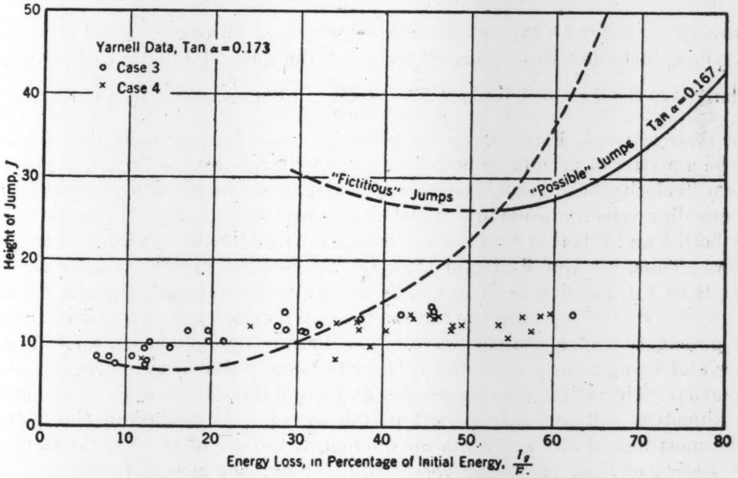

FIG. 23.—COMPARISON OF D. L. YARNELL'S DATA WITH J. C. STEVENS' FIG. 14

In the third paragraph following Eq. 36, Mr. Stevens states:

> "Analogous limitations exist in Eq. 14 from which it is seen that d_2 becomes infinite for $2\,\phi \tan \alpha = 1$ or for $(5.16 - 0.042\,\lambda) \tan \alpha = 1$ (Fig.

---

[31] "Fluid Mechanics for Hydraulic Engineers," by Hunter Rouse, McGraw-Hill Book Co., Inc., New York, N. Y., 1938, p. 301.

> 6(*a*)). This limitation will not apply to the 1 on 6 slope for which the author's formula is designed."

This statement is misleading, for, as previously noted, the algebraic expression for ϕ, Eq. 19*b*, is an equation of the curve in Fig. 6(*a*), derived from experiments in a channel with an average slope of 0.173. For this case, as observed by Mr. Stevens, a zone of fictitious jumps could not exist. The experimental data presented by Mr. Hickox subsequent to Mr. Stevens' discussion show that, similarly, for a slope of 0.336 a zone of fictitious jumps could not exist. It may be concluded, therefore, that, for every other slope, experiments will yield a separate curve of the ϕ-relation for "real" hydraulic jumps.

The Kinetic Flow Factor.—Both Mr. Stevens and Professor Posey prefer to substitute a ratio of the velocity head to the initial depth $\left(\frac{V^2_1}{2\,g\,d_1}\right)$ for the kinetic flow factor $\left(\lambda = \frac{V^2_1}{g\,d_1}\right)$ as defined by the writer. The proposed alternate, referred to by Mr. Stevens as the kineticity, k, and by Professor Posey as the velocity-head ratio, ω, is equal to $\frac{\lambda}{2}$. In recent years there has been a growing tendency to express the characteristics of all open-channel flow phenomena, including the jump, in terms of the general criterion of dynamic similarity, the Froude number, $\mathbf{F} = \frac{V_1}{\sqrt{g\,d_1}}$. For practical purposes, any of the three ratios, λ, $\mathbf{F}$, or k or ω, is applicable. The choice of definition appears to be a matter of personal preference. The writer objects to Professor Posey's term "velocity-head ratio," because it might be confused with a ratio of corresponding velocity heads in a model and its prototype. An advantage shared by both λ and $\mathbf{F}$ is that these ratios are equal to 1.0 for the condition of critical flow. Thus, for λ or $\mathbf{F}$ greater than 1.0, the flow is "rapid," and, for λ or $\mathbf{F}$ less than 1.0, the flow is "tranquil." A significant advantage of the Froude number is that it expresses the ratio of the initial velocity of flow to the celerity of propagation of a gravity wave. The Froude number has the additional merit of being widely accepted as a criterion for similarity of related phenomena. The writer, like so many who have followed the work of Professor Bakhmeteff, will probably persist in the use of λ as defined in this paper. The most logical alternative, in his opinion, is the use of the Froude number.

Energy of Flow on Steep Slopes.—In discussing the general problem of the energy of flow on steep slopes, Mr. Fee develops the concept of a "mean energy line," which is frequently misunderstood. Referring to Eq. 54, he notes a discrepancy in the cited derivation[7] and requests further reference to the work of Harald Lauffer. The discrepancy shown in Eq. 55, copied from the text cited, is distinctly a typographic error. A translation of Mr. Lauffer's work, on which the development was based, was published by the Society in 1937.[32]

Acknowledgments.—The writer is indebted to the discussers of this paper, especially to Mr. Hickox for his information on the 1 on 3 slope and his assistance in preparing Fig. 23.

RELATION OF UNDISTURBED SAMPLING TO LABORATORY TESTING

By P. C. Rutledge,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Benjamin K. Hough, Jr., F. M. Van Auken, Jacob Feld, Raymond F. Dawson, Hamilton Gray, Karl Terzaghi, D. P. Krynine, D. M. Burmister, and P. C. Rutledge.

Synopsis

Techniques and equipment for undisturbed sampling of soil, laboratory testing of such samples, the mechanics of applying the results of laboratory tests to engineering soils problems, and field observations of the effectiveness of the solution methods through the behavior of full-scale structures have frequently been considered as separate entities. They should not be so considered because each is a series of links in a chain which must reach an anchor or end result to achieve its purpose. Undisturbed sampling and laboratory testing have as their prime objective the prediction of how natural soil deposits will behave under proposed loadings. The purpose of this paper is to explore one link in this section of the chain—namely the extent to which laboratory test results approximate the physical properties of soil in natural deposits.

Since successful undisturbed sampling operations have been largely confined to plastic cohesive soils, this paper is limited to analyses of the effects of sample disturbance on the results of tests on natural clays. The analyses are based on consolidation, direct shear, unconfined compression, and triaxial compression tests on specimens ranging in disturbance from the least disturbed samples obtained to samples that were completely remolded.

Sampling of Plastic Cohesive Soils

During the early years of soil mechanics all laboratory tests were performed on soil specimens remolded from small-diameter samples taken in borings. If larger samples were taken by hand in pits, they were also remolded before test to maintain a uniformity in laboratory technique. In 1932, Arthur Casagrande, Assoc. M. Am. Soc. C. E. (1),[2] discovered that natural clays have a complex

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix).

intergranular structure that is destroyed by remolding and cannot subsequently be duplicated in the laboratory. Professor Casagrande's tests showed that there is a marked difference in the physical properties of undisturbed clay as compared with the same material remolded. The importance of determining physical properties from tests on soil in its undisturbed condition was at once apparent and undisturbed sampling came into being.

Most of the identification and classification tests used today have survived from the earlier days of soil studies, and their performance requires preliminary remolding of the soil. Therefore, they need not be considered in relation to undisturbed sampling. Laboratory testing of undisturbed samples is confined almost exclusively to those tests which measure physical properties. The most important of these tests are the consolidation tests, which measure the volume change of soil under load, and the strength tests, which measure the change in shape of soil under load and its maximum resistance to compressive or shearing stresses. The results of consolidation tests are used to analyze and predict settlements of structures. The important strength tests applied to soils are the unconfined and the triaxial compression tests and the direct shear test. Their results are used in the analysis of all problems of stability of soil masses, pressures on walls and tunnels, and ultimate bearing capacities of foundations.

In the best undisturbed samples obtainable, which are large cubical chunks of soil carefully cut out by hand in excavations, some disturbance of natural conditions is inevitable, due only to the removal of pressures of overlying and surrounding soil and their replacement by internal capillary tension in the water in the soil voids. In boring samples the degree of additional disturbance varies widely with the sampling equipment and techniques and the type of soil being sampled. Consequently, one cannot assume that the structure and physical properties of the undisturbed samples tested in the laboratory are those of the soil in the ground.

What are the effects of slight sample disturbance on laboratory testing? If samples are taken with reasonable care, using the more modern types of sampling equipment, the disturbance in plastic soils is not visually apparent. It has little or no effect on the ease of preparation of specimens for laboratory tests or on the performance of the tests. The effects of slight sample disturbance become evident only in the analysis and use of test results.

The established fact that laboratory test results are affected in some degree by inevitable sample disturbance is a challenge to the validity of laboratory soil testing and the application of test results to the solution of foundation problems. Therefore, this paper has the following three purposes:

(1) To analyze the effects of sample disturbance on the significant results of laboratory tests;
(2) To determine to what extent laboratory test results can be used in the solution of foundation and earthwork problems; and
(3) To find means for extrapolation from laboratory test results to the corresponding behavior of soil in nature.

These purposes can be fulfilled only by determining, or approximating with reasonable accuracy, the true initial conditions of the soil in the ground and its subsequent changes in volume and shape under changes in stress. Only three methods are now available for investigating the relation between actual soil behavior and laboratory test results. These are: (*a*) Comparison of test results with field performance of full-scale structures, (*b*) direct reasoning based on the evidence in the test results, and (*c*) reasoning based on hypotheses for soil action which are supported by indirect field or test evidence.

Method (*a*) is greatly to be preferred, but only in a few cases are sufficient field observation data available for its use. As a single example, records of settlements due to compression of strata of soft clay underlying structures have been published and, in some cases, the settlements have been correlated with computations based on laboratory tests (2) (3) (4) (5) (6). The observations and correlations are sufficient to substantiate, in a general way, the methods of computing settlements taught by Karl Terzaghi, M. Am. Soc. C. E., for cases of heavy structures founded on or above reasonably uniform strata of very compressible clay or organic soils. The reported deviations of the admittedly approximate theory from observations are of the same order of magnitude as the deviations of stresses computed by conventional structural theory from published observed stresses in steel and concrete structures. The observational data are not sufficient to validate theoretical solutions for all cases of settlements or to confirm the inferences from laboratory tests in regard to the effects of sample disturbance on soils other than very soft clays.

Methods (*b*) and (*c*), which are not based on direct field observations, cannot establish the validity of applications of laboratory test results to field problems. Their function is to show whether the evidence now available supports or discredits the use of laboratory tests on undisturbed soil samples.

Sampling methods and techniques for laboratory testing of undisturbed samples have been applied successfully only to plastic cohesive soils. Therefore this paper will be limited to the principal tests for the physical properties of such soils; namely, the consolidation, direct shear, simple compression, and triaxial compression tests.

Sample Disturbance and Consolidation Test Results

The consolidation test is the laboratory means for measuring the relations between vertical stress, volume change, and rate of volume change of soil. The apparatus has been described in detail elsewhere (7). The test specimen is confined laterally by a rigid brass ring and is loaded vertically through porous stones. The load is usually applied in increments. For each load increment the sample changes volume slowly, and if this volume, or the void ratio of the sample, is plotted against the vertical stress after it has become substantially constant for each load increment, curves of the type shown in Fig. 1 are obtained. Fig. 1(*a*) is used in this paper because the semilogarithmic plot accentuates certain features of the test results. The void-ratio scale can be transformed linearly into a scale of volume or of volumetric strain if desired.

Fig. 2 shows an idealized test curve of void ratio plotted against vertical stress on a logarithmic scale. Over a substantial portion of the plot, the curve is a straight line for most natural clays with initial void ratios less than 1.5. The principal deviations from the straight line are found during the initial loading of the sample and at points where the load is reduced. As a preliminary hypothesis one may reason by extrapolation that, as the soil deposit was formed, it was gradually compressed by a growing weight of overburden and that the void-ratio, pressure relationship followed the same straight line prolonged, as shown in the dash-line portion of curve (2), Fig. 2. Hence the straight-line portion of the curve is called the virgin compression curve. The formula for this curve is

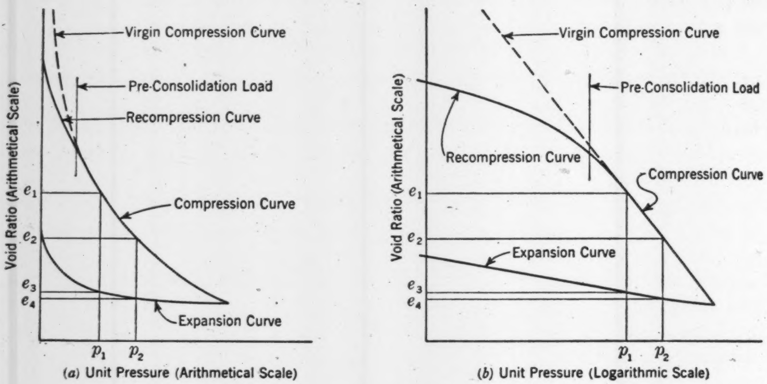

FIG. 1.—COMPRESSION DIAGRAMS

$$e_x = e_0 - C_c \log \frac{p_x}{p_0} \quad \text{.......................} (1)$$

in which C_c is a compression index and e_0 and p_0 are the void ratio and unit pressure, respectively, at an arbitrary point on the straight line, and e_x and p_x are the corresponding values at any other point in the curve. When the sample was removed from the ground it expanded with the release of the pressure of the surrounding and overlying soil (curve (3), Fig. 2) and was again compressed in the laboratory test (curve (1)). Following this reasoning, one can assume that the expansion during and after sampling, and the recompression during the initial part of the consolidation test, are identical to expansion and recompression which can be produced in the laboratory test, as shown in curves (5) and (4), Fig. 2. It is then reasonable to assume that the relation between the maximum vertical stress exerted on the soil in nature will be related to the initial laboratory compression curve (1) in the same way that some larger laboratory stress is related to its corresponding laboratory recompression curve (4). This maximum natural vertical stress is called the "preconsolidation load" (8) and can be determined approximately from the shape of the initial compression curve.

The effects of slight sample disturbance can be investigated by carrying the disturbance to an extreme—in other words, by remolding the test specimens. Figs. 3, 4, and 5 show the results of four sets of tests in each of which one test specimen, after being tested as undisturbed sample, was completely remolded with the addition of water to make its water content and void ratio as nearly equal as possible to the condition of the sample before the test. In this condition of being completely disturbed, or remolded, at the natural water content, these specimens were retested. The curves in Figs. 3 and 4 show the results for an organic clay and two glacial clays. The entire curves for the remolded

tests are displaced downward on the scale of void ratio. Thus, the void ratios for any particular vertical stress are much smaller than the void ratios corresponding to the same stress on the undisturbed specimens. Straight-line compression curves are again obtained but, in each case, they have a flatter slope than the compression curves of natural soils obtained from the tests on the undisturbed specimens in the laboratory. Also the initial parts of the compression curves slope very gradually into the straight-line portions and no definite preconsolidation loads are indicated. Prolongations of the laboratory virgin compression curves for the undisturbed samples and the straight-line compression curves for the remolded tests tend to intersect. Thus, volume change under some load would tend to remold the soil completely.

CHARACTERISTICS OF MEXICO CITY CLAYS

Fig. 5 shows the results of similar tests on a highly compressible volcanic clay from Mexico City, Mexico. The sample from which these test specimens were taken was a 12-in. cube carefully cut out by hand and shipped to the laboratory with great care. The soil was disturbed very little and, as a result, the initial compression curves for the tests on undisturbed samples break very sharply into the laboratory virgin compression curves. The tests show that the preconsolidation load should be almost exactly 1.0 ton per sq ft. The actual weight overlying the specimen was 0.97 ton per sq ft. The nature of this material is extreme in that, fully consolidated under 1.0 ton per sq ft, it had a void ratio of 14.0. In other words, only one part in fifteen of its volume was solid mineral matter. As the curves in Fig. 5 show, this material underwent tremendous volume changes under load and the resulting laboratory virgin compression curves are not straight lines. Compression curves of tests on natural soils which are slightly concave upward have also resulted from tests on other clays with initial void ratios greater than 1.5. Such curves probably are an indication of minimum sample disturbance. The compression curve for the test on a specimen remolded at its natural water content is a straight line as far as the test was carried. It falls below the curves for undisturbed tests and gives every indication of meeting tangentially and continuing with these curves.

The four sets of test results shown in Figs. 3, 4, and 5 are typical of many others and cover an extreme range in plastic soils. Remolding changes these compression curves for undisturbed samples in the following ways:

(1) It decreases the void ratio at which the soil will carry any given vertical stress;

(2) It obscures the previous stress history of the soil and its preconsolidation load; and

(3) The straight-line portion of the remolded compression curve is displaced downward from the laboratory virgin compression curve, and its slope, or the rate of decrease in void ratio with increasing stress, is less.

These results show definitely the effects of sample disturbance over the range from the best undisturbed samples which have been obtained for laboratory test to complete remolding. Any intermediate degree of disturbance must result in a compression curve which falls between the curves that would be obtained for the same soil in these two known limiting conditions. On this basis compression curves are plotted in Fig. 6 for (1) a good undisturbed specimen, (2) the same soil slightly disturbed, and (3) the same soil remolded. Curve (2), Fig. 6, is typical of actual test results on many specimens from samples taken in borings. In relation to curve (1) the effect of the previous stress history of the soil is less marked; but it is possible to estimate the preconsolidation load with decreased accuracy.

In Fig. 6, point B on curve (2) for a slightly disturbed specimen represents the preconsolidation load for the given soil. The corresponding void ratio is considerably less than the initial void ratio of the sample at point C. Without referring to curve (1), two possibilities are apparent: (*a*) The sample represented by curve (2) has expanded during and after sampling and been recompressed

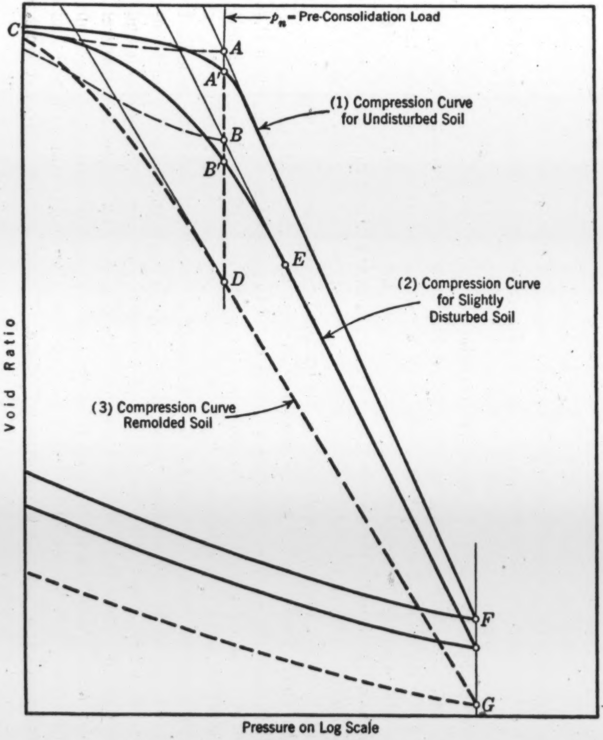

FIG. 6.—EFFECT OF REMOLDING AND SLIGHT DISTURBANCE ON THE SHAPE OF THE COMPRESSION CURVE

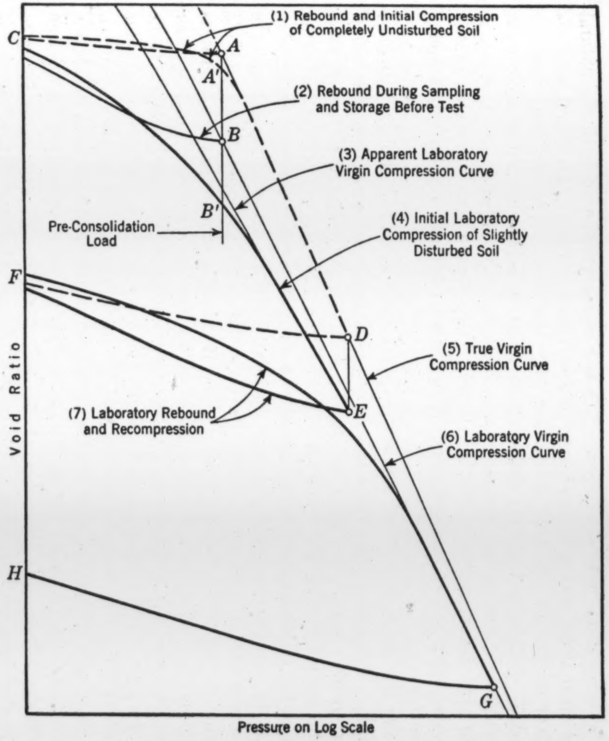

FIG. 7.—EFFECT OF DISTURBANCE DURING SAMPLING ON THE DETERMINATION OF THE PRECONSOLIDATION LOAD

in the laboratory test; or (*b*) point B is not representative of both the natural void ratio and preconsolidation load in the ground. Curve (1), Fig. 6, which is typical of test results that have been obtained for specimens from samples carefully taken by hand, indicates that point A represents more nearly the actual conditions of the soil in nature. Messrs. Casagrande (8) and M. J. Hvorslev, Assoc. M. Am. Soc. C. E. (9), have stated that saturated plastic cohesive soils probably swell very little during carefully conducted sampling operations.

Fig. 7 is a reconstruction of what may have happened to a slightly disturbed sample. Assume initially that the preconsolidation load is equal to the natural overburden pressure and that its relation with the natural void ratio of the soil in the ground is shown by point A. During the sampling operations the structure of the soil is weakened and it tends to compress under the preconsolidation stress to equilibrium at a new void ratio at point B. At the same time, the preconsolidation pressure is removed by the sampling operations and the sample is held at a constant volume by its small permeability which resists rapid outflow of water filling its voids and by the surface tension of the water at its free surfaces. The actual intensity of capillary pressure acting on the soil may be very small (it may be zero) because the reduction in strength due to disturbance removes the tendency of the mineral grain structure to expand. When a specimen from this sample is tested in the laboratory, it yields the heavy solid-line type of curve shown in Fig. 7. The preconsolidation load determined from this laboratory test falls on curve (6), Fig. 7, at point B. If point B can be determined with reasonable accuracy and if the initial void ratio of the test specimen (point C) is substantially that of the soil in nature, the intersection at point A of the preconsolidation load and the initial void ratio actually determines the condition of the soil in the ground.

Under these assumptions point A in Fig. 7 represents the natural conditions of soil with acceptable accuracy. The compression curve which will be followed actually by the undisturbed soil in the ground when it is loaded should then begin at point A. Beyond this point the investigator does not know its shape or its slope conclusively. He may assume that it is a straight line, parallel to the best laboratory virgin compression curve he can obtain. Laboratory investigations by the writer of many clays indicate that it may be a straight line slightly steeper than curve (6), Fig. 7. For practical purposes these two possibilities are identical and are shown by the broken line AD in Fig. 7.

In 1941, Professor Terzaghi presented a new hypothesis for the action of undisturbed clays which assumes a "rigid bond between the solid parts of the absorbed water films which surround the clay particles" (10). This hypothesis is based on, and explains some, field and test data not readily explained by existing conceptions. According to Professor Terzaghi, if the clay is loaded very slowly, as by the gradual deposition of overlying layers of soil over thousands of years, the "solid water" bond between particles is not broken and compression proceeds as shown by curve (2), Fig. 8. This very flat, natural compression curve has little or no relation to the results of laboratory tests on samples in which slight disturbance has broken the "solid water bond" and transformed the clay into a "lubricated" state. The possibility of its existence, however, does not affect the validity of the preceding analysis of the results below the point A in Figs. 6 and 7 of comparatively rapid laboratory tests. That analysis is based on concrete test evidence and is independent of the way the soil arrived at the condition indicated by point A. On the other hand, extrapolation of curve (5), Fig. 7, above point A may not correspond to natural phenomena. In a natural soil deposit loaded by a building, the clay may tend initially to follow some flat natural compression curve. Then, as the stress increase in the clay becomes larger, the bond might be broken and the clay might begin to compress as it does in the laboratory test. If this is the case, at stresses somewhat in excess of the preconsolidation load, the compression curve for the soil in the ground would break sharply downward toward the laboratory test curve. This is shown by the lower dotted curve (4) in Fig. 8. The tests on undisturbed specimens of Mexico City clay, shown in Fig. 5, re-

sulted in curves of this shape which break sharply and become almost vertical at a stress slightly in excess of the preconsolidation load. This is a phenomenon that has also been observed in a few tests on other clays with initial void ratios between 1.5 and 7.0.

The importance of these considerations is obvious. The engineer wishes to use the results of a consolidation test to predict the volume change in a natural undisturbed clay under an increase in stress caused by a building load, and consequently, the amount the building will settle. To do this, he must begin with the existing natural conditions and determine the actual relation between decrease in volume and increase in stress. The slight inevitable change in condition that occurs in the best undisturbed samples makes it inaccurate to apply the test results without modification. The following conclusions are a practical interpretation of the evidence now available:

(1) The preconsolidation load can be determined with reasonable accuracy from the results of consolidation tests on specimens from good undisturbed samples—for example, 8-in. to 12-in. cubical samples carefully cut out by hand in a test pit.

(2) Serious disturbance during sampling makes inaccurate, or prevents entirely, the determination of the preconsolidation load.

(3) If the Terzaghi hypothesis is accepted (and it seems to explain discrepancies between predicted and observed settlements under small stress increases as well as observed uniformities of water content over large depths of uniform clay strata) volume changes corresponding to changes in vertical stress in natural clay caused by foundation loads may be computed as follows:

(*a*) Volume changes caused by very small increases in stress will follow curve (3), Fig. 8, and may be neglected.

(*b*) Volume changes caused by larger increases in stress will break the rigid solidified water bond between clay particles. For all practical purposes the compression will then parallel the laboratory virgin compression curve (7) from the intersection with the preconsolidation load.

(*c*) The division point between these two possible actions has not been determined by field evidence. In present applications its selection is a matter of judgment, a division point at zero change in stress representing the present method of computation neglecting the Terzaghi hypothesis.

From these conclusions it is evident that a purely theoretical solution for settlement problems is not consistent with the character of the data derived from test results.

The effect of sample disturbance on test rates of volume change and prediction of rates of settlements of structures founded on clay soils has not been considered. There is little test evidence to show whether or not sample disturbance has any marked effect on rate of volume change except in so far as it affects the slopes of the compression curves. If the natural compression follows substantially the laboratory virgin compression curves, Professor Terzaghi's original theory of consolidation (11) (12) probably is adequate and well within the accuracy of field determination of drainage conditions. If the natural compression occurs without breaking the "rigid clay bonds," the rate will be entirely different from the rates obtained from laboratory tests, but the magnitudes of the settlements probably will be small and the rates unimportant.

STRENGTH TEST RESULTS

The strength tests are those tests which measure the resistance of soil specimens to change in shape and their ultimate strengths in shear, compression, or tension. The principal types of strength tests for soils are the direct shear, the simple or unconfined compression, and the triaxial compression tests. Within these three types many variations in test equipment and technique are found. They have been described in detail by many writers, including a symposium on shear testing published by the American Society for Testing Materials (13) and a recent comprehensive listing by B. K. Hough, Jr., Assoc. M. Am. Soc. C. E. (14).

The Direct Shear Test.—Direct shear testing of remolded clay has been studied exhaustively by Mr. Hvorslev (15); and L. Jurgenson (16) has studied direct shear tests on both undisturbed and remolded clays. These studies show that the shearing resistance of a clay depends on a number of factors, among which the previous stress history of the soil and its preconsolidation load are important. Consolidation test data have shown that sample disturbance modifies the effects of previous natural stresses in clays. Therefore, the shearing resistance must be affected in some degree. The direct shear-test data are inconclusive in regard to the magnitudes of effects of slight disturbance or remolding on the shearing strength of undisturbed clay. The only conclusion to be drawn from the existing data is that sample disturbance definitely affects the resistance of clay specimens to direct shear. The magnitude of the effect cannot be estimated with any assurance.

THE UNCONFINED COMPRESSION TEST

The unconfined compression test is easier to perform on undisturbed samples of plastic soil than the direct shear test and shows promise of becoming the more generally accepted of the two. It is performed on prismatic or cylindrical specimens in a manner almost identical to compression tests on concrete and other engineering materials. Precautions are taken to distribute the axial load uniformly to the ends of the specimen and the specimen is protected against evaporation. Longitudinal deformations are observed during the test. The results are plotted as longitudinal strain versus longitudinal stress acting on the average actual cross-sectional area for each load. The maximum longitudinal stress sustained by the sample in an unconfined compression test is called its "compressive strength." The slope of the initial portion of the stress-strain curve, which is frequently a straight line for the best undisturbed specimens, is called the "modulus of deformation" or the "modulus of elasticity" (17). Many natural clays are elastic in the sense that stress and strain are approximately proportional for continuously increasing compressive stress. They are not elastic in the sense that they will return to their original shape upon release

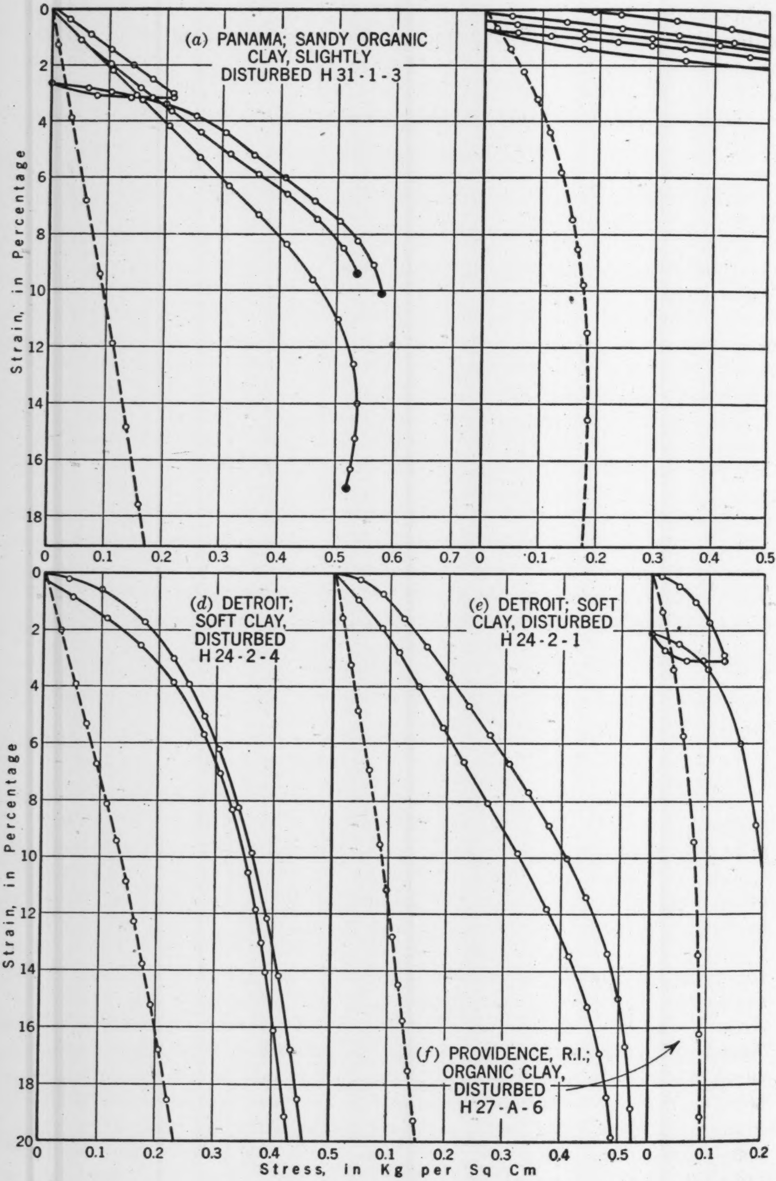

FIG. 9.—TYPICAL STRESS-STRAIN

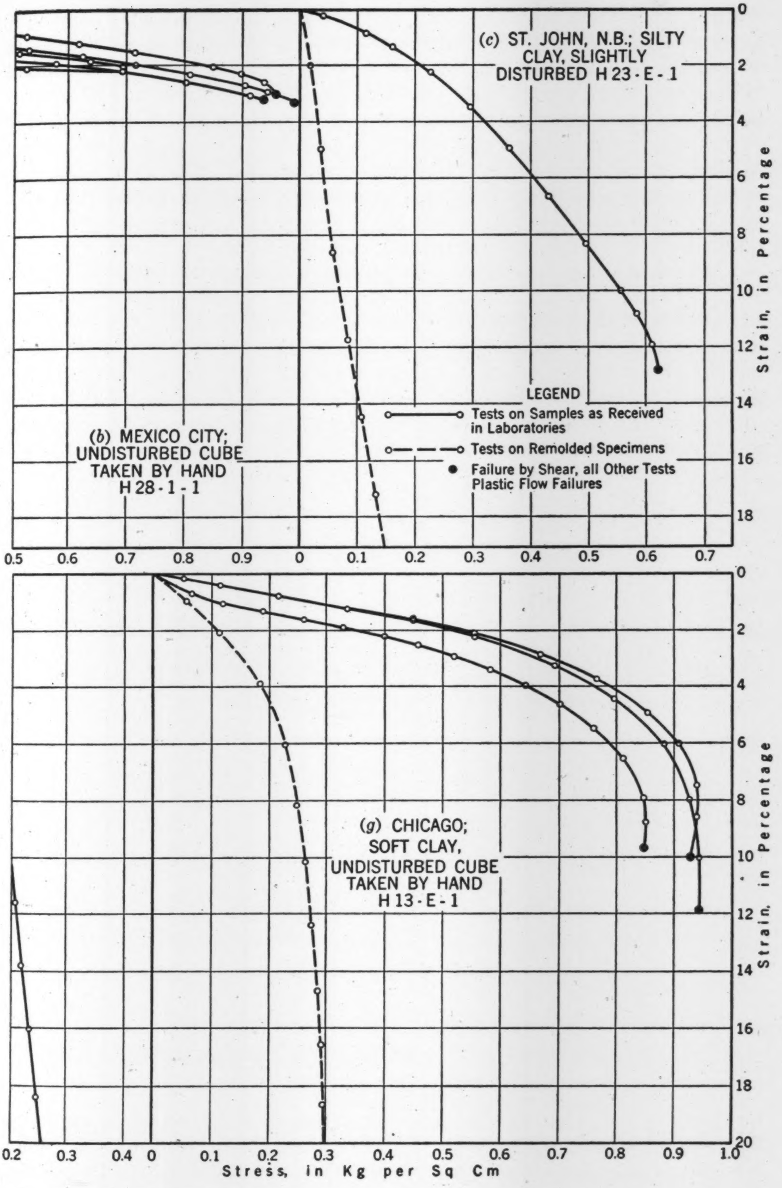

Curves for Natural Soils

of stress. The term "modulus of elasticity" is used because it is the commonly accepted term for the coefficient of proportionality between stress and strain for specified conditions of loading, and because most field loadings of concern to engineers cause continuously increasing compressive stress in soil deposits (17). The use of this term should not imply that the modulus can be used in elastic theory without review of its limitations.

Fig. 9 shows a group of typical stress-strain curves for unconfined compression tests on natural clays. Specimens from each of these undisturbed samples were tested in the condition the samples were received. Then the undisturbed specimens were remolded to form one specimen for a test on the same soil in a completely disturbed condition. The difference between the results of tests on undisturbed and remolded specimens is striking. Specimens of Mexico City clay (Fig. 9(*b*)) were cut from the cubical sample described under consolidation tests and were little disturbed. The Chicago clay sample (Fig. 9(*g*)) was a similar cube cut out by hand in an excavation. The two sets of curves for these samples are representative of results of good tests on undisturbed samples. In the writer's experience tests on specimens from such samples invariably result in stress-strain curves which are straight lines to 30% or 40% of the maximum stress, whether the soil fails by rupture at 2% strain or by plastic flow at 20% strain. In contrast to these curves, the curves for the St. John, New Brunswick (Fig. 9(*c*)), Detroit, Mich. (Figs. 9(*d*) and 9(*e*)), and Providence, R. I. (Fig. 9(*f*)), clays are typical for tests on specimens disturbed during

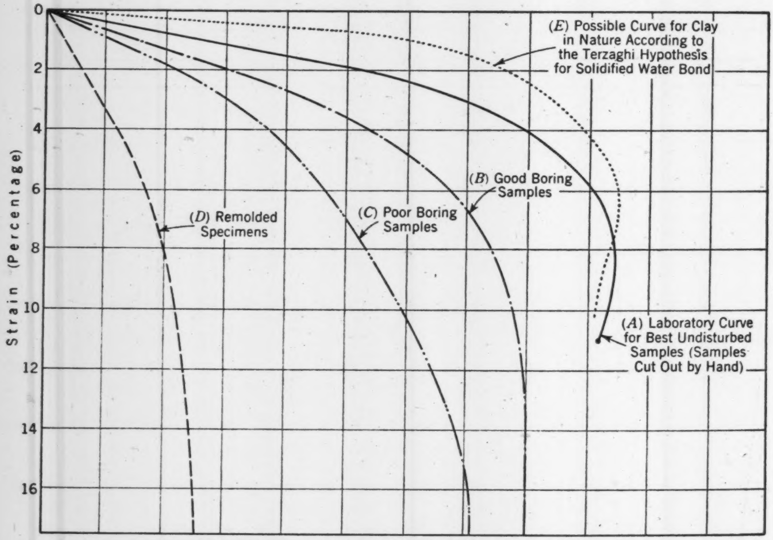

FIG. 10.—EFFECTS OF SAMPLE DISTURBANCE ON STRESS-STRAIN CURVES FROM UNCONFINED COMPRESSION TESTS

sampling. Curvature within the first 20% of the maximum load on a stress-strain curve is almost positive evidence of sample disturbance. Two series of tests by the writer on undisturbed specimens have shown that these results are not measurably affected by rates of application of strain varying between 1% per min and 1% per hr.

A specific study of the effects of disturbance during sampling on the results of unconfined compression tests was undertaken in connection with the soil investigations for the Chicago subway. The results were reported by R. B. Peck, Jun. Am. Soc. C. E. (18), in 1940. Mr. Peck has presented stress-strain curves which are remarkably similar to curves for approximately corresponding degrees of disturbance in Fig. 9. He plotted the test compressive strengths of remolded and of thin-walled seamless-steel tube samples against corresponding test compressive strengths for specimens from samples carefully cut out by hand, and found that compressive strengths varied between 65% and 75% of the "undisturbed" strength and the remolded strengths were 22% to 45% of the "undisturbed." The relative effects of sample disturbance on the initial slopes of the curves were much greater (18*a*).

As a result of the study of these test curves, and many others, with the same general characteristics, it is possible to formulate an hypothesis for the effect of sample disturbance on the results of unconfined compression tests. In Fig. 10, curve (A) represents typical results of laboratory tests on the best undisturbed specimens—for example, those cut from large cubical samples taken by hand in test pits or excavations; curve (B) represents typical results for tests on samples taken in bore holes by the most modern types of sampler; and curve (C), tests on disturbed samples taken by undisturbed sampling methods in bore holes. Tests on these same specimens, remolded at their natural water contents, would yield results shown approximately by curve (D), Fig. 10. Test measurements of the reductions in compressive strengths

and in "moduli of elasticity" from curve (A) to curve (D) (Fig. 10) are shown in Table 1.

According to Professor Terzaghi's hypothesis (10) for the "solid" versus "lubricated" states of natural clays, the rigid cementing action of the solidified water bond between clay particles may cause the soil to offer much greater resistance to deformation in its natural condition in the ground than can be obtained in a laboratory test. Thus the true initial slope of the stress-strain curve may be much flatter and the "modulus of elasticity" much greater than the best test specimens indicate. Small deformations, however, will destroy this bond as effectively as small deformations during sampling and, beyond a strain of 1% or 2%, the true stress-strain curve for the soil should be essentially parallel to, or should approach, the curve obtained from a laboratory test on the least disturbed type of specimen. On the basis of this hypothesis the true stress-strain curve for natural clay may have a shape similar to curve (E), Fig. 10. The compressive strength will practically be the same as for curve (A) if the strain at the maximum strength is greater than 2%. This conclusion has been verified partly by correlation of unconfined compressive strengths of samples carefully cut out by hand with field observations of lateral pressures exerted on the sheeting and bracing of open-cut sections of the Chicago subway (20).

These observations can be summarized by the following conclusions in regard to the effect of sample disturbance on the results of unconfined compression tests:

(1) Serious sample disturbance is indicated if, (*a*) the stress-strain curve is not a straight line for the first 30% of the compressive strength, or (*b*) the stress-strain curve falls close to a stress-strain curve for the same specimen remolded.

(2) Compressive strengths determined from tests on specimens cut from large cubes taken by hand are probably equal, for practical purposes, to the compressive strengths of completely undisturbed soils.

(3) Test compressive strengths of samples which are slightly disturbed during sampling may be considerably less than the compressive strengths under conclusion (2).

(4) The "modulus of elasticity" of a clay in nature will not be less than that obtained from the tests described under conclusion (2), but it may be greater by an amount which cannot be predicted from the results of laboratory tests.

THE TRIAXIAL COMPRESSION TEST

In the triaxial compression test a cylindrical soil specimen, enclosed in a thin rubber membrane, is placed under a constant hydrostatic pressure and then tested in compression. A schematic diagram of typical equipment for this test is shown in Fig. 11. The additional compressive load in the direction of the axis of the specimen is applied by a piston which slides freely in an opening in the top of the pressure chamber. The axial compressive stress in excess of the constant hydrostatic pressure is called "deviator stress." The test results are plotted as a curve of axial strain versus deviator stress. Volumetric strains are measured by the quantity of water flowing into or out of saturated specimens and are also plotted against the deviator stress.

Triaxial compression tests on plastic, cohesive soils are divided into quick tests, consolidated quick tests, and consolidated slow tests. All have the advantage that the lateral forces of the hydrostatic pressure simulate the confining effect of surrounding soil in nature. Thus lateral expansion of the specimen with increasing vertical strain causes decreases in the radial and circumferential compressive stresses rather than tension as in the unconfined compression test. Observed increases in compressive strengths and in strains at failure of brittle clays in triaxial compression are due in part to the fact that lateral tensile stresses have been reduced or changed to compression.

FIG. 11.—TYPICAL SETUP FOR TRIAXIAL COMPRESSION TEST

In the quick test hydrostatic pressure is applied to the specimen and it is tested immediately in compression, the entire process requiring less than thirty minutes. If the specimen tends to change volume during the test, and most undisturbed clays do, some of the hydrostatic and deviator stresses are carried by pressure in the water filling the clay voids which does not have time to flow out. Thus the actual stresses acting on the clay are difficult to evaluate. Sample disturbance increases the tendency of clay to consolidate and increases the error.

In both the consolidated quick and consolidated slow tests the specimens are placed under hydrostatic pressure and allowed to consolidate fully before being tested in compression. If the sample were perfect and undisturbed and the hydrostatic pressure were not greater than the preconsolidation load, little or no consolidation would take place and the test would begin with the soil in its natural condition. The results of consolidation tests show, however, that most undisturbed clay specimens in the laboratory consolidate under their preconsolidation loads. Therefore laboratory specimens under triaxial compression are not tested in their natural condition. As an example, the results of consolidated triaxial compression tests on undisturbed Chicago clay are shown in Table 2, each set of data being the average of two or three tests (21). All the specimens in these tests were prepared from one 12-in. cubical undisturbed sample, each specimen being consolidated fully before the test. The "modulus of elasticity," E, was computed from the formula

TABLE 2.—AVERAGE RESULTS OF TRIAXIAL COMPRESSION TESTS ON UNDISTURBED CHICAGO CLAY

(All Stresses Are in Kilograms Per Square Centimeter)

Description	HYDROSTATIC PRESSURES:									
	0		0.5		1.0		2.0		4.0	
Type of test	Quick	Slow	Quick	Slow	Quick	Slow	Quick	Slow	Quick	Slow
Natural void ratio	0.762	0.762	0.754	0.755	0.743	0.758	0.769	0.765	0.758	0.777

"Modulus of elasticity"[c]	26.7	27.5	54	67	75	90	114	134	176	282
Maximum deviator stress	0.46	0.42	0.73	0.92	1.26	1.50	1.62	2.64	3.13	5.31
Void ratio at maximum stress	0.762	0.762	0.703	0.670	0.672	0.630	0.587	0.573	0.533	0.512

[a] These are values from tests at 1.0% strain. [b] Slope of the deviator-stress versus axial-strain curve. [c] Computed from Eq. 2.

$$E = \frac{1}{\epsilon} (\sigma_1 - 2 \mu \sigma_3) \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which ϵ = unit strain; σ_1 = vertical soil stress; σ_3 = lateral soil stress; and μ = Poisson's ratio.

The preconsolidation load for this clay was approximately 1.3 kg per sq cm. The data in Table 2 show the decrease in void ratio of good undisturbed specimens under hydrostatic pressures less than the preconsolidation load and the difficulty of separating the effects of change in void ratio and of the applied hydrostatic pressures on the observed increases in strengths and "moduli of elasticity." The increases in test strengths with increasing lateral pressures, which have been attributed to an angle of internal friction in undisturbed clay, may, in fact, be due entirely to decreases in void ratio. Observations by Professor Terzaghi on the field behavior of undisturbed soft clays (22) (23) indicate a zero effective angle of internal friction in natural deposits of considerable depth.

The fact that most undisturbed clay specimens consolidate during triaxial compression tests apparently overbalances the advantage of the test as a method for measuring the strength and elastic properties of soil in its natural condition. It is possible that quick tests and tests under hydrostatic pressures less than the preconsolidation loads may be used successfully on good undisturbed samples to predict actual soil properties. With present methods the possible results do not represent an improvement over the results of unconfined compression tests.

Applications of Results of Laboratory Tests on Undisturbed Samples

The value of the preceding analyses of the effects of sample disturbance on laboratory test results, and indeed the value of laboratory testing of undisturbed samples, depend on the extent to which the results can be applied in practical foundation work. All existing methods for the solution of problems in earthwork and foundation engineering can be placed in one of three categories, each of which uses test results in a different way and to a different extent. In terms of their underlying philosophies these three arbitrary groups can be called empirical, theoretical, and semi-theoretical. If a solution method is based purely on mathematical analysis of an idealized material, it is theoretical; if it is based on theory modified by field observations, it is semi-theoretical; and if it has no theoretical basis or justification, it is empirical. This definition of "empirical" applied to foundation engineering is correct only in regard to the underlying conceptions of the solution methods, some of which (for example, the direct use of unit loads obtained from small-scale field loading tests in foundation design) do not have the support of direct observational evidence.

The true objective of the empirical methods is to establish statistical correlations between soil classes and the field behavior of structures. This is the approach adopted by the Society's Special Committee on the Bearing Value of Soils for Foundations in the early twenties, by highway engineers, and by agricultural soil scientists. Large volumes of data have been accumulated and synthesized into rules for the construction of highways, dams, and foundations and into building code tables of bearing values. The soil classes in these tables and construction rules are identified by verbal descriptions of their appearance, feel, and odor, and by numerical results of simple classification tests performed on remolded specimens. Therefore the application of empirical methods does not require undisturbed samples. The history of every science, and of foundation engineering, shows that progress solely on an empirical basis is painfully slow. F. M. Baron, Assoc. M. Am. Soc. C. E. (24), quoting long-forgotten engineering articles, demonstrates the fact that empirical foundation design has changed little in the past thirty years and, in fact, has changed only in details in two thousand years. Therefore, the fact that empirical methods do not require undisturbed samples cannot be considered a serious indictment of laboratory testing of such samples.

On the opposite extreme, purely theoretical methods proceed through mathematical analyses of forces, stresses, and strains to numerical solutions for deformations or for limiting conditions of stability. Problems in soils engineering, involving large, continuous, indeterminate masses, require the assumption of simplified physical properties for the soil for mathematical solution. The degree to which the assumed properties deviate from the real soil properties depends on the theory. The "classical" soil theorists, for example, Coulomb and Rankine, assumed that the limiting strengths of soils depended only on friction and cohesion without any reference to strains or deformations. Theoretical methods are increasingly popular today because they are the familiar approach of applied mechanics and because the powerful tools of theories of elasticity and plasticity, which are based on strains and deformations, have become widely known. A simple example is found in theory of elasticity solutions for the settlements δ_c at the centers of loaded areas carried by an infinite depth of homogeneous elastic material, all of which can be reduced to the form:

$$\delta_c = C \frac{P\,b}{A\,E} (1 - \mu) \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which P is the total load on the area, A and b are the area and width of the loaded area, and C is a numerical constant which depends on the shape and rigidity of the loaded area. Both lateral squeezing and volume change of the soil contribute to settlements. As shown by Professor Casagrande (25), Poisson's ratio, μ, is equal to 0.5 when no volume change occurs and to zero when settlement is due exclusively to volume change. Thus, the equation can be written:

$$\delta_c = C \frac{P\,b}{A} \left(\frac{0.75}{E} + \frac{1.0}{K} \right) \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which K = the bulk modulus for the soil. In this form, E may be determined from unconfined or triaxial compression tests and K from consolidation tests, both on undisturbed samples. Laboratory tests on undisturbed samples have shown that the "modulus of elasticity" determined from either type of compression test may not be the effective modulus for the natural soil and furthermore that the modulus may increase with increasing depth and confinement of surrounding soil. The theory assumes that both E and K are constants throughout the soil mass. Derivation of an effective bulk modulus for the natural soil from consolidation test results poses a similar problem. Neither the theory nor its applied results are more accurate than are laboratory test results in relation to natural soil properties and both depend on the extent to which assumed physical properties approximate natural conditions. Rigorous theoretical solutions are deceptive because they have the superficial aspect of precision. Nevertheless, for progress and development in foundation engineering the theoretical method is preferable to an empirical approach which is unrelated to theory because, paradoxically, in a few years, theories have given foundation engineers a means of transmitting to others experience with the actual behavior of soil in construction operations which was lacking after hundreds of years of empiricism. The present situation in soils engineering is precisely parallel to that of structural engineering in the nineteenth century.

Cautious and intelligent use of theoretical conceptions and methods is the hope of the future in foundation engineering. The restrictive assumptions of rigorous theoretical methods mean that they can never be applied safely to soils without full-scale field observations to determine their limitations. This leads to a modified or semi-theoretical method in which rigorous theoretical solutions for idealized materials are used as a guide to the phenomena which may affect field performance and as a basis for field observations. Theoretical solutions are then modified and simplified into a workable form with a degree of accuracy compatible with the accuracy of determination of soil properties from tests. Tests on undisturbed samples are needed in this method both in conjunction with field observations and, later, in applications to design studies, because unpredictable, erratic effects of severe sample disturbance lead to unsafe inconsistencies in the correlation of tests with observations. The test results are corrected as well as possible for effects of minor sample disturbance and other sources of error and are used with the simplified theory. Field observation data sufficiently complete to be used in this way are rare and, in many problems, engineers must still struggle with empirical or theoretical methods supported by hypotheses based on indirect evidence. An outstanding example of the semi-theoretical approach is the Swedish circular-arc method for the analysis of stability of slopes. It is based on adequate field observations and sound mechanics and has been confirmed repeatedly at the expense of purely theoretical methods.

The problem of determining safe bearing values for footing design affords an excellent comparison of these three approaches to foundation analysis. Followers of the empirical or "practical" method consult tables of bearing value for the soil immediately below the footings or perform small-scale field loading tests on that soil and use the results directly in design. The theorists realize that stresses in the soil at considerable depths as well as immediately below the footings affect the performance of the structure. They solve for stresses and deformations by the theory of elasticity. From these solutions bearing values for design are selected which will cause the soil stresses and deformations to remain within acceptable limits, assuming that soil has all the properties of an ideal elastic solid. The semi-theoretical or realistic method accepts the conceptions brought out by the theoretical solution and retains its basic principles but, since soil is neither homogeneous nor elastic, it employs simple approximations to compute soil deformations and limiting footing loads, for example the Terzaghi, modified Prandtl, or Krey methods for approximation of ultimate bearing capacities. Undisturbed sampling and accurate laboratory testing of the samples are a vital part of the theoretical and semi-theoretical methods. The major difference between these two methods in regard to samples and laboratory testing appears in the way in which the test results are interpreted and used.

CONCLUSION

Thoughtful evaluation of possible methods for progress leads to the conclusion that laboratory testing of undisturbed samples will play an increasingly important rôle. As rational methods become more reliable the necessity becomes greater for evaluating the effects of sample disturbance on laboratory test results and for extrapolating from the test results to actual soil behavior. The effects of sample disturbance discussed in this paper show that laboratory testing becomes reliable only for samples which have undergone a minimum of disturbance. In the writer's experience only 8-in. to 12-in. cubical samples cut out by hand in test pits fall in this category. If sampling equipment and careful techniques can be evolved which produce samples which are comparably undisturbed, they are well worth additional effort and cost in sampling operations. The most costly sampling operations are those in which large boring samples are obtained in a partly disturbed condition because laboratory tests on such samples yield results that have little relation to reality and in which the effects of previous stress history and actual properties have been so distorted that a reconstruction of the probable true conditions is impossible.

An attempt has been made, in this paper, to extrapolate from observed data to the true natural properties of the soil, with some support from field observational evidence. This method leads to the following conclusions:

(1) Consolidation tests on good undisturbed clay specimens yield results that can be extrapolated to reasonably close approximations of the stress-volumetric properties of natural deposits.

(2) The effects of sample disturbance on direct shear tests have not been evaluated.

(3) Unconfined compression tests on specimens from undisturbed samples cut out by hand in pits or excavations yield compressive strengths that approximate natural strengths reasonably well, but may not produce stress-strain curves or elastic constants comparable with those of the natural soil.

(4) Triaxial compression tests on consolidated specimens of undisturbed clays do not yield properties comparable with those of natural deposits because even a minimum of sample disturbance results in consolidation under lateral pressures to test void ratios smaller than those of the natural deposit.

(5) Laboratory testing of undisturbed samples is valuable in the analysis of engineering soils problems only if its limitations are known and strictly observed.

In the writer's opinion, undisturbed sampling and laboratory testing of undisturbed samples are worthwhile provided:

(6) The economic importance of decisions based on the results of an analysis and the degree of reliability of the solution methods for the particular problem justify the cost of obtaining the best possible samples.

(7) Care is taken that samples undergo an absolute minimum of disturbance.

(8) The differences between test specimens and soil in nature are understood and can be evaluated.

(9) The test results are applied with an understanding of their limitations and the limitations of the solution methods.

DISCUSSION

Benjamin K. Hough, Jr.,[3] **Assoc. M. Am. Soc. C. E.**—Although the paper is entitled "Relation of Undisturbed Sampling to Laboratory Testing," the author has extended his remarks to include a discussion of the broader subject of the practical application of test results in soils and foundation engineering problems. This more comprehensive view of the subject is justifiable since soil sampling and testing are obviously only initial steps in solving practical soil problems and no matter how well they may be performed they cannot be considered an end in themselves. Furthermore, it can be maintained that the degree of precision which is necessary in sampling and testing depends on the nature of the analytical method in which the data are to be used. On this basis, it is possible that in some cases more time and money have been expended in obtaining undisturbed samples than can be justified in view of limitations in the method of applying the test data. For example, expense is often a major consideration in deciding whether to conduct exploration in test pits or by drilling. The writer does not entirely agree with the view that test-pit samples are superior to those from drill holes; but even if this were true, it would not follow that test pits are always preferable unless it is also true that they are, in general, more economical. It is the writer's experience that test pits more than about 5 ft deep, and particularly test pits that are extended below ground water, are considerably more expensive than even fairly elaborate drilling operations and, for this reason, test pits should not be used unless the results obtained clearly justify the additional expense.

In discussing ways of determining whether soil samples have been disturbed and, if so, to what extent, Professor Rutledge refers to data from consolidation and shearing tests on the best obtainable undisturbed samples and on the same material remolded. One of the materials referred to as being practically undisturbed is a volcanic clay from Mexico City which was obtained by manual sampling in an open pit. A characteristic of this clay is that it contains more than 90% voids. It is assumed by the writer that in addition to the care which was exercised in the sampling operation, some very special precautions were taken in packing and shipping this rather delicate material to the Harvard testing laboratory since considerable disturbance might well be caused by rough handling during transportation. In view of the real grounds for suspecting that some injury might have taken place during shipment, the writer feels that it might be advisable to omit this reference or to substitute data from tests made in the locality from which the material was obtained.

A further comment on the author's treatment of consolidation tests is that he has possibly created the impression that if a sample is practically undisturbed the compression-test diagram will have a certain more or less standard character such as that illustrated in Fig. 2. Two features of this idealized diagram, which are not always found in actual practice, are the straight-line "natural-soil" compression curve and the complete return to this curve of each cycle of reloading. That the "undisturbed-soil" curve is not always straight is evidenced by the author's tests on the Mexico City clay, and also by tests recently made by the writer on certain St. Lawrence River clays with an initial void ratio of about 1.6 instead of the unusual value of 14.0. Definite curvature in practically all the semi-log compression diagrams for these Laurentian clays was found to be characteristic. It has also been observed by the writer that, more often than not, release of load and subsequent recompression during a consolidation test has the effect of offsetting the compression diagram somewhat to the left so that the successive cycles fail to form an extension of the original or undisturbed-soil curve. It is not the writer's belief that these discrepancies between actual test curves and the idealized diagram in Fig. 2 are evidences of undue disturbance of the test specimens during sampling operations. The writer agrees, however, that sample disturbance does obscure the preconsolidation point and that great care in sampling must be exercised when a determination of this point is a matter of importance.

---

[3] Capt., Corps of Engrs., U. S. Army, U. S. Engr. Office, Boston, Mass.

In connection with the Terzaghi theory to which the author refers, that the amount of compression produced by application of a given load may be influenced by the rate at which the load is applied, the writer presents some data obtained during tests on the previously mentioned St. Lawrence River clays. At one point where subsurface investigations were made by the writer, the clay deposit is approximately 60 ft deep. The upper 10 ft or 15 ft of this deposit is altered somewhat by oxidation and has dried out to some extent. In the remaining depth, however, the material is remarkably uniform in appearance and even lacks the usual stratification and traces of bedding planes which mark many clay deposits. In this uniform section of the deposit, water-content determinations were made on samples taken at fairly frequent intervals, and it was found that the water content (and hence the void ratio) of the material remained substantially constant with depth. In fact, in one location there was a slight trend toward higher water contents near the bottom of the deposit than at the top. Water contents in all cases, incidentally, even at 60-ft depths, were found to be well above the liquid limit, a fact which is in contrast with the usual assumption that clays are laid down initially at the liquid limit. This clay is classified as a post glacial, marine deposit which has never been subjected to any loading other than its own weight and its age is sufficient to warrant the assumption that the clay is fully consolidated under its own weight. It would therefore appear reasonable to expect that samples taken from the bottom of the deposit would be in a more dense condition than those at the top instead of having practically uniform density as indicated by the data from water content determinations. This apparent discrepancy may be explained by the theory that rate of loading is a very important consideration and that the "sedimentation curve" may be nearly flat instead of an extension of the relatively steep compression curve obtained from laboratory tests. It also has bearing on certain aspects of the shearing strength of clays, a subject which the author discusses in connection with the effects of sample disturbance.

From the aforementioned evidence it appears to be a physical possibility for a clay deposit of considerable depth to exist without variation in void ratio from top to bottom. Despite this fact, it seems undeniable that intergranular stresses must increase steadily with depth in such a deposit, provided it is fully consolidated. Under these circumstances, it might well be expected that the shearing strength of the clay would gradually increase with depth in proportion to the increase of intergranular pressure; yet in the case of the St. Lawrence clay the evidence from drilling records, from visual inspection of the material in place in open test pits, and from an extensive series of direct, unconfined, and triaxial shear tests is that there is no appreciable change in shearing strength with depth. This finding, if valid, is a direct contradiction to the widely accepted Coulomb relation for the shearing strength of soils and establishes grounds for a major revision in many current soil theories. Space does not permit extensive treatment of this subject, but it is interesting to consider the possibility that at least in clay deposits of similar origin, shearing strength is to some extent a function of void ratio and hence water content, rather than being entirely due to intergranular pressure. Laboratory experimentation on this subject would be a difficult matter for, although nature can apparently produce deposits with uniform void ratio yet increasing intergranular pressure, any change of pressure in laboratory samples results in a change of void ratio. If shearing strength is suspected of varying with either void ratio or pressure, it is difficult to determine the basic relationship in a test in which both these factors vary.

To turn briefly to the author's suggested methods of applying test data, the writer agrees that purely theoretical methods are unsatisfactory and also that adherence to purely empirical methods is not always wise; but, of the two, the writer is inclined to favor the latter. The method designated by the author as semi-theoretical might perhaps be termed the rational method. Whatever name is used, however, for analytical methods which combine experience, judgment, and engineering ability, the writer feels that emphasis should be given to the need for careful substantiation of each new development before it is expounded. On the whole, the writer agrees that recent studies in soils engineering have given better insight into the behavior of soils than hundreds of years of empiricism, but it is also true that the path of progress has been considerably cluttered with theories which have been hastily proposed and, with equal or greater haste, discarded.

In closing, the writer suggests that the author's selection of the Terzaghi approximate relationships as an example of the preferred "semi-theoretical" method of applying test data is unfortunate. It is the writer's understanding that these approximations were developed for idealized soil types seldom if ever encountered in actual practice. Furthermore, the writer has found that the Terzaghi approximate relationships are not in agreement with the observed behavior of large-scale field tests, specifically tests to determine the effect of the size of loaded area on the bearing power of cohesionless soils.

F. M. VAN AUKEN,[4] ESQ.—An excellent treatment of the relation of undisturbed sampling to laboratory testing has been presented in this paper. The methods that can be used as "pilot" tests to determine whether or how much a sample is disturbed are particularly enlightening.

Engineers have long recognized that laboratory tests performed on disturbed and partly disturbed soils are not in themselves of great value. Fair interpretation of results is difficult; consequently, the data are usually relegated to the "files" where they well belong.

---

[4] Chf. of Soils Laboratory, U. S. Engr. Office, Denison, Tex.

It is fortunate for the soils engineer that only two major test divisions require the use of undisturbed soil specimens. Once the consolidation and strength characteristics of a soil are known completely, all other tests become mere pawns of the former. However, since the scope of the present paper is limited entirely to plastic soils—soils that under stress generally disclose great volume changes—its scope is somewhat narrow and cannot hope to cover, even by indication, the entire field of undisturbed sampling and testing. Unfortunately this is not the case. The choice of highly compressible clays as the subject for discussion, although they do furnish unusually fine examples for a study of this type, may indicate that it is relatively easy to determine the state of disturbance that invariably accompanies all attempts to sample soils.

Probably no one consideration is of more importance than a complete reconstruction of the geologic history of the soil before it is sampled and tested. In fact, a straightforward dependence on the so-called "preconsolidation" load, as determined by the consolidation test without a thorough knowledge of past geologic history, is probably as bad as not knowing whether a given material is disturbed.

Certain clays, such as the volcanic clays from the bed of Lake Texcoco, Mexico, D. F., for which the geologic history is well known and which are compacted to abnormally high void ratios, make perfect examples of the determination of the preconsolidated load because of the "classic, almost photographic enlargement," of the consolidation test features.

Other clays like the glacial clays from the Great Lakes region, in which the geologic history is more obscure, are difficult to rate with respect to determination of the preconsolidation load and condition of soil. Recently reworked alluvial, plastic clays also present problems identifying sample disturbance. Other soils that present even more difficulty in the determination of condition are marly and shaley clays. Although they are somewhat brittle in their initial state of consolidation, these materials become truly plastic when the structure is broken down and the material remolded. Soils of this type are usually laid down as sedimentary deposits and consolidation effected by the weight of material that the forces of nature have long since removed. It may be probable that periods of recompression have occurred, caused by deposition of additional material, with re-expansion upon its removal, so that the number of compression and expansion cycles to which the material has been subjected is problematic. One may never know whether a soil is now in a period of compression or expansion. Even with an accurate knowledge of that fact the determination of the preconsolidation load by means of the shape of the pressure, void-ratio curve is practically impossible. Additional complications arise when primary expansion occurs.

Although the effect of disturbance is pronounced on the determination of the consolidation characteristics of a soil, it is not a factor that will vitally affect a consolidation study which (because of the number of theoretical assumptions, drainage, and boundary conditions, etc.) is in itself only a fair estimate of expected settlement. On the other hand, the effect of disturbance on the strength of soils is profound. Soils under vertical stress undergo a gradual rearrangement of internal structure as the stress is slowly increased, thereby resulting in consolidation or reduction in volume. Assuming a somewhat flexible confining restraint such as would be afforded a loaded element in a soil mass, the investigator will note that, as the vertical stress is increased, although consolidation is occurring, a gradual approach to a state of shear is apparent. Hence, a semiconfined stressed soil is only in a transitory stage which, as pressure is increased, rapidly progresses into fully developed shear, and when no further strain can be taken either ruptures suddenly or undergoes metamorphosis and fails in plastic flow. Disturbance in sampling merely places a soil well along in that vague but nevertheless always present stage in which the application of even a minor stress could produce failure. Therefore, regardless of testing technique, tests that are used to measure the strength of soils should show a corresponding percentage decrease in strength if a material is disturbed during or after sampling.

The writer concurs with Professor Rutledge in passing over the direct shear test rapidly, not because the effect of disturbance cannot be ascertained, but because the test in itself furnishes data that are difficult to apply. Although the slope and shape of the stress-strain curve may furnish data from which possible disturbance of a soil specimen may be detected, it is quite probable that this is true only for sensibly plastic materials. Unfortunately the ordinary range of soils runs the gamut of plastic to brittle materials; hence, it may be that internal grain structure, pseudo structures set up by fusion or cyclic desiccation, relation of moisture content to capillary and chemical forces, have as much to do with the determination of the apparent shape of the stress-strain curve as possible disturbance. The simple compression test is probably a better test than the direct shear test, but since the application of a primary vertical stress sets up secondary stresses over which the investigator has no control it appears that the triaxial test would have more significance.

Professor Rutledge has condemned the triaxial test for the simple reason that some specimens tend to consolidate during the test, and since disturbance accentuates consolidation, as shown by consolidation test research, unmeasurable errors may be introduced. The writer takes exception to this theory on the basis that the approach to the shear problem absolutely necessitates volume changes. In a coplanar system, any loaded mass of soil will be subjected to major and minor stresses which, for given boundary conditions, have some definite ratio. To alleviate the effect of preconsolidating a test specimen prior to application of deviator stresses, there are a number of methods of doing the triaxial compression test. One such method is to set up a particular stress ratio $\frac{\sigma_1}{\sigma_3}$ and maintain that ratio until the volume of the soil is stabilized; then increase the major principal stress until failure occurs. In this manner the investigator has attempted to simulate what may happen in nature.

Professor Rutledge has shown a plot of stress-strain curves for the so-called quick and slow triaxial compression tests, but it is pointed out that no effect of disturbance can be ascertained from a singular comparison of these tests. In addition, the final strength obtained from the slow test is a function of time; that is, one can obtain increasing strength values depending on whether the strain is applied at the rate of 1% per minute, per hour, per day, or per month.

This fact has been substantiated by slow triaxial compression tests performed in the writer's laboratory in conjunction with the design of a dam where some tests were continued nearly 12 months before failures were obtained. Tests on remolded specimens, as in the case of the simple compression tests, disclosed far lower ultimate strengths and flatter stress-strain slopes.

If it is assumed that a perfectly undisturbed sample retains more elasticity than a disturbed specimen (that is, the structure set up by nature has not been sensibly altered), one can determine with a certain degree of success the effect of disturbance by cyclic loading, provided the strain has not exceeded 25% to 50% of the ultimate. Other triaxial compression-test series, performed in the writer's laboratory, have shown that the apparent preconsolidation load can be determined approximately by the proper combination of quick and slow tests, provided the samples were truly undisturbed.

A review of the various proposed methods of determining how much disturbance affects soil test results shows that all methods are still problematic in aspect. That disturbance does affect both consolidation and strength values is a fact that cannot be overlooked. However, during any complete soil investigation, the scope of the problem is often such that only pilot tests to determine how much disturbance is being caused by the adopted sampling methods can be performed. On the basis of those tests one must either discard or improve the sampling technique or recognize the limitations of the soil test data obtained. In years past, soils engineers, although probably recognizing the effect of sample disturbance on test data, were prone to pick the "yield point" from the stress-strain curve, resulting in the use of values far below the ultimate ones. However, during the past few years, ultimate values are more generally used, but the one redeeming feature that has covered many errors is the fact that sample disturbance generally lowers the obtained values.

Professor Rutledge's paper will have accomplished its prime purpose if only through stimulation of a timely subject. In closing, the writer wishes to emphasize two facts often overlooked and having a decided effect on the accuracy of soil-test data. Those facts are "too long" a time lapse between sampling and testing, and "too little" emphasis on the choice of sampling and testing technique.

JACOB FELD,[5] M. AM. SOC. C. E.—The careful analysis of the problem of undisturbed soil samples, in which the author lists proof of each point, is a contribution to the subject of soil mechanics. The identification of clays by the shape of the stress-strain curve may well be considered a means of classification sufficiently accurate to be used as a design tool. Many structures are planned to be located on clay soils, where the cost of expensive sampling and testing has not been warranted. If the engineer is certain that the samples and the tests will indicate correctly the future action of the structure, he might be justified in ordering the expenditure. The use of full-scale data from previous experience (and troubles) with foundations as a basis of design of other structures is not feasible without a guarantee that the soils encountered are similar. The author's method can be used to prove similarity, even without the exact sampling procedure.

---

[5] Cons. Engr., New York, N. Y.

The action of clay soils under loadings, in test samples and in nature, can be described by an analogy. Assume the existence of a large continuous bed of sponge living at the bottom of the sea. The density of the sponge is the result of the hydrostatic pressure above it, within it, and around it, together with its skeleton strength. Change in water depth will affect the density immediately, subject to rebound with time as the internal water pressure (from osmosis) changes to balance the new loading. A load imposed on the sponge bed will settle, immediately due to compression of the skeleton and of the water and additionally as the water under the load is pressed outward, to the extent that the adjacent sponge will absorb the surplus. The volume change in the sponge under the load will affect the adjacent materials.

Excavating a test pit for determining sponge conditions at any depth is likely to yield unreliable results, because of the expansion at the new surface as soon as the pit is dug. The job of removing an "undisturbed" sample for testing, without changing the physical characteristics, is almost hopeless. However, if a sample can be subjected to approximately the same exterior forces and moisture conditions in a laboratory test, its natural reactions under new loading can be determined. This paper indicates how one can be assured that the laboratory procedure reproduces original or natural conditions (natural void ratio and preconsolidation load). Such assurance will go far toward instilling confidence in the value of soil sampling and of soil testing.

RAYMOND F. DAWSON,[6] M. AM. SOC. C. E.—Because the expansive clays of the Southwest present unusual problems as foundation materials, a comparison of these soils with those included in Professor Rutledge's paper is of interest. The writer has never found an undisturbed sample with all the voids filled with water. The initial degree of saturation usually ranges between 94% and 99% and has been found as low as 89%. Since many of these samples were taken at a considerable depth below the surface, where ample water should have been available to fill the voids, this indicates a swelling of the specimen. Perhaps the initial degree of saturation is a measure of disturbance in these clays.

These samples continue to expand at a very slow rate after they have been removed from the ground. Specimens covered with paraffin and stored in the moist room will eventually expand enough to break the covering. With some samples this will occur in only a few weeks whereas others require many months to produce failure. This condition has caused local laboratories to apply two special procedures to the consolidation test: Samples are tested as quickly as possible after being removed from the ground; and the initial void ratio is held constant until sufficient load has been applied to offset the swelling pressure. The latter step is accomplished by applying small increments of load to the specimen after it has been placed in the consolidometer, the amount of load applied being sufficient to prevent movement of the dial gage. When no further load is required to keep the dial constant, the sample is loaded in the usual manner, starting with the next increment of load generally used in the consolidation test. On the pressure, void-ratio, curve this part will be a

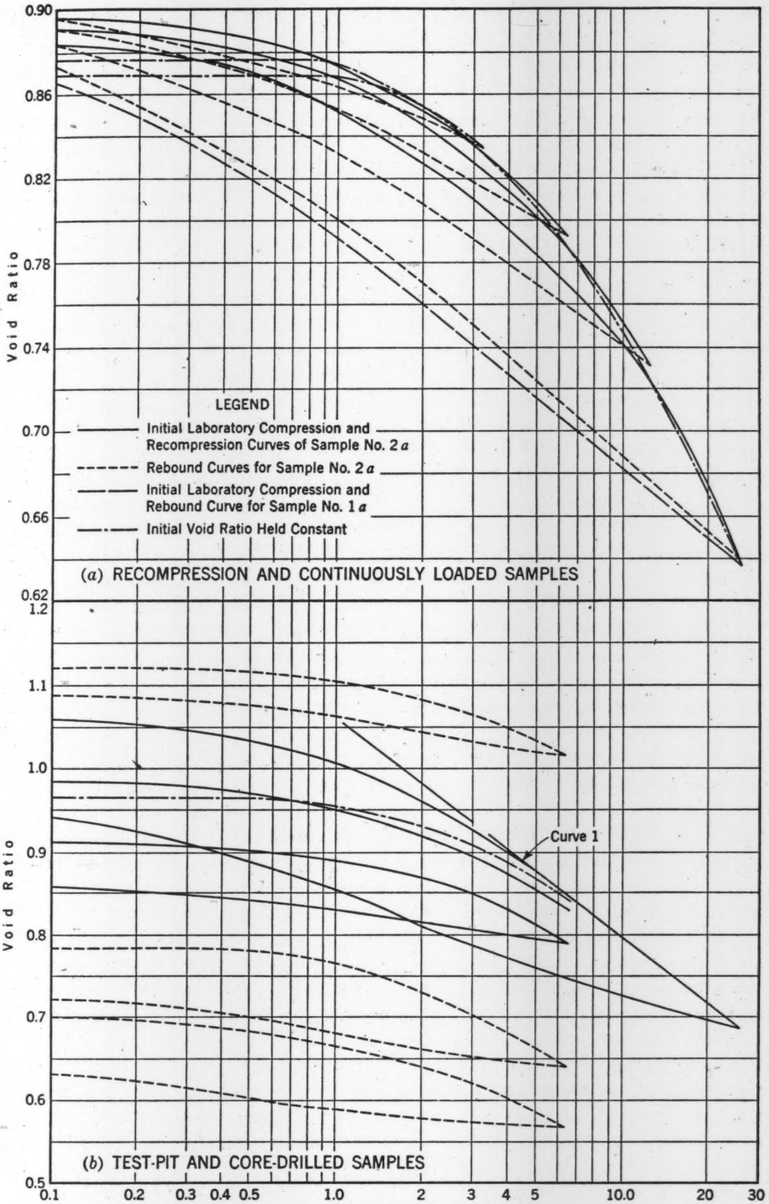

FIG. 12.—EFFECT OF SWELLING ON THE CONSOLIDATION CHARACTERISTICS OF EXPANSIVE CLAYS IN THE SOUTHWEST

straight line since the void ratio is constant and is usually indicated by a broken line.

In order to study the effect of swelling on the consolidation characteristics of these soils the test shown in Fig. 12(*a*) was made. A sample was prepared in the usual manner and the initial void ratio was held constant, as indicated by the dash-dot line. The soil was then loaded in increments to a total pressure of 3.2 kg per sq cm and the load removed to produce the rebound curve. With a load of 0.1 kg per sq cm (200 lb per sq ft) the specimen had expanded considerably above its original void ratio and the recompression curve started. In each cycle of recompression the maximum load was twice that used in the previous cycle. The recompression curves indicate that each cycle of loading changes the slope of the lower portion of the curve in a downward direction. The results of a consolidation test, made in the usual manner on a sample of similar soil, are shown in Fig. 12(*a*) by the dashed line. This indicates that the change in character of the curves due to recompression is not as important as the recompression curves alone would lead one to believe. The soil used in the recompression tests (sample 2*a*) had an initial void ratio of 0.869 and initial degree of saturation of 98.5%, whereas the continuously loaded specimen (sample 1*a*) had an initial void ratio of 0.877 and an initial degree of saturation of 97.5%. Continuous loading tests on other samples from the same site gave pressure, void-ratio, curves with shapes similar to sample 1*a* but with higher or lower initial void ratios.

Although it is agreed that cubical samples, taken carefully from a test pit, give more nearly undisturbed test specimens than those obtained by any other method, it may not be possible economically to use this procedure, especially in the case of a deep stratum. In 1942, the writer supervised the sampling of clay soils on two projects where it was impracticable to use test pits and where no special sampling spoon was available. On both jobs samples were taken by using what the drillers call a "poor-boy" sampler. This sampler consisted of a piece of seamless steel tubing, $\frac{1}{8}$ in. thick, with a 5-in. outside diameter. The lower edge was sharpened, but the 12-in. long tube had the same internal and external diameters for the entire length. Holes, 6 in. in diameter, were advanced by usual drilling methods until the desired depth was reached at which point the sampling tube was inserted for the drilling bit. The sampling tube was forced into the soil for a depth of 8 to 10 in. by means of a hydraulic jack and the bit rotated one turn to shear off the soil at the bottom of the bit. When it was necessary to advance the hole by wet drilling, the top 2 to 3 in. of the core was removed and discarded. As soon as the cores were removed from the tube, they were coated with several layers of paraffin and cheesecloth and tested immediately after being transported to the laboratory. These sampling tubes had an area ratio (9) of less than 10% as compared with about 40% for the usual sampling spoon. Therefore, they probably caused less disturbance than some of the more elaborate sampling devices. On one project a seamless steel tube only $\frac{1}{32}$ in. thick was used part of the time. This gave an area ratio of about 5% and proved satisfactory until a pebble which forced it out of shape was encountered. Visual examination showed very little disturbance of cores taken by this method.

On one project the investigators were able to compare the results obtained on cores taken as outlined, with the consolidation characteristics of the same soil as determined from cubical samples cut carefully from test pits; Fig. 12(*b*) gives this comparison. The solid-line curves were obtained for specimens taken from the test pits and the broken-line curves were for the core-drilled samples. There is little difference in the shape of the curves, indicating either (*a*) that there was practically no disturbance in taking the samples with the core drill; or (*b*) that the entire soil deposit is in a disturbed condition.

A further examination of all the curves shown in Fig. 12 might lead also to the conclusion that the soils were disturbed because they do not possess the general shape indicated by Professor Rutledge and most of them do not have a straight-line section. This is a result of the type of soil rather than disturbance at the time of sampling. When high consolidation loads are used on these soils, the lower portion does become a straight line as shown on curve (1), Fig. 12(*b*). Such a curve indicates a preconsolidation load of about 2 tons per sq ft, which is about twice the weight of the overburden; and, since the clays are of recent geological origin, one would not expect that any great amount of overburden has been removed. These clays have been badly fissured and break with slickensided surfaces, many of which contain thin layers of clay of a different color. It is assumed, therefore, that the clay dried and cracked after it was deposited and that the next flood filled the cracks with the lighter-colored clay; then, when the original clay expanded by taking up moisture, internal stresses developed because the cracks were filled, therefore causing the high preconsolidation load.

Engineers and investigators should underline Professor Rutledge's statement (paragraph following Eq. 4):

> "Cautious and intelligent use of theoretical conceptions and methods is the hope of the future in foundation engineering. The restrictive assumptions of rigorous theoretical methods mean that they can never be applied safely to soils without full-scale field observations to determine their limitations."

Certainly many more full-scale field observations accompanied by complete laboratory analyses must be conducted before final conclusions may be reached.

HAMILTON GRAY,[7] JUN. AM. SOC. C. E.—The principal steps involved in a foundation analysis have been aptly likened by the author to "links in a chain" of procedures which are intended to reach a definite point that may be considered the solution of the problem at hand. Conditions which produce inaccuracies in any link—figuratively changing the length of the link—tend to affect the length of the chain and hence the distance by which it fails to reach the desired terminal point. Such inaccuracies, of course, may be compensating, the effect of a "short" link being offset by that of a "long" one; but such an occurrence would be purely fortuitous. A close agreement between predicted and observed behavior associated with any physical phenomenon does not necessarily assure that each of the steps involved in making the prediction was flawless. Similar methods may not give as "satisfactory" results when applied another time. Hence, if the methods of soil mechanics are to achieve their full usefulness, the magnitude of the inaccuracies in the individual links must be known quantitatively so that the error in the length of the chain may be determined with reasonable certainty. Actually this chain consists of three major links, which, together with the chief source of error in each, may be listed as follows:

---

[7] Asst. Prof., Civ. Eng., New York Univ., New York, N. Y.

(1) Sampling (distortion of the soil and hence alteration of its physical properties during the sampling process);
(2) Testing (inappropriate testing methods for determining the pertinent physical properties); and
(3) Prediction (unsuitable analytic methods for predicting the behavior of the underground on the basis of values determined under Item 2).

If one were in a position to evaluate, confidently, the magnitudes of the errors inherent in each of these three steps, the science of foundations would be practically complete. Professor Rutledge has made an encouraging start toward determining the effect of imperfect sampling on certain of the physical characteristics which are determined by experimental means. It is clear, however, that the numerical and graphical comparisons are made between samples, and not between samples and the soil in place. Consequently, it remains difficult to know quantitatively how truly a sample represents its parent stratum.

Only by comparing properly conducted field observations with the solutions secured by means of steps 1, 2, and 3 in a large number of cases can one ever hope to determine the sources of discrepancy between predicted and actual observed behavior. In the present state of knowledge, an agreement between prediction and field behavior does not assure perfection of all links in the chain; nor may a discrepancy between prediction and behavior definitely be attributed to any one of them. One simply cannot state, in the light of present knowledge, what quantitative influence is exerted by inaccuracies in any or all of the three steps enumerated. Hence, only rough estimates can be made of foundation behavior.

The paper does suggest means of forming qualitative opinions as to the possible value of a sample in representing the stratum from which it was secured, and shows, further, that a given degree of soil disturbance influences certain physical properties more than others. This signifies, for example, that great caution should be employed in utilizing the modulus of elasticity as obtained from unconfined compression tests. On the other hand, the compressive strength secured in the same test is more nearly representative of the behavior in nature. Although it is easy to establish a numerical measure giving the degree of disturbance intermediate between complete remolding (100%) and the best available undisturbed sample (0%), comparison with the behavior of the parent stratum remains a matter of guess or judgment.

In connection with the consolidation test, the author leaves the impression that a pressure, void-ratio curve for a loose clay, which shows upward concavity (see Fig. 5) instead of being precisely linear (see Fig. 2), when plotted on semilogarithmic paper represents a minimum amount of disturbance. The writer has observed such upward concavity in loose clay samples of 2.5-in. diameter, which were taken in a sampling spoon (3-in. inside diameter) of a type no longer considered suitable for securing first-class undisturbed samples, and believes that there was no minimum of disturbance in these cases. Further, since a sample taken by spoon is generally subject to the greatest amount of distortion at its periphery, one is led to consider the extreme case of a "composite" sample consisting of a wholly undisturbed core of diameter, say 3 in., surrounded by a completely remolded soil annulus of the same material to give a total sample diameter of 4 in. When subjected to a consolidation test, the deformation of both core and soft annulus will be identical, but the annulus will be subject to a far lower stress because of its different pressure, void-ratio diagram (see Figs. 3, 4, and 6). An analysis of the loading and deformation of such a sample leads to the conclusion that the resultant pressure, void-ratio diagram would be slightly concave upward at the lower end just as are the curves in Fig. 5. Until further information is available, therefore, it would seem wise to accept, with definite reservation, the author's statement concerning the evidence of a minimum of disturbance. The foregoing inference should be easy to check experimentally for the behavior of composite samples of various clays.

In discussing the triaxial compression test the author touches upon the somewhat controversial subject of the proper type of test to be made in simulating certain field conditions. Similar differences of opinion exist in connection with quick and slow shear tests. The type of test to be used should be one which either simulates field behavior, or gives results that may be used somehow in analyzing conditions of soil in place. If two or more kinds of tests can furnish usable results in a given set of circumstances, that one which is performed more readily probably will be used the more widely. On the other hand, the method of testing always must be adapted to the type of analysis employed in predicting field behavior. For example, the author cites Eq. 4 for computing settlements. The use of this formula entails the previous determination of the soil properties, defined by K and E, which in turn require two types of tests. There are various other ways of estimating settlements, each with its proponents, and each necessitating knowledge of certain physical properties, determination of which may require more, or less, experimental work than do the constants of Eq. 4, depending on the details of the method. In all probability, the method that is best never can be decided by theory alone; but, in time, the compilation of observed behavior may give a clue as to the most reliable method.

A compilation of observational data of similar nature from several foundations which differ somewhat in such details as—(*a*) relative positions and thicknesses of soil strata; (*b*) size of loaded areas; (*c*) increase in net load; and (*d*) sampling technique—might permit a segregation of the inaccuracies inherent in the various steps involved in making a forecast of behavior. The data from a single foundation may or may not suffice to justify assigning the source of any discrepancy between prediction and observation to one of the steps employed in making the prediction. To cite a specific example, assume that a building imposing a uniformly distributed net increase in pressure of 1 ton per sq ft at the level of its foundation rests on a bed of dense sand. The sand extends to a depth of 15 ft below the foundation and is underlain by compressible clay overlying rock. If the building covers a very large area and the clay stratum is thin, any variation between observed and predicted subsidences may be attributed to disturbance during sampling or to improper testing technique with the former constituting the more probable source. On the other hand, if the area covered by the building is relatively small and the clay stratum thick, the variation of pressure increase with depth is introduced. This brings up the question of the applicability of the "Problem of Boussinesq," and, in addition, the more difficult matter of the effect of the sand layer in distributing loads to the more compressible clay. This latter problem in all probability cannot be treated satisfactorily by analysis alone, and hence it appears evident that a widespread collection of observational data, followed by an intensive study of its significance, would be required before an understanding of such conditions is reasonably complete. However, as suggested herein, a relatively small amount of data probably would suffice, under favorable conditions, to determine the influence of sample disturbance on the laboratory test results alone. That modification of the test results requisite to predict the actual behavior of the foundation then could be adopted readily. However, without the correlation between laboratory results and observed field behavior, the magnitude of the desired modification cannot be known with any certainty.

KARL TERZAGHI,[8] M. AM. SOC. C. E.—An up-to-date inventory of what is known or believed concerning the influence of the disturbance due to sampling operations on the physical properties of cohesive soils has been presented by Professor Rutledge. Since the growing realization of the importance of this influence constitutes a vital phase in the development of soil mechanics, some data concerning the historical background of this phase may be of interest.

The credit for the discovery of the mechanical effects of remolding belongs to the Swedish Geotechnical Commission. The final report of the commission was published in 1922 (26). The report contains many examples of the mechanical effects of remolding and the description of a method for expressing the sensitivity of the structure of the clay by numerical values. Opinion concerning the physical causes of the observed phenomena still is divided. In 1932, Professor Casagrande proposed a hypothesis according to which the sensitivity of the structure of the natural, undisturbed clays is due to a peculiar arrangement of the clay particles, which he called the clay structure. On the other hand, the writer believed—and still believes—that it is chiefly due to slow physico-chemical processes which take place in any clay. Fortunately the issue is only of theoretical interest.

The work of the Swedish Commission initiated the development of the technique for securing undisturbed samples. The first sampling tool of the modern type was proposed by John Olsson in 1925 (27). However, since undisturbed sample borings are much more expensive than the traditional wash or auger borings, it required many years for engineers and contractors to accept the new methods of sampling. In the meantime, investigators had to be content with whatever samples they could afford. Even the so-called drive samples were considered a luxury.

---

[8] Winchester, Mass.

Several years after the publication of the Swedish report, the writer investigated the influence of remolding on the modulus of elasticity of clays (28). In those days, consolidation tests still were made on completely remolded samples. In order to correct for the influence of remolding on the relation between pressure and void ratio, the graphical method illustrated in Fig. 13 was used (29). In Fig. 13 the symbol e_0 indicates the initial void ratio and p_0, the vertical unit pressure which acts on the clay in the ground at the depth where the sample was obtained. The curve C_1 represents the results of a consolidation test on a remolded sample. On this curve the pressure p_0 corresponds to a void ratio e_1 which is much smaller than the void ratio e_0. The difference between e_0 and e_1 represents the effect of remolding on the void ratio at a given unit pressure p_0. It seemed obvious that the clay in its natural state, with a void ratio e_0 at a pressure p_0, should be more compressible than the remolded clay, with a smaller void ratio e_1 at the same pressure p_0. Therefore, the writer assumed that the pressure, void-ratio curve for the clay in the ground can be determined approximately by multiplying the ordinates of the C_1 curves by $\frac{e_0}{e_1}$. Thus he obtained the curves C_2.

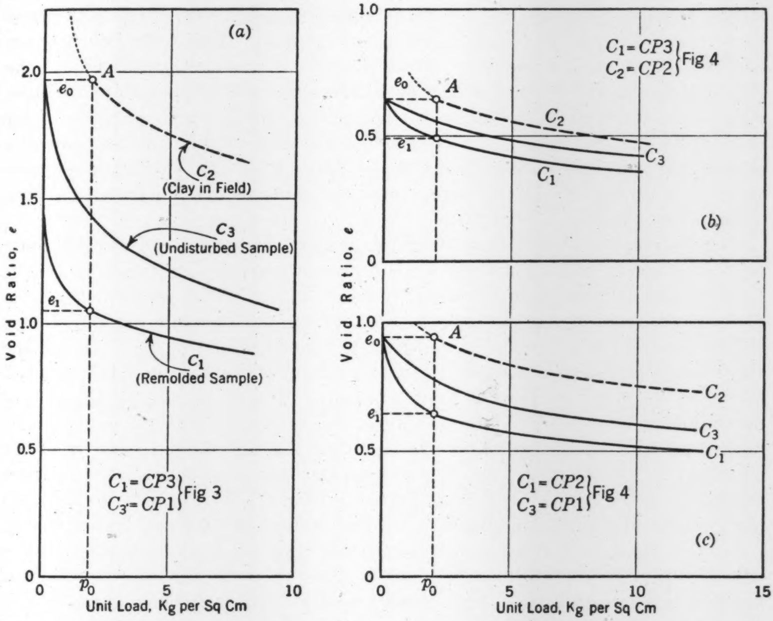

FIG. 13.—GRAPHICAL METHOD FOR ESTIMATING THE RELATION BETWEEN PRESSURE AND VOID RATIO FOR NORMALLY CONSOLIDATED CLAY IN THE FIELD (CURVES C_2) ON THE BASIS OF RESULTS OF CONSOLIDATION TESTS ON REMOLDED SAMPLES (CURVES C_1)

Curves C_1 in Fig. 13 were plotted by means of the data contained in Figs. 3 and 4. The corresponding pressure, void-ratio curves for undisturbed samples are represented by curves C_3.

In 1932 Professor Casagrande published, for the first time, the results of consolidation tests on undisturbed clay samples. Curves C_3, Fig. 13, are examples of the general character of the curves thus obtained. In the diagram they occupy a position intermediate between the pressure, void-ratio curves for the remolded samples and curves C_2 which represent very roughly the pressure, void-ratio curves for the clay in the ground. The difference between curves C_2 and C_3 is a measure of the increase of the compressibility of the clay due to the disturbance of the structure by sampling operations. Settlement computations require a knowledge of the relation between p and e for the clay in the ground. In order to determine this relation on the basis of a consolidation test on undisturbed samples (curves C_3, Fig. 1), certain assumptions must be made. In the paper these assumptions are illustrated by Figs. 6, 7, and 8.

To the general reader, these diagrams may be somewhat confusing because no distinction is made between what is known and what is merely believed. Each of the diagrams contains two rebound curves. The upper one, labeled (2) in Fig. 7, is assumed to represent the rebound during sampling and storage before test. It is generally agreed that the increase of the void ratio of the clay during sampling is insignificant and that, after the sample is taken out of the hole, its water content is kept constant. Therefore, the processes that occur during sampling and storage should appear in the diagrams as a straight, horizontal line whose ordinates are equal to the initial void ratio e_0 of the clay; yet in the diagrams the line which corresponds to these processes rises as steeply as the laboratory rebound curve (curve (7), Fig. 7), which represents the swelling of the clay in contact with free water after the removal of a load.

If the upper rebound curve is eliminated and replaced by a straight line with the ordinates e_0, all the other constructions shown in the diagrams become more or less meaningless. The writer proposes that they be replaced by the simple diagram Fig. 14, which leaves no doubt about what is known and what is believed. In Fig. 2(*a*) (which shows the relation between pressure and void ratio for different samples of a normally consolidated clay) the full-line curves represent empirical curves. The dashed and dotted curves are lines obtained by inference.

While the pressure on the clay increased in the field during the process of sedimentation from its initial value, zero, to the final value p_0, the void ratio of the clay decreased as indicated by the gently sloping curve ab. This curve is an empirical, and not a hypothetical, one, as suggested by the label in Fig. 8, because it can be constructed, without any assumptions, by combining two sets of empirical data. One of them is the water-content profile of the stratum, and the second is the profile that shows the relation between depth and the overburden pressure p_0. The process of sampling and the period of storing are represented by the horizontal line bc. Curve cd_1e_1 in Fig. 14 shows the results of a consolidation test on an undisturbed sample and curve cd_2e_2 those of a test on a remolded sample. In order to obtain the relation between pressure and void ratio for the clay in the ground, the straight line be is traced through point b, parallel to the straight part d_1e_1 of the pressure, void-ratio curve cd_1e_1 for the undisturbed sample. There is no theoretical justification for this method. Therefore, the procedure can be advocated only on the strength of empirical arguments. If the weight of a structure increases the load on the clay very considerably, the resulting disturbance of the structure of the clay is at least as important as the disturbance due to the sampling operations. Under this condition it appears reasonable to assume that the pressure, void-ratio curve for the clay in the ground should be roughly parallel to that for the undisturbed sample. By comparing the settlement of heavy structures computed on the basis of this assumption with the observed settlement, it was found that the agreement is usually satisfactory.

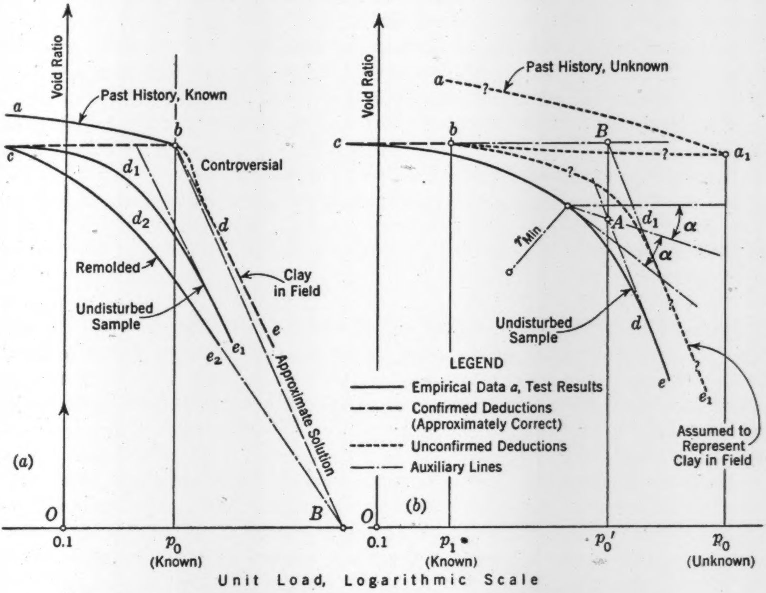

FIG. 14.—RELATION BETWEEN PRESSURE AND VOID RATIO FOR (a) NORMALLY CONSOLIDATED AND (b) OVERCONSOLIDATED CLAY

On the other hand, if the increase of the load on the clay due to the weight of a structure is small, the analogy between the clay in the ground and the undisturbed sample does not exist, and no reliable data concerning the settlement of light structures on clay foundations are available. Therefore the upper part of the line bd in Fig. 14(*a*) has been marked as controversial.

If a job involving a foundation above a stratum of normally consolidated clay is not important enough to justify the expense of securing undisturbed samples, the consolidation tests can be made on remolded samples. Each test yields a pressure, void-ratio curve similar to curve cd_2e_2 in Fig. 14(*a*). The continuation of the straight part d_2e_2 of this curve intersects the horizontal axis of the diagram ($e = 0$) at point B. In most instances, the slope of the line bB is somewhat greater than that of the line be, obtained from a consolidation test on an undisturbed sample; but the difference is not important enough to be of any practical consequence on a routine job. This approximate method of evaluating the relation between pressure and void ratio is identical with the method illustrated by Fig. 13. However, in Fig. 13 the pressures have been plotted on a natural, and in Fig. 14(*a*) on a logarithmic, scale.

Fig. 14(*b*) shows the relation between pressure and void ratio for an overconsolidated clay. The symbol p_0 denotes the highest pressure that acted on the clay during its geological history. It is greater than the present overburden pressure p_1. The changes of the void ratio which occurred during the gradual rise of the pressure from zero to p_0 and the subsequent decrease from p_0 to p_1 are not known. Therefore they are indicated by dotted lines, aa_1 and a_1b. The value of p_0 can only be guessed at on the basis of geological data. The changes that occurred during sampling and storing are shown by the broken horizontal line bc. The results of a consolidation test on an undisturbed sample are shown by curve cde.

By means of the graphical construction indicated in Fig. 14(*b*), a point A is obtained which is located on the straight-line continuation of curve de (30). The pressure $(p_0)'$ which corresponds to the abscissa of this point is assumed to be roughly equal to the preconsolidation pressure p_0. The controversial issues associated with this assumption have been discussed by the writer elsewhere (31). Since the author has made a considerable number of consolidation tests on shaft and tunnel samples from Chicago, Ill., and other localities, he could assist materially in clarifying these issues by presenting, in his closure, a list of the preconsolidation loads that were obtained for these samples, together with the data which determine the position of the samples with reference to the water table and to the ground surface. The importance of the difference between $(p_0)'$ and the real preconsolidation pressure p_0 cannot yet be estimated; but it is fairly certain that the ratio $\frac{(p_0)'}{p_0}$ depends to a large extent on the method of sampling. The greater the disturbance of the clay due to sampling, the smaller will be the ratio $\frac{(p_0)'}{p_0}$, all other factors being equal. The ratio $\frac{(p_0)'}{p_0}$ may also depend on the depth at which the samples were secured.

The next step consists in tracing a vertical line through point A. This line intersects the right-hand continuation of bc at point B. Finally Be_1 is traced parallel to de. The pressure, void-ratio curve for the clay in the ground is assumed to be tangent to Be_1, and the upper part bd_1 of this curve is assumed to have the same trend and curvature, roughly, as the upper part of the laboratory consolidation curve.

The most essential requirement for the application of the procedure illustrated by Fig. 14(*b*) is to secure first-class undisturbed samples, because a slight disturbance of the structure of the clay effaces almost completely the traces of the loading history of the clay. Even if the samples have been secured with utmost care in test shafts, however, the procedure still leaves ample margin for error. Therefore, it is not surprising that the agreement between the results of the settlement computations for structures on overconsolidated clays and the true settlements are rather unsatisfactory in most instances, whereas the settlement computations for heavy structures on normally consolidated clays consistently are found to be reliable.

The two diagrams in Fig. 14 are so simple that no special terminology is required; yet they show everything that is really essential.

Triaxial compression tests are an inexhaustible source of information concerning the behavior of soils subject to stress in space under laboratory conditions; but the practical benefits of these investigations cannot be reaped until the difference between field and laboratory behavior has been explored by means of field observations on full-sized structures. At present the evaluation of this difference still is based chiefly on opinion.

In the last part of his paper, the author mentions semi-empirical methods for dealing with foundation problems. The essence of these methods consists in adapting the fundamental assumptions of the theories to the results of observations in the laboratory and in the field. As experience increases, the methods are modified and generalized in accordance with findings. The Swedish circular-arc method is a good example. After the method was devised, it was found to be not applicable to the failure of fills above thin clay strata. Therefore it was necessary to supplement it by a method based on assuming the possibility of a failure along a composite surface of sliding. For similar reasons, Coulomb's theory of earth pressure had to be expanded into the general wedge theory (32). Because of its inherent adaptibility, a semi-empirical method does not deserve its name unless it agrees, at any time, with the experience which has been accumulated up to that time. The theories of bearing capacity which the author quotes as examples were published many years ago. Therefore they should be discounted until they are again brought up to date.

On account of the impressive diversity of its contents, the paper contains a vast amount of food for thought. Therefore, it will not fail to exert a stimulating influence on many readers.

D. P. KRYNINE,[9] M. AM. SOC. C. E.—The material testing laboratory is closer to the activities of an engineer when he deals with the foundations of a structure than when he works on the structure itself. This is because the medium surrounding the foundation, and acting together with it, cannot be purchased or ordered to satisfy certain specifications. Some evidence must be furnished by the soil laboratory in each particular case. The writer wishes to emphasize the word "some" in the preceding sentence. Every engineer understands very clearly that a soil laboratory does not test the earth material itself, but merely furnishes information on the properties of the samples tested, under the limitation, of course, that proper tests have been performed properly. In this connection an authoritative and frank explanation of the value of soil samples and of the tests themselves, as issued by Professor Rutledge, should be welcomed by the profession.

Consolidation Test.—To determine how much a deep clay layer will decrease in thickness (settle) due to the pressure from a proposed structure, a model of this layer (an "undisturbed" thin soil sample) is tested. It is subjected to the same conditions as the natural clay layer so far as the initial pressure p_1 (before construction) and the final pressure p_2 (after construction) are concerned. The main object of the test is to find the relationship between the "void ratio" of the clay (ratio of the volume of voids to the ratio of solids) and the applied unit pressure. On semilogarithmic paper, this relationship is approximately expressed by a straight line termed "virgin compression curve" (Fig. 1(*b*)). It is assumed that the change in void ratio, $e_1 - e_2$, due to an increment in pressure, $p_2 - p_1$, is the same for the model and the prototype. The final settlement (or the decrease in thickness) of the layer may be computed easily from the value $e_1 - e_2$; and the steeper the "virgin compression curve," the larger the expected settlement will be.

---

[9] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

The "virgin compression curve" is supposed to be tangent to the laboratory compression curve (Fig. 1(*b*)). The latter is obtained in the laboratory by applying rather large increments of load at a rather quick rate and the test cannot be done otherwise. According to Professor Terzaghi (10) in doing so, the laboratory worker breaks "rigid clay bonds" and transforms the clay of the sample into a soft ("lubricated") mass. In nature load increments are applied slowly—grain by grain, particle by particle. Hence the field "virgin compression curve," before construction, is flat (curve (2), Fig. 8) whereas the laboratory curve (curve (7), Fig. 8) is steep. What happens in the natural clay layer after the construction is not known; but it may be assumed that what may be termed the "true compression line" is somewhere between the continuation of curves (2) and (7) in Fig. 8. Professor Rutledge shows it under the form of curve (4), Fig. 8, close to the laboratory compression curve. The writer disagrees with this visualization for the simple reason that, although the load increments are equal in the model and in the prototype, the rate of application is about fifty times slower in the latter case than in the former. In fact, the same final unit load is reached perhaps in one week in the laboratory and roughly in one year on the construction job. Besides, no one can be sure whether the mechanics of this breaking of bonds, if any, is the same in a sample ½ in. or 1 in. thick and in a clay layer, say 40 ft thick. Hence the writer believes that curve (4), Fig. 8, should be flatter.

Thus the settlement analysis using laboratory data apparently furnishes exaggerated values of settlement, the order of magnitude of this exaggeration being uncertain. Of course, the settlements thus computed are always on the safe side; but this safety is of such a nature as to permit an experienced engineer to believe, and with some reason, that a simple guess of the value of the expected settlement may be not less correct than the result obtained in most elaborate tests.

However, the writer is hopeful about the future of the consolidation test. Professor Terzaghi is to be commended highly for publishing the theory cited (10). The theory may prove incorrect, in which case everything will remain as it was before the publication of Professor Terzaghi's paper. If the theory is correct (and probably it is correct), steps should be taken to correlate the laboratory tests with that theory, and this undoubtedly will be done.

Shear Tests.—Professor Rutledge discusses the direct shear test, the triaxial test, and the unconfined compression test, and apparently prefers the latter.

This is indeed a promising simple and nonexpensive test performed on prismatic or cylindrical specimens cut out from large cubes taken by hand or from undisturbed samples extracted from certain depths using samplers. Any disturbance of the sample furnishes results on the safe side; but evaporation (drying out of the specimen during the test) unduly increases the shearing strength of the sample and should be avoided.

During the Annual Meeting of the Society in January, 1943, M. Juul Hvorslev, Assoc. M. Am. Soc. C. E., demonstrated his apparatus for making the unconfined test on tiny prisms or cylinders cut from undisturbed samples. It would be interesting to know Professor Rutledge's opinion of this method.

A worth-while addition to the paper by Professor Rutledge is a discussion by A. E. Cummings, M. Am. Soc. C. E. (33), in which the comparison between the unconfined compression test and the ring test by W. S. Housel, M. Am. Soc. C. E., is thoroughly discussed. The ring method itself (34) consists in pulling out a slice from a cylindrical undisturbed sample. In other words, this is double shear as in the case of a rivet which works in that manner.

Coulomb Formula.—This is another important soil mechanics item which, together with the consolidation test, passes now (1943) through a crisis. It is rightly stated by Professor Rutledge (35) that: "The results of shear tests must eventually be reduced to the Coulomb equation or a simple modification of it." The Coulomb formula states that the shearing resistance (shearing strength) of a soil, s, is the sum of its unit cohesion, c, visualized for a given soil as a constant, and the product of the normal pressure, σ, acting at the given point, by a certain coefficient depending on the properties of the given soil. This coefficient is visualized as a tangent of an angle ($\tan \phi$), the angle ϕ being termed "angle of internal friction," "effective angle of internal friction," or "angle of shearing resistance." It follows from the Coulomb formula that the shearing resistance should increase with the depth of the deposit, since the normal pressure, σ, depends on the weight of the overburden; but this is not always the case. Some engineers believe that the angle of internal friction for plastic clays, ϕ, is equal to zero, which means that the shearing strength is constant throughout a mass of plastic clay. Some others, including Professor Rutledge (see paragraph following Eq. 2), believe that "the increases in test strengths * * * which have been attributed to an angle of internal friction in undisturbed clay, may, in fact, be due entirely to decreases in void ratio." In other words it is believed that the smaller the volume of the voids, the larger the shearing strength of the clay will be.

The writer believes that the shearing strength of a clay mass may be practically constant throughout, due to the peculiar structure of some clays which prevents consolidation. Another possibility is the reinforcement of a clay deposit by calcium carbonate (or other chemical) due to the action of fluctuating ground water as in some places in Arizona. Furthermore, the writer wishes to warn against attributing the increase in shearing strength during consolidation solely to the decrease of the volume of voids. Possibly, the increase in shear strength in such cases is due mostly to the interaction of mutually approaching surfaces and hence may be influenced by adding chemicals which change the surface conditions. In this connection acquaintance with the work by Prof. H. F. Winterkorn, Assoc. M. Am. Soc. C. E., may be helpful (36).

Runways and Highways.—The paper by Professor Rutledge considers primarily the tests used in the study of foundations of heavy structures such as bridges and tall buildings. The field of tests which are necessary for runways and highways is excluded from consideration. It is true that one of the most widely used tests in that field—the so-called "California bearing ratio test" does not require undisturbed samples. In this test moistened soil material is consolidated in a mold and tested for penetration; but capillary tests and tests of permeability may be made both on disturbed and undisturbed samples, and comparison of both may be of importance. In this connection some acquaintance with the theory of "capillary potential" used by soil scientists may be of interest (37).

Terminology.—In the opinion of the writer the term "idealized" is very correctly used in this paper. An "idealized" material or object is assumed to possess properties or qualities which in reality it possesses only in part or to some extent; or, possibly, it lacks entirely. The virgin compression curve in Fig. 2 may or may not be a straight line (as is the case of some clays); but in this paper it is "idealized" and visualized in the form of a straight line. Eq. 1 obviously refers to the "idealized" virgin compression line and not to the actual curve. If an able draftsman happens to trace a straight line, as in Fig. 2 or elsewhere, in an irreproachable manner, it will be an "ideal" straight line.

D. M. BURMISTER,[10] ASSOC. M. AM. SOC. C. E.—The extent to which the strength properties of clay may be affected by disturbance during sampling is treated in this worth-while contribution to soil mechanics. The author has suggested fairly reliable methods for determining whether a sample may be considered relatively undisturbed. There are some points, in connection with the curves and data presented, on which the writer wishes to comment.

The consolidation curve CP1, for example, in Fig. 3 represents a relatively undisturbed sample, which possesses the greater part of its natural structure at the preconsolidation pressure of approximately 0.5 kg per sq cm. This natural structure, which is the source of the strength of the clay, may be that visualized by Professor Casagrande or that due to physicochemical processes, as believed by Professor Terzaghi. The maximum effect of disturbance, resulting from a complete remolding of the material at approximately constant moisture content, is shown by the vertical decrease in void ratio under constant pressure (0.5 kg per sq cm) to curve CP3. The vertical void-ratio intercept represents the change in void ratio (and hence settlement) required before equilibrium can be achieved under the same pressure, as a result of complete disturbance. The remolded material now possesses an entirely different type of structure, which involves a complete breakdown in the natural bonds between grains. The structure is characterized by a homogeneous, dispersed state of the "remolded structure." The void ratio at any given pressure, which is consistent with this structure at the equilibrium condition, is much smaller than for the undisturbed material. Therefore, having reached equilibrium under this pressure at a smaller void ratio, the material will compress less in the next load increment than does the undisturbed material. This means that the consolidation curves for the undisturbed and remolded clays must always intersect at some pressure (40 to 50 kg per sq cm in this case), as shown in the upper part of Fig. 4, where the curves for this material are reproduced. The magnitude of this pressure depends primarily on the mineralogical character of the clay.

---

[10] Asst. Prof., Civ. Eng., Columbia Univ., New York, N. Y.

The vertical intercept between consolidation curves for the undisturbed and remolded clay at the preconsolidation pressure is one important physical measure of the natural structure the clay possesses, and indicates the maximum effect of complete disturbance. It is to be noted that, at higher pressures, structure becomes less important and the effect of disturbance is less. This indicates that structure is more important for clays consolidated under relatively light loads, and that the effect of disturbance during sampling on the consolidation properties is likely to be greater than for clays consolidated under heavy loads.

It is believed that the consolidation curves intersect, not because the undisturbed clay becomes completely remolded by compression, as suggested by the author, but because a stage is reached at which a characteristic change in the compression phenomena occurs for the given clay (at least, laboratory consolidation phenomena). Curvature of the compression curve on a semilogarithmic plot, therefore, is not necessarily an indication of minimum disturbance of the clay. In the first stage of consolidation, the loose open structure and the chains of clay grains have been compressed in a vertical direction only, and possibly have been folded down upon each other, with some disturbance to the bonds, to form a structure under increasing pressure consistent with the void ratio, but still characteristic in form. No such complete remolding can possibly occur as a result of disturbance by compression which will cause the material to assume the dispersed remolded structure. During compression the remolded clay has also acquired structural bonds between grains (thixotropic effects). Beyond the intersection of the curves, the structure of the undisturbed and remolded clay has approximately identical effects upon compression, which takes place approximately along the flatter slope of the remolded consolidation curve, although the two structures are not identical in form.

This phenomenon is clearly evident in the case of the Mexico City clay in Figs. 5(*a*) and 5(*b*), where a break in the consolidation curve for the undisturbed clay occurs in the region of 5 kg per sq cm, and thereafter follows approximately along the curve of the remolded clay. The writer has observed such curvature in the consolidation curves of many different types of clays, the break occurring more frequently under rather low pressures for soft organic clays. This curvature or break in the slope of the compression curve of undisturbed clays is only one of several stages in the ultimate consolidation of soft clay deposits to shale. These stages are evident only on the semilogarithmic plot of void ratio against pressure.

Another point that should be mentioned is that disturbance to the natural structure tends to make the clay less permeable and hence also tends to make the coefficient of consolidation too small. The actual rate of settlement, therefore, will be more rapid than the estimates. The effect of disturbance cannot be detected in the form of the time-consolidation curves.

From the viewpoint of the application of the results of laboratory tests, the primary purpose of laboratory analyses is to furnish suitable representative averages for soil properties to be used in settlement and stability investigations. The writer has used a "Control Test Method" as an aid in selecting the least disturbed samples for test. Unconfined compression tests are made on all samples, as soon as received, to determine their quality, using prismatic specimens trimmed from the least disturbed central portion of the sample. It has been observed that the compressive strength of specimens, using specimens the full diameter of the sample (3-in. sampler or 2-in. seamless tubes), was 50% to 75% of the strength of small specimens obtained by trimming away the circumferential disturbed material. The ratio of the unconfined compressive strength, remolded to undisturbed, is used as a measure of the quality of the sample. This strength ratio should be less than some fraction, which is determined and revised as the testing progresses. For clays consolidated under light pressures, the ratio may be as low as $\frac{1}{5}$ to $\frac{1}{10}$, or less, depending on the character of the clay, but may be only $\frac{1}{2}$ to $\frac{1}{5}$ for clays consolidated under high pressures. However, this criterion alone is usually not sufficient, because its significance varies with the character of the clay. Frequently, the variations observed in the horizontal direction in the character of the clay of a given stratum are considerably less than those normally found in the vertical direction in this same stratum, due to changes in the geological and sedimentation conditions as the deposit was formed.

It has been observed frequently that the liquid limit, as a valuable measure of the character of the clay, increases consistently with depth, with a corresponding increase in the compression index in the consolidation test (a steeper compression curve denoting a clay that is more compressible) and with changes in the unconfined compressive strength and strength ratio, which may or may not be consistent. To provide a suitable and fairly reliable basis for judging the quality of the clays for the purpose of selecting test results and computing averages of properties from samples, which are judged to have suffered the least disturbance and to be most representative of subsurface conditions, the characteristics of the clay must be studied. Diagrams of soil properties are extremely useful for this purpose, and form a valuable part of any report of settlement or stability investigations. The diagrams should show the following:

(1) The variation with depth of the unconfined compressive strength, strength ratio (remolded to undisturbed), moisture content, liquid limit, and other test properties, if considered pertinent to the problem.

(2) The relationship between moisture content as a common argument and these same properties, in order to indicate the range of materials encountered and the characteristics of each type.

The writer believes that the triaxial compression test offers greater possibilities for the future than any other method of determining the shearing properties of soils. However, a direct application of test results cannot always be made, such as in the case of the unconfined compression test for determining the bearing capacity of clays, because of testing difficulties, but primarily because engineers do not know what the lateral pressures are in different types of deposits in nature and how they vary as the foundation loads are increased from zero to their ultimate value. In the unconfined compression test, unknown lateral restraints also exist, the magnitudes of which depend on the capillary pressure developed and the expansive properties of the clay at the preconsolidation pressure. These lateral forces probably are quite different from those existing in the deposit, being isotropic in character and also probably varying in magnitude as the vertical pressure is increased during the test. The issue has been merely side-stepped in this case. It is believed that curvature of the stress-strain curve in the first 20% of the unconfined compressive strength is not necessarily an indication of disturbance for clays consolidated under light loads and with compressive strength less than about 0.5 kg per sq cm, because of the variation in the magnitude of the lateral pressures that may be developed as loading progresses.

The fact that clays consolidate during triaxial compression tests should not be considered as a disadvantage of the test. This must be accepted as the normal phenomenon of clays, which are in a natural state of consolidation under their present overburden pressure. The primary problems are to reestablish the natural state of stress on the sample that existed in the deposit, and then to increase the stresses on the specimen in such a manner as to resemble those imposed on the actual material in place. Although the preconsolidation pressure determined by a consolidation test may fairly represent the natural vertical stress conditions, the lateral pressure may be of the order of 50% to 75% of this value, depending on the type of clay and the geological and load history of the deposit. It may be possible to obtain some approximate information on the natural pressure ratio—vertical to lateral—from careful measurements of the stresses set up in the consolidation ring after equilibrium has been reached under each pressure increment in the consolidation test.

The important question is: Are the final results the same and are they equally representative for the following test procedures?

(*a*) The clay specimen is preconsolidated by suitable increments under an all-around pressure, σ_3, equal to some fraction of the vertical preconsolidation pressure. The vertical stress is then increased until failure occurs.

(*b*) The clay specimen is preconsolidated by suitable increments, maintaining some constant stress ratio, σ_1/σ_3, until σ_1 becomes equal to the vertical preconsolidation pressure. Thereafter, the vertical stress is increased until failure occurs.

In either case, to simulate rapid failure conditions in a thick clay deposit, a slow triaxial compression test should be run as a closed system with measurement of pore water pressures as the vertical stress is increased to failure. If special care is taken in setting up the test and running it, and a balanced pressure system is used for measuring pore water pressures at the top and bottom of the specimen, fairly reliable information may be obtained on the effective stresses acting during the test and at failure. Tests run at pressures somewhat below and above the vertical preconsolidation pressure would provide a relation between the strength properties and void-ratio change to be used for estimating the natural strength properties. It is obvious that the triaxial compression test can never be reduced to the simple testing procedure and method of interpretation used in the unconfined compression test, and in this respect the unconfined compression test has a great advantage of simplicity. In the final analysis, it is the correlation with the actual behavior of full-scale structures that should determine the relative reliability of any test method.

Professor Rutledge has presented a very timely paper on this subject and has opened up a valuable field for further research.

P. C. Rutledge,[11] Assoc. M. Am. Soc. C. E.—The several discussers of this paper have contributed significantly to an understanding of the effects of sample disturbance on the results of soil tests. The discussions constitute ample evidence to support the underlying premise of the paper—namely, that the results of soil tests cannot be used directly to determine the behavior of soil in nature. In most applications, unmodified test results lead to solutions that have little meaning in terms of the true behavior of the soil and may result in unsafe conclusions. This is a significant factor in the application of soil mechanics to practical problems. It is an important reason why such applications cannot be reduced to simple terms and formulas, and is a serious obstacle to understanding by the average engineer working with structural materials. The errors introduced by differences in behavior between tests on structural materials and the finished product are usually small compared with the commonly used factors of safety; and, therefore, engineers have come to accept unquestioningly the direct use of the results of simple tests in machine and structural design. This fortunate situation does not exist for soils because neither the condition of the test specimen nor the stress conditions within the specimen are like those in nature.

Sample Disturbance and Consolidation Tests.—Three effects of sample disturbance on the results of consolidation tests have been emphasized by the discussers: (*a*) The significance of concave virgin compression curves; (*b*) the determination and significance of the preconsolidation load; and (*c*) the location of the most probable natural compression curve. These will be considered in order.

Concave Virgin Compression Curves.—Major Hough cites consolidation test results for St. Lawrence River clays with an initial void ratio of 1.6 in which the semilogarithmic virgin compression curves were concave upward. The writer has observed the same type of curves for many soils with initial void ratios larger than 1.5 but only when the test specimens had undergone a minimum of disturbance. For good samples with large initial void ratios, such curves are probably the rule rather than the exception. Major Hough also questions the undisturbed condition of the Mexico City clay which was used by the writer as an example. The samples were taken under the supervision of A. E. Cummings, M. Am. Soc. C. E., and J. A. Cuevas. Mr. Cummings arranged the transportation of the samples to the laboratory at Harvard University, Cambridge, Mass. Every precaution was observed to protect the samples and, as received in the laboratory, this clay had a rubbery consistency similar to artgum. It was not sensitive to shock or vibrations and was difficult to remold. The character of the clay, the fact that the laboratory preconsolidation load is within 3% of the existing pressure on the clay, and the sharp curvature of the compression diagram at the preconsolidation load—all indicate that this clay had suffered a minimum of disturbance, in spite of its extreme natural void ratio of 14.0.

---

[11] Prof., Civ. Eng., Technological Inst., Northwestern Univ., Evanston, Ill.

Professor Gray has presented a challenging hypothesis for the compression of a "composite" specimen consisting of an undisturbed core surrounded by a disturbed or remolded annulus. The compression curve for such a specimen could well be slightly concave upward in the semilogarithmic diagram. The writer has never observed curves of this type for specimens known to be partly disturbed, possibly because the annulus of extreme sample disturbance was always trimmed from the test specimens. Professor Gray's example emphasizes: (1) The necessity for trimming off the outer annulus of bore-hole samples; and (2) the dangers of concluding that concave virgin compression curves represent minimum sample disturbance when there is a change in the techniques of sampling and sample preparation.

Professor Burmister's hypothesis for successive stages of compression of undisturbed clay and for the differences between the compression of undisturbed and remolded clays is based on a visualization of a chain-like structure of clay grains in undisturbed soil. He assumes that this structure is modified but not destroyed by compression whereas remolding causes a homogeneous dispersed state of the soil grains. These assumptions lead to an explanation for concave virgin compression curves and to the conception that the compression curve for remolded clay at large loads may intersect and lie above that for the same soil undisturbed. There is justification for the conception of successive stages of compression. At very high loads as the void ratio approaches zero, there must be a change in phenomena because compression can no longer be accomplished by reduction in void space. The slope of the curve should finally become the bulk modulus of the mineral making up the clay grains. What actually happens to compression curves at pressures greater than 25 kg per sq cm and to their relation to the curves for remolded specimens is speculative. The writer is not familiar with any tests that have resulted in either the joining or the intersection of the compression curves for undisturbed and remolded specimens.

The Preconsolidation Load.—Mr. Van Auken and Professor Dawson have shown the difficulties in determining the preconsolidation load from laboratory tests on clays that have been subjected to a complex geological history and on those that have been subjected to alternate shrinkage and swelling due to surface drying conditions. Mr. Van Auken recommends careful study of all geologic evidence. The value of study of all such information is unquestioned but Professor Terzaghi (31*a*) makes the restrained but pertinent statement: "* * * as a rule, geological evidence regarding the thickness of vanished strata leaves a wide margin for interpretation."

For "normally" consolidated clays, Professor Terzaghi recommends the use of the existing overburden pressure in place of the preconsolidation load determined from laboratory tests. It remains, of course, to determine whether or not any particular clay specimen is "normally" consolidated. Certainly expansive clays that have been subjected to forces of surface drying, for which Professor Dawson has drawn curves, are not normally consolidated even though they have never been subjected to an overburden greater than that existing at the time of sampling.

The writer is indebted to Professor Terzaghi for clarifying the historical background of knowledge of the effects of disturbance due to sampling on the test behavior of clays. Professor Terzaghi has also succinctly differentiated between those parts of the writer's compression diagrams that are based on experimental evidence and those parts that consist of extrapolations based on assumptions which have not been proved. The distinction should have been stated more clearly in the paper.

Professor Terzaghi states that the actual condition of most clays during sampling and preparation for testing is one of practically constant void ratio while the externally applied pressure is reduced to zero by taking the sample out of the ground. Hence, the horizontal line is derived from the natural void ratio at the preconsolidation load to zero pressure in Figs. 8 and 14. The writer cannot agree, however, that this simplified picture, which does represent what actually happens, renders meaningless points A and B in Figs. 6 and 7 or the constructions whereby they were obtained. Most consolidation tests result in curves of the type of the heavy solid line curves CB'E in Figs. 6 and 7. Point B is located by comparing the shape of the initial part of the test curve with laboratory recompression curves that follow rebounds from known laboratory preconsolidation loads. Hence, the significance of point B can be stated briefly as follows: Had the clay been preconsolidated under conditions identical to those of the laboratory test, point B represents approximately the pressure and void ratio that the clay would have attained during its preconsolidation. Therefore, the pressure at point B should be called the "laboratory preconsolidation load" because it is dependent on laboratory conditions of compression.

The meaning of the void ratio at point B is less directly apparent. Sampling operations weaken the soil structure simultaneously with the removal of natural external pressure. The void ratio at point B is the laboratory equilibrium point that would have been obtained had the soil structure been weakened without removal of the external pressure. As the writer stated in reference to Fig. 7, an imagined rebound from the fictitious void ratio at point B gives a direct measure of capillary pressure in soil test specimens. The hypothesis has been advanced that capillary pressure replaces in full the natural external pressure when a soil sample is removed from the ground. Analyses based on the void ratio at point B indicate strongly that any such capillary pressure is always less than the external pressure and is usually small if not zero.

The laboratory preconsolidation load is derived exclusively from similarity to laboratory precompression and recompression. Any relation between it and the maximum load to which a clay was subjected in nature requires the assumption that natural compression is similar in character or effect to laboratory compression. This assumption is not entirely without empirical justification. An example is the Mexico City clay for which the test results, shown in Fig. 5, yield a laboratory preconsolidation load almost exactly equal to the known pressure acting on the clay. A second example is a Chicago clay sample, for which consolidation and triaxial compression test results are shown subsequently in Fig. 15. Comparisons of approximate overburden pressures and laboratory preconsolidation loads for these soils and other soft saturated clays which contained no visible evidences of drying are shown in Table 3.

[a] Percentage of dry weight. [b] Approximate pressure. [c] Natural void ratio, 14.0. [d] One foot below stiff yellow clay. [e] Two consolidation tests.

Unfortunately the data referred to in the preceding paragraph are for samples at single depths in the upper parts of different deep beds of clay. The data from tests on bore-hole samples taken throughout the full depth of thick clay strata are not conclusive for the following reasons: (*a*) The soil pressure changes and mechanical sampling operations causing sample disturbance increase with the depth of sampling; and (*b*) increasing sample disturbance has a tendency to decrease the indicated laboratory preconsolidation load.

As a result of the several preceding considerations in regard to the laboratory preconsolidation load, this value, determined by extrapolation from the results of consolidation tests, should have definite physical meaning, and studies to ascertain correctly its relation to overburden pressure under varying conditions should be continued. For such research the best possible undisturbed samples are required.

Location of the Natural Compression Curve.—Much of the discussion regarding the most probable location of the natural compression curve for clays refers to the flat curve in Fig. 8 and also to curve ab in Fig. 14. This type of natural compression curve was proposed by Professor Terzaghi (10), who has presented strong arguments in its favor. The writer has not been entirely convinced, however, that water content and overburden pressure data are sufficient to establish the curve as empirical (as Professor Terzaghi states) rather than hypothetical. The effects of changes in either plasticity or natural water content or both on the laboratory compression characteristics of clays have not been sufficiently explored to constitute conclusive evidence in either direction.

Professor Krynine has argued in favor of the flat type of natural compression curve as opposed to curve (4) in Fig. 8. In the case of soft clay subjected to loads at least as great as those of a medium sized building, these arguments have been answered by Professor Terzaghi's discussion, in which observed agreements are cited between settlements and predictions based on curves similar to curve (4), Fig. 8.

An important utilization of simplified soil sampling and testing operations is the approximate method, described by Professor Terzaghi, for determining the natural compression of clay from the results of tests on remolded specimens. This method, published in 1929 (29), has not been widely known or used. It is an example of the "flashes of engineering intuition" to which Professor Terzaghi refers (31). The writer has applied the method to the results of tests on remolded specimens of soils for which test results for undisturbed specimens were also available. Except in the case of highly compressible volcanic and organic clays, the results were practically identical with the best estimates resulting from tests on undisturbed specimens. The writer agrees with Professor Terzaghi's evaluation of uses of this method. In particular, it is less expensive and no less reliable than results obtained from tests on inferior "undisturbed" samples. When the size of a job justifies the expense, the additional information obtained from the best possible undisturbed samples is a sound investment both for obtaining practical results and for increasing existing knowledge about the behavior of clays.

Sample Disturbance and Strength Tests.—Professor Burmister advocates triaxial compression tests in preference to unconfined tests on the basis of an unknown capillary pressure acting on the clay in the latter. The writer cannot agree with the arguments presented for the following reasons:

1. The application of lateral pressure through a rubber membrane does not eliminate or make known the stresses in the soil pore water.
2. Analyses of consolidation test results, previously described, indicate that initial capillary pressures in soil samples are small. Before testing they will be increased only by drying or by expansive tendencies caused by evolution of gas.
3. During the test, changes in capillary pore-water pressure can be caused only by volume changes in the specimen. No conclusive evidence is available, but existing data indicate very little tendency toward volume change of saturated clay tested in unconfined compression.
4. The unconfined compression test necessarily measures the applied vertical stress. This stress, when an unknown hydrostatic pore-water stress is considered, becomes the difference between major and minor principal stresses.
5. For a saturated plastic clay which does not change volume, the difference between principal stresses is substantially independent of small changes in the minor principal stress.

Mr. Van Auken and Professor Burmister both take exception to the writer's statements regarding the effects of volume change on triaxial compression tests of undisturbed natural clays. Both of them recommend preloading of triaxial compression test specimens by maintaining a constant ratio between major and minor principal stresses until the major principal stress reaches some desired overburden pressure. The writer does not question the fact that clays consolidate both during triaxial compression tests and in nature but wishes to emphasize that, because of sample disturbance, the consolidation, the void ratios at which the clay is tested, and the pore-water pressures are completely different from those which will result in nature. The effects of sample disturbance on consolidation occur whether or not the test pressure conditions are like those in nature.

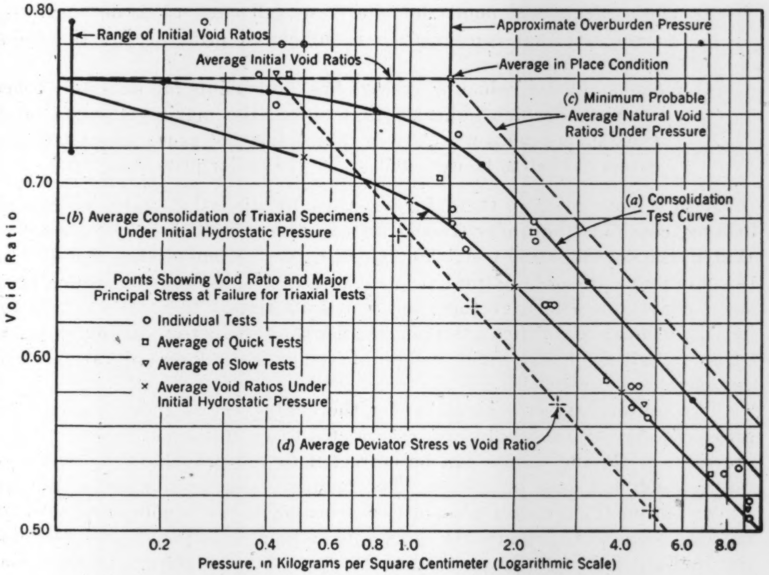

FIG. 15.—VOID RATIOS VERSUS MAJOR PRINCIPAL STRESSES

An example of the void-ratio changes during consolidated triaxial tests on soft clay is found in Table 2. The complete series of tests from which these data were abstracted was performed by H. H. Ku, Jun. Am. Soc. C. E. (38). In Fig. 15 the data are plotted in terms of void ratio. Curve (a) is the result of a consolidation test on one specimen from the cubic foot, hand-cut sample. The initial void ratio of the consolidation specimen is almost exactly the average of initial void ratios of all test specimens from this sample. Curve (b) is the average result of initial consolidation under hydrostatic pressure of all triaxial specimens. The maximum major principal stresses and the corresponding void ratios for individual tests and for averages of quick and slow tests are plotted as individual points. The consolidation time allowed in both the consolidation test and the preliminary consolidation of triaxial specimens was twenty-four hours, which was well beyond the theoretical 100% consolidation point for both. The maximum duration of the slow tests was also twenty-four hours.

Several facts should be noted in connection with Fig. 15:

(1) Curve (b) for consolidation under hydrostatic pressure falls below curve (a) for the consolidation test, indicating either that the preparation of triaxial specimens caused greater sample disturbance or that hydrostatic loading caused greater compression than consolidation test loading;
(2) The breaks in the compression curves (a) and (b) occur at almost the same stress and indicate the same laboratory preconsolidation load;
(3) The average final points for slow tests fall close to or on curve (b), signifying that consolidation is influenced primarily by the major principal stress; and
(4) None of the individual or average final test points fall definitely below curve (b), which indicates that shear (the maximum strain in all triaxial specimens was 20% or more) does not cause consolidation in excess of that to be expected under the major principal stress.

With the exception of the unknown cause for deviation under hydrostatic loading, consolidation under triaxial test conditions is found to be parallel to that in the consolidation test. Therefore, curve (c) was plotted representing the minimum probable natural void ratios that would occur in nature under stress conditions similar to those in the triaxial tests. In the tests, both the initial and final void ratios are much smaller than the corresponding values on curve (c) although the final values of the quick (20-min duration) tests approach curve (c).

Two options are now available for the evaluation of these triaxial compression tests: (*a*) The results can be corrected to a condition of zero pore-water pressure; or (*b*) the results can be corrected to the probable minimum void ratios which will exist in nature. The methods of correction are as follows: Under option (*a*) the maximum major principal stress is compared with the pressure required to produce the same void ratio in a comparable consolidation test and the difference is assumed to be pore-water pressure. Under option (*b*) the void ratio for any chosen minor principal stress is determined from curve (c), Fig. 15, and the difference between major and minor principal stresses corresponding to this void ratio is determined from the curve of deviator stress versus void ratio that is also plotted in Fig. 15. Both methods require radical assumptions. The first method assumes that consolidation under triaxial compression is exactly similar to that in consolidation tests. The data in support of this assumption have previously been presented. The second method assumes that all increase in strength is caused by decrease in void ratio.

The results of these two types of corrections are shown in Fig. 16. Corrections of the first type were made for each of the five series of individual tests. The total average correction line is also plotted for each of the five series. The close agreement supports this method for correcting for pore-water pressure. Corrections of the second type were made only for the average test results. There is a wide difference between the results of the two methods of correction. The evidence available (for example, the data cited by Major Hough) seems in favor of corrections by the second method although it is far from complete and

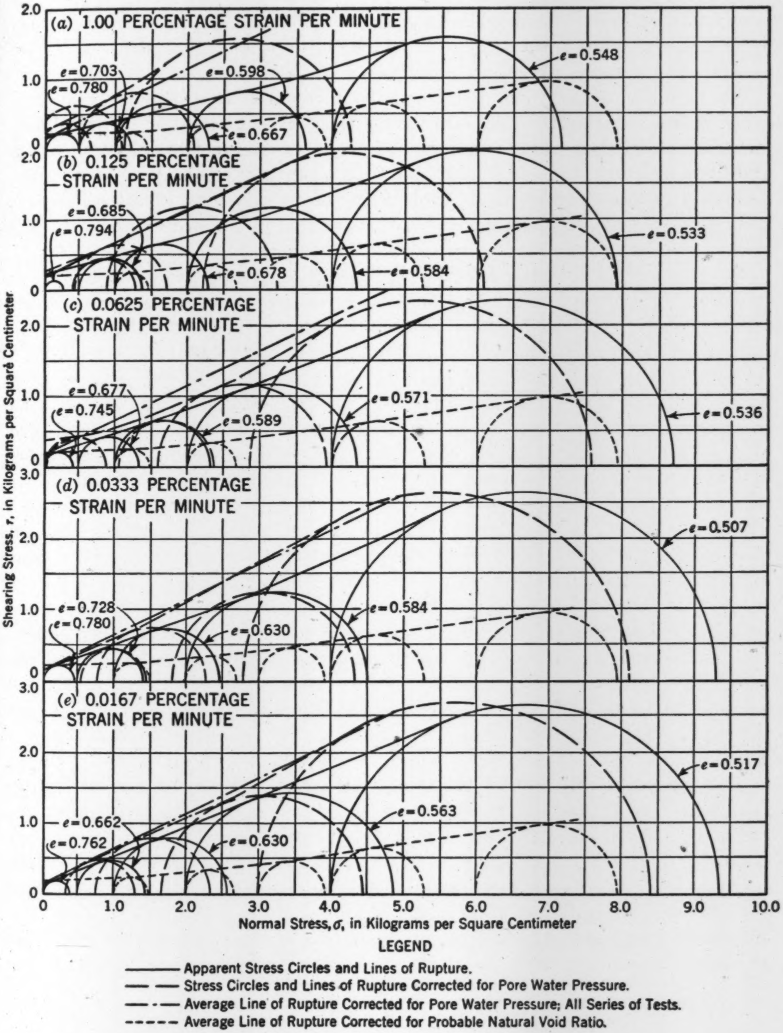

FIG. 16.—FAILURE DIAGRAMS—TESTS ON UNDISTURBED CHICAGO SOFT CLAY

(All Tests on Specimens Cut from 12-In. Cubical Sample with Average Initial Void Ratio = 0.759. Void Ratios Shown Are for Maximum Stress) correct. Therefore, the writer concludes that neither the strengths nor the pore-water pressures obtained from consolidated triaxial tests on undisturbed natural clays are representative of field conditions and that the results are unsafe when considering actual conditions.

It should not be concluded from these remarks that the triaxial compression test is without value. On the contrary, it is a tool of great usefulness. Even for plastic, saturated, undisturbed clays, testing in triaxial compression under small lateral pressures may be advisable for convenience in making the necessary test measurements. Another factor (which most of the discussers have agreed is important) that was not considered in the preceding analysis is the direct effect of sample disturbance on soil strength.

In connection with the effects of void-ratio changes, Professor Krynine's discussion of applications to the Coulomb formula conveys the impression that assumption (1) of a zero angle of internal friction for plastic clays and assumption (2) of void-ratio changes as a primary factor in observed strengths in triaxial tests are unrelated and have opposing results. This is not the case. Assumption (2) simply presents a means of explaining the results of triaxial compression tests in terms of assumption (1). Assumption (1) is based primarily on the results of field observations. As Major Hough has stated and the preceding analyses indicate, assumption (1) is difficult to substantiate by means of laboratory tests.

Summary.—Professor Gray's extension of the "chain" analogy to the solution of foundation problems appeals particularly to the writer. The clear statements of the limitations in present knowledge, contained in his first four paragraphs, cannot be improved. The writer wishes to re-emphasize the one statement that individual cases of numerical agreement between predictions and field observations do not constitute proof that the methods used are generally applicable. The validity of the several links of the chain (that is, sampling, testing, analysis of stresses, and prediction) can be established only through (*a*) the accumulation of large numbers of complete field and laboratory observations; and (*b*) analysis of all observations by coordinating agencies. Such a program will require the concerted effort of every one interested in foundation problems. In this connection Mr. Feld has suggested that the methods of extrapolation described by the writer may be used to establish similarity between soils of known and unknown behavior. The suggestion has merit but is perhaps too optimistic an adoption of the methods, considering their present limitations. The writer thanks the discussers of this paper for their contributions to the subject of the effects of sample disturbance and for the stimulus of their ideas.

Paper No. 2230

A METHOD OF COMPUTING URBAN RUNOFF

By W. I. Hicks,[1] Esq.

With Discussion by Messrs. C. S. Jarvis, S. W. Jens, W. W. Horner, and W. I. Hicks.

Synopsis

The purpose of this paper is to present the results of certain hydraulic investigations and rainfall-runoff gagings for improved urban drainage areas of different sizes and types of development, to analyze data from these results, to develop hydrographs of runoff for areas of various sizes, development, and times of concentration, to present methods of computing runoff for use in design offices, and to compare actual values of runoff with those computed by these methods. Much of the complete research, upon which this paper is based, has been placed on file for reference in Engineering Societies Library.

Basis of Runoff Computations

Rainfall-runoff relations in Los Angeles, Calif., are characterized by (*a*) a winter rainy season with consequent low evaporation and soil losses; and (*b*) wide variation in rainfall intensities on account of the mixed mountain, valley, and coastal plain terrain.

For urban areas, runoff is almost wholly that part of the rainfall which is not lost by infiltration into the soil or left in surface depressions and on vegetation surfaces to evaporate or sink into the ground.

The hydrograph of the net rainfall before it runs off the lot has the pattern of the rainfall intensities modified by the losses. Between this point and the point of concentration in the drain, the pattern is altered further by detention, which is the varying volume of water that must be built up to induce flow at the varying intensities of runoff. The general classification of detention is overland, gutter, and conduit.

This theory of runoff has been advanced by a number of engineers: The late C. E. Grunsky,[2] Past-President, Am. Soc. C. E., advocated the modifica-

tion of net rainfall by storage; Robert E. Horton,[3] M. Am. Soc. C. E., made a complete analysis of the theory; W. W. Horner, M. Am. Soc. C. E., and S. W. Jens, Assoc. M. Am. Soc. C. E., applied the theory[4] to the runoff from a city residential block and suggested its projection into the drainage network.

I. Analysis of Rainfall Records

Intensity, Frequency, and Variation with Locality.—The Los Angeles County Flood Control District, H. E. Hedger, M. Am. Soc. C. E., chief engineer, has analyzed rainfall records operated by the District and other agencies to derive intensity-duration curves (Fig. 1) and an isohyetal map of the county showing the variation in the intensity of the 50-yr 1-hr duration over the mixed mountain and valley terrain. The map in Fig. 2 is based on studies of the Flood Control District, the U. S. District Engineer, and the writer (for the coastal region).

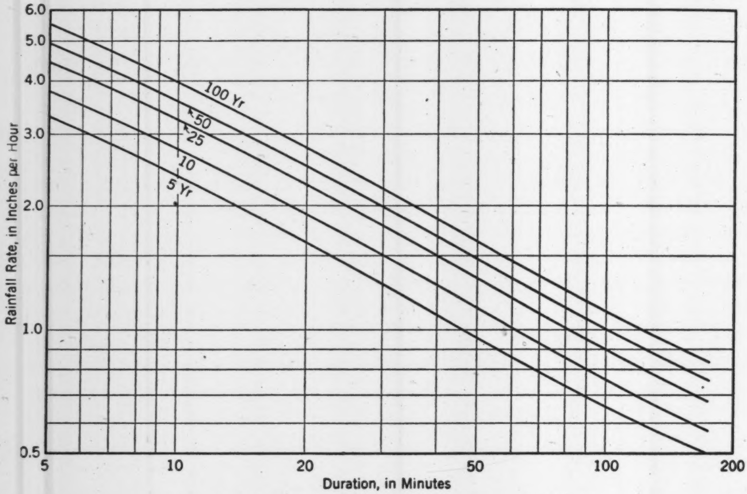

FIG. 1.—LOS ANGELES COUNTY FLOOD CONTROL RAINFALL

Storm Pattern.—The storm pattern was derived by plotting the major storms of the Los Angeles Station of the U. S. Weather Bureau as mass curves with the center of the most intense 5-min duration at a common point (90-min elapsed time for design purposes). The result was a pattern storm between "medium" and "delayed" and is illustrated in Fig. 3.

The rainfall intensity-duration curve (Fig. 1) is based on the analysis of a great number of individual storms; there is nothing in the construction of the curves which implies that a storm having a 10-yr frequency for any stated

time duration will have the same frequency for any other time duration. A statistical study of the more intense of the storms shows that the intensities for the shorter durations are lower than would be indicated by the storm's frequency rating corresponding to the intensity for a longer duration; and that the greater the longer duration defining the frequency, the lower (relatively) will be the intensity corresponding to the stated shorter duration. This variation finds application in computing runoff hydrographs for various times of concentration.

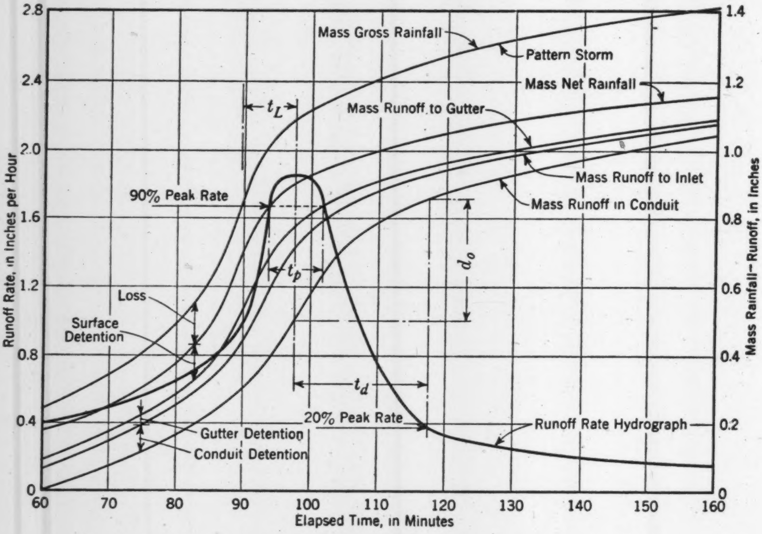

FIG. 3.—ELEMENTS OF THE HYDROGRAPH

Antecedent Precipitation.—For determining the values of antecedent precipitation, probability studies were made (using the method of H. Alden Foster,[5] M. Am. Soc. C. E.) of two composite factors of the rainfall records of the Weather Bureau, $I \times F$ and $I \times F \times M$. The composite factor M is defined by

$$M = \frac{E\,(d_{60} + 1)}{10} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

and I = intensity of rainfall, in inches per hour (for a specific time duration). The rainstorm shape factor F is obtained by summing the values of the maximum 5, 10, 15, 20, 30, 45, and 60-min rainfall (d') in inches, in the order named and dividing by a corresponding summation of d''-values from the standard design rainfall curve (10-yr B curve, Fig. 1); or, $F_{15} = \frac{(d')_5 + (d')_{10} + (d')_{15}}{(d'')_5 + (d'')_{10} + (d'')_{15}}$

---

[5] "Theoretical Frequency-Curves and Their Application to Engineering Problems," by H. Alden Foster, *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 142.

for $t_c = 15$, etc. The evaporation factor E is an arbitrary value based on the average evaporation for the 60-day period preceding the storm, derived from seasonal variation of evaporation. Antecedent precipitation, in inches, is expressed as $d_{60} + 1$, in inches. This is equivalent to the summation of 100% of the rainfall for 0 to 4 days antecedent, 50% of that for 5 to 9 days, 25% of that for 10 to 14 days, 15% of that for 15 to 30 days, and 10% of that for 31 to 60 days, antecedent. The residual soil moisture is allowed for by "+ 1" in.

The application of the divisor 10 to the term, $E\ (d_{60} + 1)$ to derive M, a moisture factor, is made in order to correlate M to Fig. 4,[6] rainfall-rate loss-rate curves, in which the values of soil-loss rate were based on the local storm of March 2, 1938, when the value of $E\ (d_{60} + 1)$ was approximately 10 for the drainage areas subject to analysis.

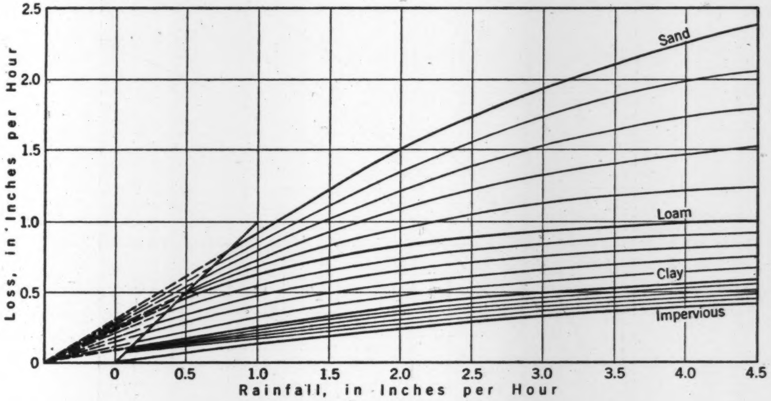

FIG. 4.—RAINFALL-RATE, LOSS-RATE CURVES

When $I\ F\ M$ for a given duration and frequency is divided by the corresponding product $I\ F$, the result is the value of the weighted moisture factor, M, equal to 0.39 on the isohyetal of 1.33 at the Weather Bureau station.

Because lawns and parks are irrigated between storms during the rainy season, an estimated 0.11 is added to the original value of M, making a total of 0.50 for isohyetal 1.33. The analyses show that this value applies to all frequencies of rainfall.

Rainfall Distribution.—The method of Frank A. Marston,[7] M. Am. Soc. C. E., for distributing rainfall intensities was applied to a large area centering in Pasadena, Calif., where records are available from a large number of automatic rain gages. These gages are located on isohyetals of varying intensity (see Fig. 2), and the records were corrected by the ratio of the value of the

50-yr isohyetal on which the selected central gage was located to the value of the 50-yr isohyetal on which each individual gage was located. The results of the study are shown in Fig. 5.

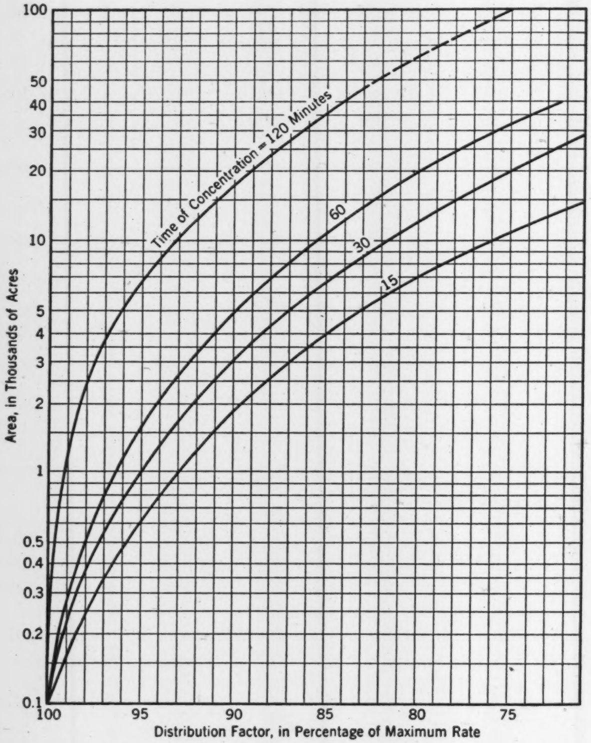

Fig. 5.—Rainfall Distribution Chart

II. Soil Infiltration Tests

A detailed report of soil infiltration tests on small soil plots with artificial precipitation was made in 1935 by L. W. Armstrong,[8] M. Am. Soc. C. E. Another method was the analysis of rainfall-runoff records for losses from large partly pervious drainage areas. From these sources, the rainfall-rate loss-rate curves for a moisture factor, *M*, of 1 were derived for use in preparation of design data (see Fig. 4).[6] A value of 1 for *M* denotes that the soil is well saturated and that the lower and more stable values of infiltration capacity prevail.

---

[8] Progress Report, Conference on Water Conservation, Los Angeles, California, by Committee on Conservation of Water, Irrig. Div., Am. Soc. C. E., December, 1935, p. 50.

In the paper by Messrs. Horner and Jens[4] and the discussion by the writer,[6] the question of variation of infiltration capacity with rainfall intensity was raised. Local experimentation shows predominant variation for bare soil as noted by the authors and a lesser amount of variation for sodded areas. The curves in Fig. 4,[6] used for design data, reflect the presence in urban areas of imperfectly graded lawns, bare soil, garden plots, and other departures from the plane surface on which any depth of detention spreads uniformly and utilizes the full infiltration capacity of the soil.

III. Experimental Analysis of Overland Flow and Gutter Flow

For a thorough treatment of this subject the reader is referred to the aforementioned paper by Messrs. Horner and Jens, on the development of the runoff hydrograph for a city block, and to the discussion by the writer introducing details of experimentation made in Los Angeles on overland flow on turf and various types of paving surface.

IV. Analysis of Rainfall-Runoff Records from Local Urban Areas

In attempting to solve analytically a problem with as many variables as runoff, the possibility of piling up accumulated errors through comparatively small errors in assigning values to these variables may be checked and minimized by collecting and analyzing rainfall-runoff records from drainage areas of various types and sizes. Further uses for rainfall-runoff records are the derivation of time and volume relations of the rainfall and the runoff, and the analyses of the shape and time elements of the runoff hydrograph.

Drainage Area Survey.—Drainage maps, improvement plans, and soil survey maps of the U. S. Department of Agriculture formed the basis of the survey. The drainage ridge was located by field surveys, and determinations were made of the percentages of pervious area A_p, impervious area A_i, and that portion of the impervious area directly tributary to the drain or gutter without flow over open soil A_d. Pertinent information is listed in Table 1. Runoff for Stations 10 and 11 was recorded with gutters calibrated from fire hydrant flow measured with a rated meter. All other runoff and rainfall were measured with automatic recorders using large scale charts.

TABLE 1.—Characteristics of Local Drainage Areas

Station	Location of runoff station[a]	Area (acres)	Soil type	Improvement (%)			Channel type
				A_i	A_d	A_p

4	Broadway Channel[a]	1,549.0	Heavy loam	52.2	36.3[b]	47.8	Gutter, pipe, arch, lined channel
10	Spring St. at 5th St.	0.80	....	100	100	....	Gutter
11	5th St. at Spring St.	2.17	....	100	100	....	Gutter

[a] In Los Angeles, Calif., except Station 4 which is in Pasadena, Calif. [b] Estimated.

Time of Concentration.—This has been defined as the time for the storm water to flow from the ridge to the point of gaging, excluding finger-like pro-

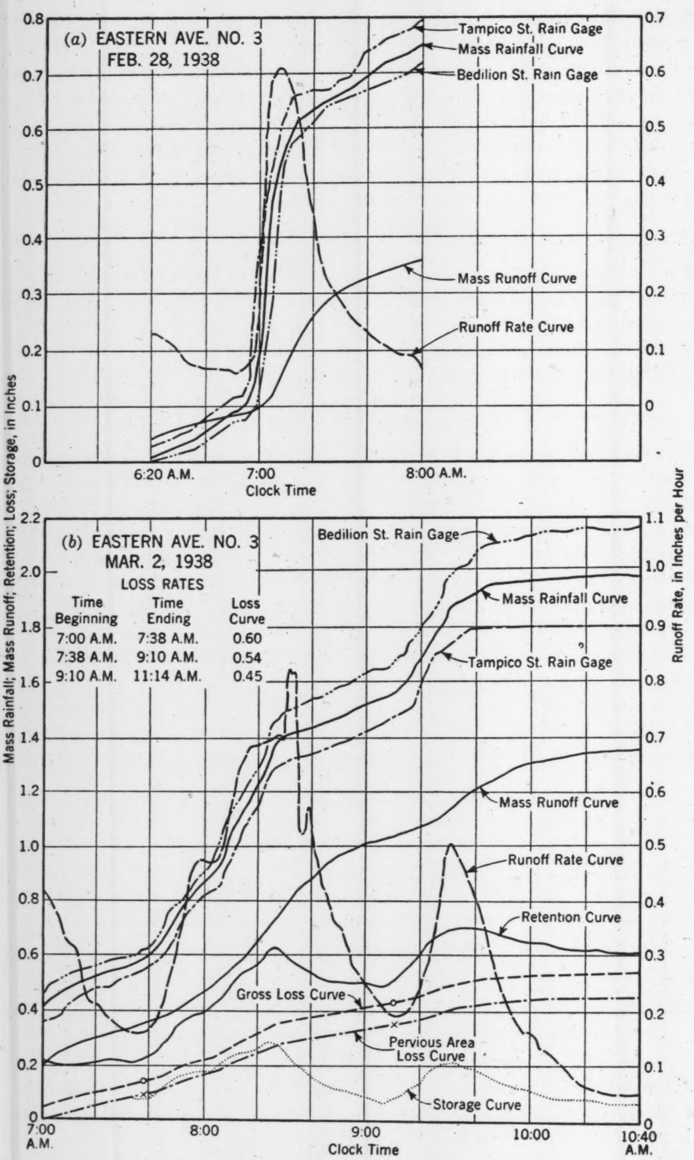

Fig. 6.—Analysis of Storms Recorded at Eastern Avenue, Station 3

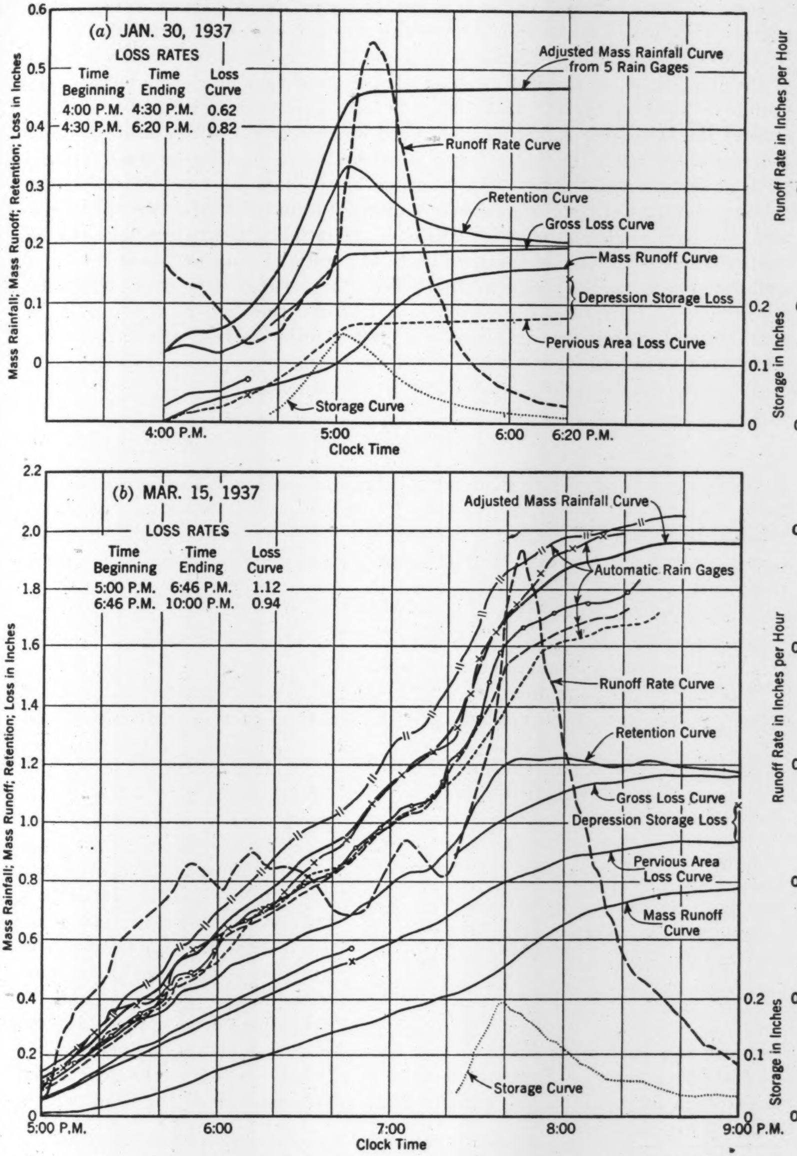

FIG. 7.—ANALYSIS OF STORMS RECORDED AT BROADWAY, STATION 4

jections of area. It is also the measure of an intercept on the mass rainfall curve which, with base flow, is effective in producing a peak of runoff.

In design work (for assumed conditions) the time of concentration consists of the inlet time for the initial block plus time of flow down the conduit (in minutes). For analysis of runoff records from partly pervious areas, the inlet time of the initial block is affected by the weights of the volumes of overland flow delivered from the lawns (slow flow) and from the impervious surfaces (fast flow). Account must be taken also of the fact that in normal design tabling, the time of flow in a closed conduit is computed for full-wetted perimeter (velocity = 86% of that for free flow); that the ultimate drainage system contemplates extension of the conduit to the initial block; and that flow in a well-designed drain is at efficient depth (free flow) except at points of hydraulic disturbance. Therefore, for analysis of records, the free flow velocities in conduits and gutters are multiplied by 0.86 in order to keep the data on the same basis as in design.

Time for overland flow is computed by the equation

$$t_c = \frac{60\ \delta_a}{\sigma} \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which δ_a (average depth of flow) is computed for the various types of surfaces by formulas presented elsewhere;[9] and σ = rate of supply of excess rainfall, in inches per hour. Eq. 2 represents the horizontal (time) distance between the mass curves of rainfall supply and runoff. Gutter flow time is computed by[10]

$$t = \frac{0.0443\ l^{0.732}}{(S_o)^{0.39}\ \sigma^{0.252}} \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which l = length of overland flow, in feet.

For partly pervious areas, such as Station 3 (Table 1), a series of time of concentration curves is needed, varying from a dry soil condition (about 18% runoff) to a saturated condition (about 76% runoff). Data for plotting these curves are presented in Table 2.

TABLE 2.—DATA FOR PLOTTING TIME-OF-CONCENTRATION CURVES

q_1	TIME, t_c, PERCENTAGE OF RUNOFF	
	76%	18%
0.15	59.7	32.3
0.20	54.8	30.9
0.40	43.2	27.0
0.60	36.5	24.3
0.80	32.3	22.7
1.00	28.7	21.7

Plotting.—Using a part of the storm of March 2, 1938, on gaging Station 3 (Fig. 6(*b*)) as an illustration, the mass rainfall curve (in inches), the runoff rate curve (in inches per hour), the mass runoff curve (in inches), and the retention curve or the difference between the mass rainfall curve and the mass runoff curve (in inches) need no further explanation for their method of plotting. The gross loss curve and the storage curve, both expressed in inches, are more involved and require more detailed explanation.

[9] *Transactions*, Am. Soc. C. E., Vol. 107 (1942), p. 1100, Eqs. 17, 18, and 19.

[10] *Ibid.*, p. 1102, Eq. 20*b*.

First, select clock-time points on the record where the runoff rate is low and the rainfall rate has been low and fairly uniform for the preceding 20 min. With curves for the drainage area of depths of surface detention for low rates of rainfall and of depths of gutter and conduit storage for low rates of runoff, values of composite storage were plotted down from the retention curve; these points lie on the gross loss line and are control points.

Second, the value of impervious surface loss (experimentally determined as approximately 10% of the rain falling on the impervious surface) is computed for the reach between control points ($0.10\ A_i\ d_f = 0.0237\ d_f$ for Station 3, d_f being the volume of rainfall, in inches) and is plotted down from the control point at the right of the reach.

Third, the pervious surface loss is a function of the rain falling directly on the pervious surface plus the rain falling on the portion of the impervious surface discharging runoff on to the pervious surface; 10% of this latter rainfall is already lost on the impervious surface, leaving 90%, which will be subject to further loss on the pervious surface on to which it flows. The rainfall rate is adjusted therefore in the ratio: $\frac{A_p + 0.9\ (A_i - A_d)}{A_p}$, or 1.09, for Station 3.

Fourth, the reaches between control points are analyzed by the following check list:

(*a*) Time to time (for an intercept on the mass rainfall curve having an approximately uniform rate);
(*b*) Rainfall rate;
(*c*) Amended rainfall rate ($1.09\ I$);
(*d*) Infiltration rate (from Fig. 4[6]), for $1.09\ I$;
(*e*) Infiltration rate $\times\ A_p$ (76.3%);
(*f*) Impervious loss rate ($0.10\ A_i\ I$ or $0.0237\ I$); and
(*g*) Summation of items (*e*) and (*f*) (gross loss rates).

If the sum of the products of the rates in item (*g*) and the time intercepts in item (*a*) (in hours) does not equal the gross loss for the reach, recompute the tabulation with another infiltration curve from Fig. 4.[6] When a balance is secured, plot the pervious and gross loss curves. (The loss curves noted in Figs. 6 and 7 are identified by the loss intercept on a 3-in. rainfall rate in Fig. 4.[6])

Fifth, it is found frequently that, when a reach between control points contains high rates of rainfall and runoff, the infiltration curve required for balancing is greatly in excess of those used on both sides of the reach. Actually, the curve will lie between those for the reaches immediately before and after; the excess loss is depression storage. In this case, the tabulation is made for an intermediate infiltration curve; the products of items (*a*) and (*g*) are summed and deducted from the total divergence between control points; the result is a measure of depression storage loss. (For illustration, see Fig. 7 for Station 4.)

The storage curve, embracing surface, gutter, and conduit storage, is plotted as the vertical divergence between the retention curve and the gross loss curve. Analyses of other rainfall-runoff records are filed in the Engineering Societies Library.

Derivation of Hydraulic Phenomena.—A chart, showing a typical runoff hydrograph, its relation to the mass rainfall curve, and various factors to be analyzed in this paper, is delineated in Fig. 3. On the recession side of the hydrograph (see Figs. 6 and 7), when the depth of composite storage (D), in inches, is plotted against the coincident rate of runoff (q), in inches per hour, the resulting curve on rectangular coordinate paper is a straight line below 90% peak runoff rate. When the slope of this line $\left(\frac{\Delta D}{\Delta q}\right)$ is plotted against time of concentration, the result is also a straight line. Sample curves for Stations 3, 4, 10, and 11 are shown in Fig. 8. Fig. 9(a) shows the relation of the slopes

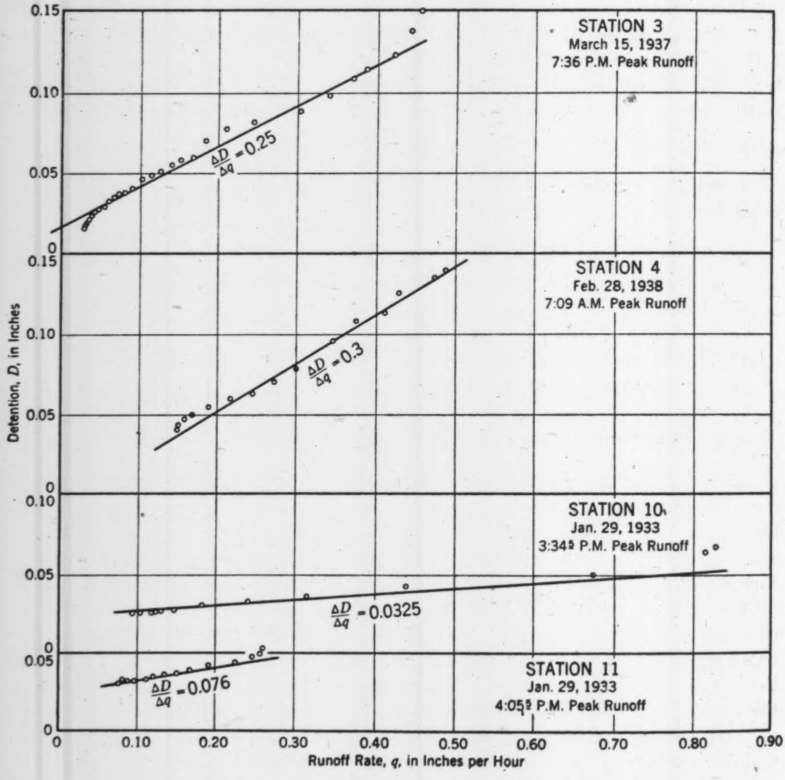

FIG. 8.—DEPTH OF STORAGE WITH COINCIDENT RUNOFF RATES, RECESSION SIDE OF HYDROGRAPH

of the storage-runoff rate curves and times of concentration as derived from analyses of records of Stations 3, 4, 10, and 11. Data are recorded in Table 3. In Col. 4, Table 3, percentage of runoff = ratio of the volume of runoff to volume of rainfall.

In the analysis of storm records, it is necessary to reproduce the recession curve by computation as it would occur if the rainfall following 90% peak of runoff were in the adopted standard pattern (see Fig. 10 for Station 4, February 28, 1938). The net rates of rainfall adjusted in ratio to the standard pattern rates are 0.110 and 0.036; the value of storage at 90% peak is 0.125 in.; the time of concentration is 44.3 min. Using a value of $\frac{\Delta D}{\Delta q}$ (Fig. 9(*a*)) of 0.311 for 44.3 min, the theoretical recession curve is plotted to a point where the runoff rate is less than 20% peak:

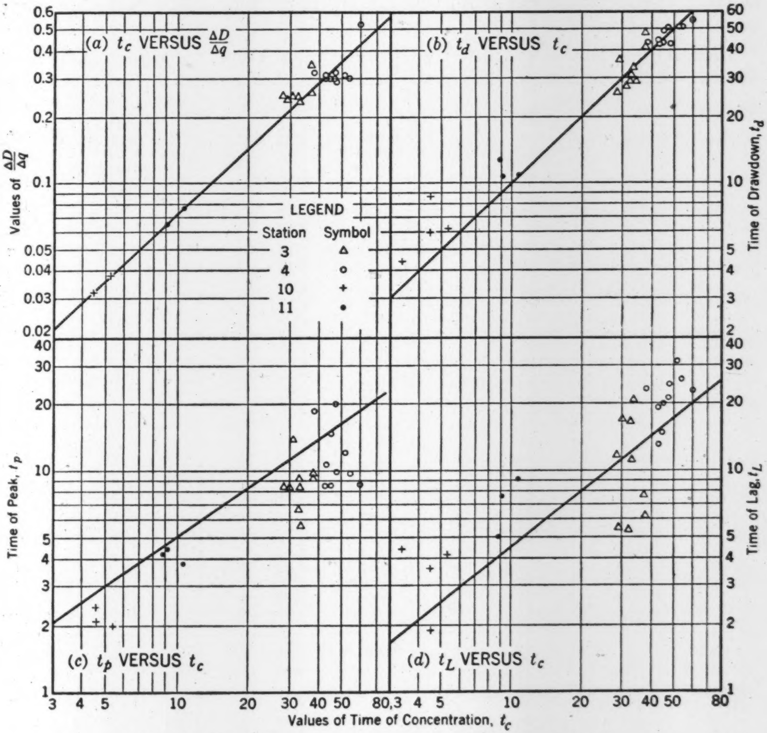

FIG. 9.—TIME ELEMENTS OF THE HYDROGRAPH FROM RECORDS

1. From 7:13 to 7:14 a.m., plot the 90% peak runoff rate as a mass runoff curve, distant below the mass curve of net rainfall 0.125 in. (the value of storage), measured at 7:13½.
2. From 7:14 to 7:16, prolong the mass runoff curve with a rate (0.4224 in. per hr) so selected that the value of storage measured at 7:15, the center of the reach, lies on the curve of $\frac{\Delta D}{\Delta q}$ (0.117 in.).
3. Continue with 2-min reaches.

From these curves, the time of drawdown (t_d), or the elapsed time (in minutes) between 100% and 20% peak runoff rate, is measured (see Table 3 and Fig. 9(*b*)).

Another derived phenomenon of the runoff hydrograph is disclosed by plotting the recession curve on semilogarithmic paper. The recession curve after 90% peak tends to be a straight line. In Fig. 11, recession curves have been plotted, both revised as indicated in the preceding paragraph and without revision. It will be noted that, for the records having small times of concentration, the curve tends to draw to the right, away from a straight line, at a point well above the 20% peak runoff rate; for the long times of concentration, the curve remains a straight line down to a low percentage of peak rate. An explanation is that, as the time of concentration increases, the greater depth

of water stored in transit governs the pattern of runoff for a greater length of time.

An equation for peak runoff rate has been derived from a study of the elements of the hydrograph (see Fig. 3):

$$q_c = \frac{K\,d_o}{t_d} \qquad (4)$$

in which q_c = the computed peak runoff rate, in inches per hour, K varies from 96 for a 5-min time of concentration to 108 for 60 min, and d_o = volume of runoff on the recession side of the hydrograph between 100% and 20% peak runoff rate, in inches of depth on the drainage area.

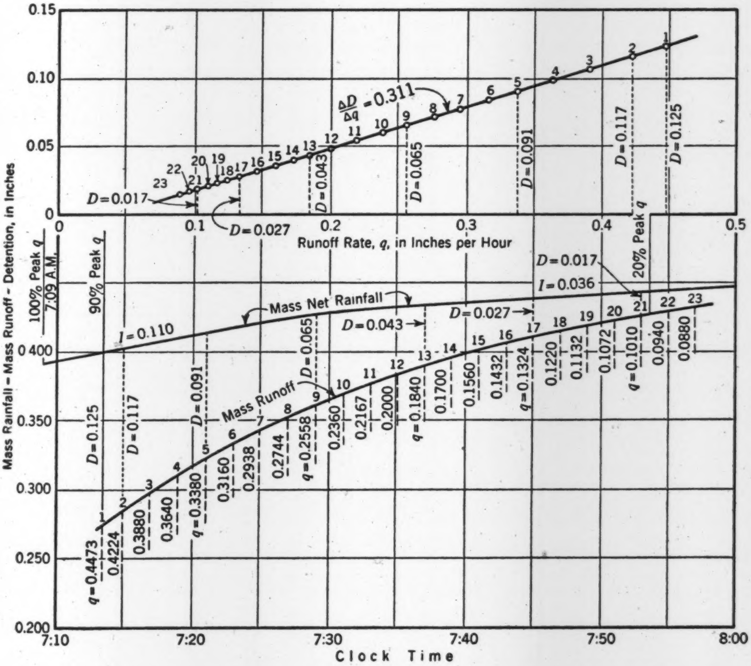

FIG. 10.—COMPUTATION OF THEORETICAL RECESSION CURVE (STATION 4, FEBRUARY 28, 1938)

The foregoing hydraulic phenomena are characteristic of urban runoff but are not found in certain types of mountain runoff.

Derivation of Time Factors.—The meaning of the time factors is shown graphically in Fig. 3. Values derived from records are listed in Table 3. Comparison of their values with corresponding times of concentration is shown graphically in Fig. 9. The curves used hereinafter in the synthesis of the standard hydrograph are delineated as solid lines.

The lag time (t_L) can be defined as the time distance (in minutes) between the centroid of the intensities of the effective rainfall curve, for the intercept thereon of the time of concentration, and the time of peak runoff rate. It is dependent on the shape and distribution of impervious development of the

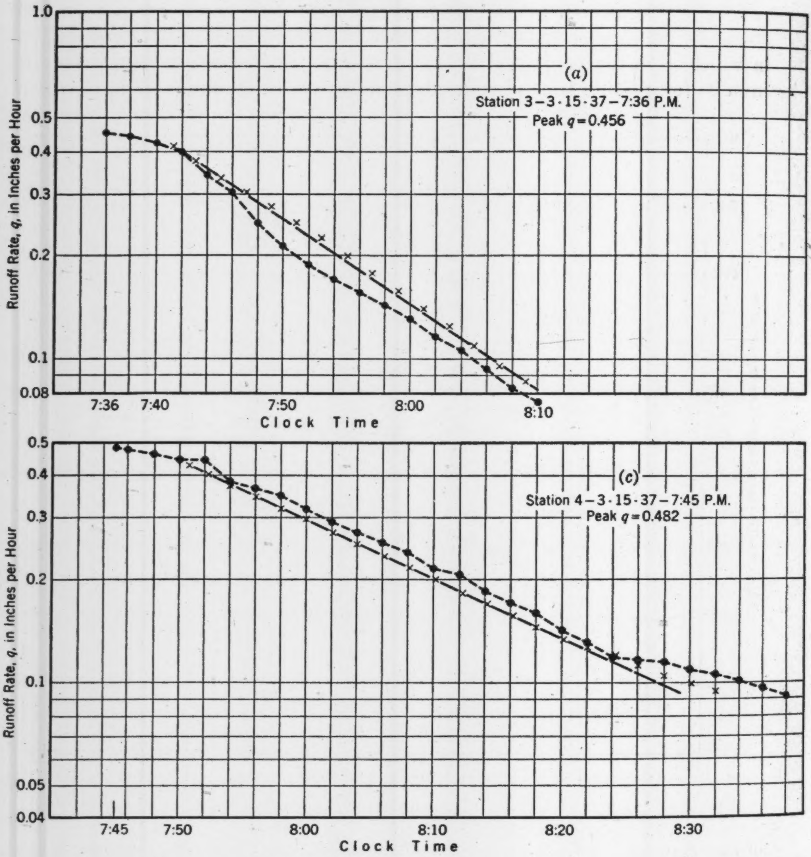

FIG. 11.—TYPICAL

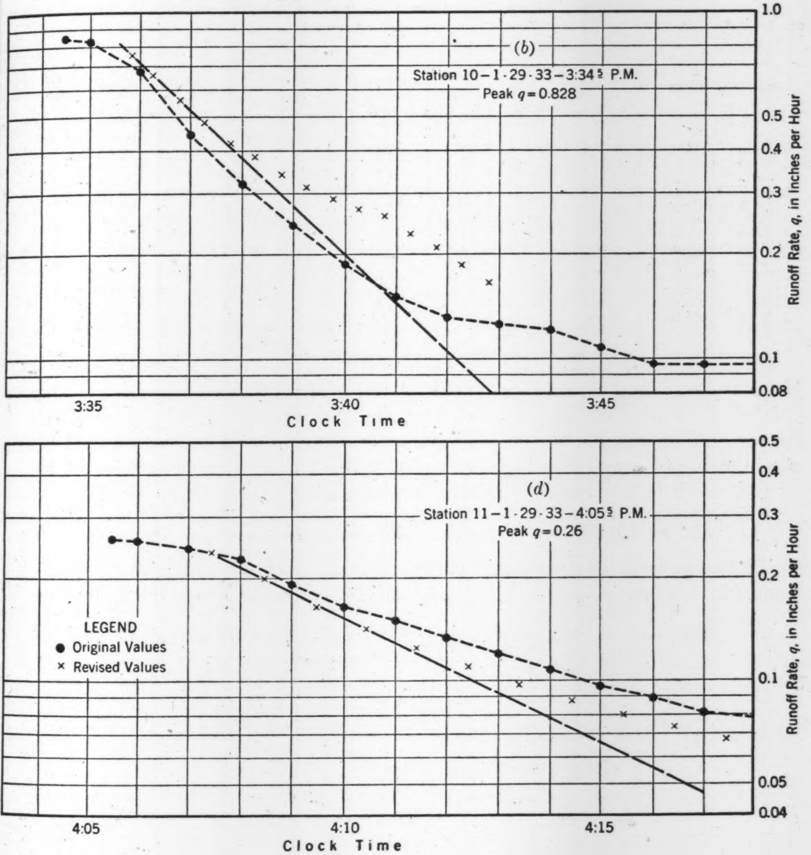
drainage area and no curve of fixed values can be derived from the data (see Fig. 9(d)). The time of drawdown (t_d) is shown by Fig. 9(b) to be approximately equal to the time of concentration for the adopted rainstorm pattern. The time in minutes from 90% to 90% peak runoff rate (t_p) is weighted by comparison with the time from 80% to 80% peak (see Fig. 9(c)).

V. Runoff Frequency

The frequency of runoff is dependent in part on the amount of open soil in the drainage area and the wetness of that soil. This wetness is caused by precipitation antecedent to the high-intensity storm which produces the peak runoff. Infiltration tests and analyses of rainfall-runoff records show that runoff increases as the saturation of loams and clays progresses; this saturation is measured by the moisture factor M.



Recession Curves

Although sands, free of colloidal swelling, respond to an antecedent precipitation of much shorter duration, their infiltration capacity is so great that the use of the same moisture factor as for clays and loams causes no material error.

Analysis has been made of the factors in the equation

$$q_c = K_1\,(I\,F\,M^{A_p})^x \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

for the 515 acres of predominantly pervious area of Station 3 (see Table 4).

If $I\,F$ is considered constant, q_c varies as M (or M^{A_p}) to the exponent x. For Station 3, $K_1 = 1.00$ and $x = 0.55$. Based on studies of this and similar curves and on results of the trial-and-error development of the method of computation of runoff (see Fig. 12), runoff from open soil has been assumed to vary as $M^{0.59}$ for the range of rainfall intensities used in urban design.

VI. SYNTHESIS OF THE HYDROGRAPH FROM DERIVED DATA

Preliminaries to computing runoff hydrographs for use in design are assumptions for rainfall intensities (Figs. 1 and 2), antecedent precipitation (see Section I and Table 5), and classification of drainage areas as to impervious development. This classification is given in Table 6, which is based on surveys

TABLE 5.—MEAN VALUES OF THE MOISTURE FACTOR M

Impervious; business and manufacturing	100	100	0	....

and zoning ordinances. For brevity, the percentage A_d and the soil type (1 for clay, 2 for loam, and 3 for sand) are used to designate an area (15 − 1 denotes "park, with clay soil").

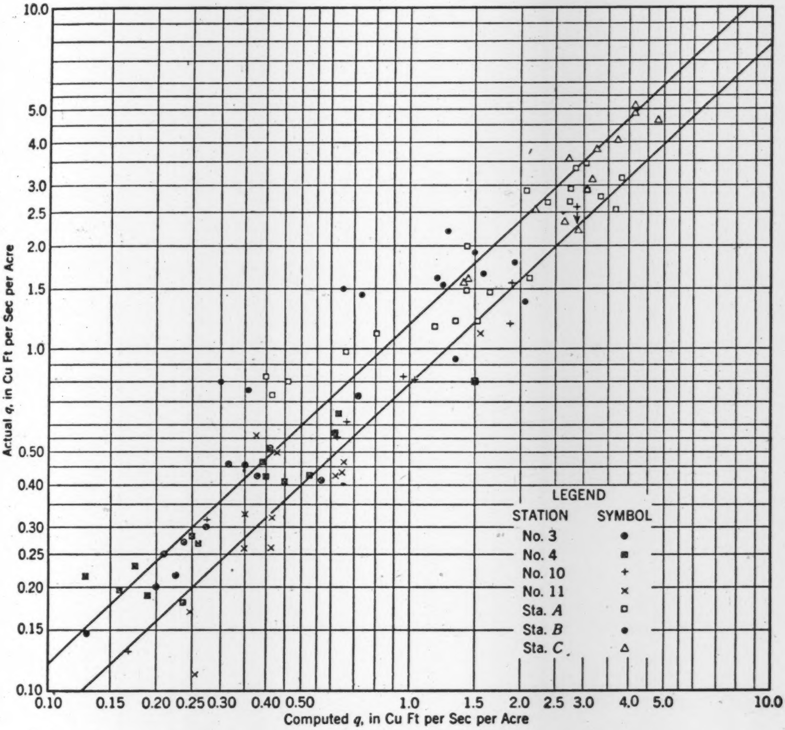

FIG. 12.—COMPUTED AND ACTUAL RUNOFF RATES—URBAN AREAS

The method of development of the runoff hydrograph follows (see Fig. 3):

1. Plot the gross mass rainfall curve (10-yr B curve, Fig. 1);
2. Deduct losses to form the net rainfall curve—
    (*a*) Impervious area losses;
    (*b*) Pervious area losses—depression storage and infiltration;
3. Deduct the varying depth of overland flow detention to form the mass runoff-to-gutter hydrograph;
4. Deduct the varying depth of gutter storage to form the mass runoff-to-inlet hydrograph; and
5. Deduct the varying depth of conduit storage to form the mass runoff-in-conduit hydrograph.

In the paper by Messrs. Horner and Jens,[4] the method has been developed down to, and including, the runoff-to-inlet hydrograph.

The writer has derived runoff-to-inlet hydrographs for the area classifications of Table 6 and for various types of soil. As the shapes of the resulting hydrographs were similar, they were plotted for the more intense portion of the storm on a common clock-time scale with percentages of accumulated depth of runoff as ordinates. The curves nested with slight variations; therefore the runoff-to-inlet hydrograph of the 10-yr rainfall curve on the 1.33 iso-

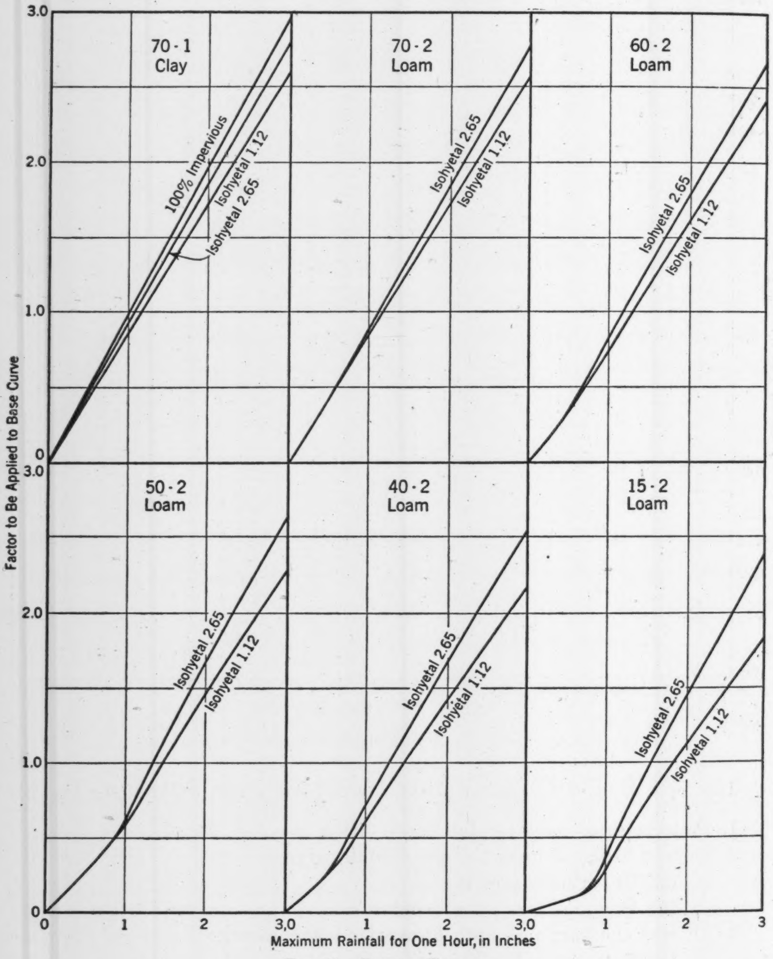

FIG. 13.—RUNOFF FACTORS

hyetal (Fig. 2) for 100% impervious development was selected as a base for the computation of hydrographs of runoff in the conduit, from which were derived the basic runoff rates for times of concentration from 5 min to 120 min (Table 7),

the variation for other rainfall curves and states of areal development to be secured by applying to the basic values a runoff factor (Fig. 13) based on their volume of flow for the intercept of clock time containing the intense runoff to gutter.

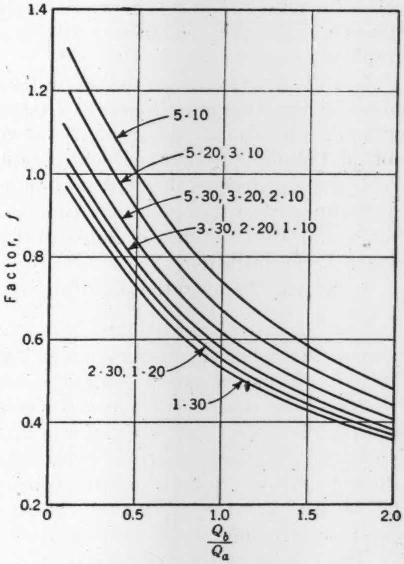

FIG. 14.—CHART FOR COMPUTATION OF POINTS OF CONFLUENCE

Construction of the Runoff-in-Conduit Hydrograph.—The drainage area for the computation is rectangular in shape with the unit areas consisting of five-acre blocks, 330 ft by 660 ft, with the long side north and south; drainage flow south and east. The trunk drain (13,860 ft long) flows south along the east side of the drainage area and intercepts a lateral (4,290 ft long) every 660 ft. Each lateral serves 14 blocks. The rectangular shape, although common in urban drainage, is a special condition of shape; a method of correction of time of concentration for variation of shape is developed subsequently herein (see Fig. 14).

The inlet time of the initial block is 5 min. The mean velocity of flow in the conduit (V), based on full wetted perimeter, is assumed as 5.5 ft per sec. A number of tabulations of conduit storage capacity using different velocities of flow showed the same depth of storage capacity, when spread over the drainage area, for any given time of concentration.

The factors assumed for computations are peak runoff rates (Table 7), lag time (Fig. 9(*d*)), time duration of 90% peak (Fig. 9(*c*)), and time of drawdown (Fig. 9(*b*)). The curves on these charts indicate the final values obtained from these studies, determined after numerous trial computations.

The steps of computation and construction are:

1. Plot the 5-min hydrograph from the initial block as a rate curve and as a mass runoff curve by altering the net rainfall curve for detention on the surface and in the gutters.
2. Plot a trial 10-min hydrograph as a rate curve.
3. At selected points on the clock-time scale, compute the cross-sectional area of conduit for the 5-min and 10-min hydrographs and calculate ratios thereof to full cross-sectional areas; the average of these ratios multiplied by the volume capacity of the conduits between 5-min and 10-min times of concentration equals the volume of water in the conduits at each selected clock time. These volumes (in cubic feet) divided by the square feet in the drainage area having the 10-min time of concentration yield depths of conduit storage in feet over the drainage area.
4. Plot the depth of conduit storage (in inches over the drainage area) below the mass runoff curve for the 5-min hydrograph for the clock time at the left side of the chart; beginning at this plotted point, plot the 10-min hydrograph as a mass curve.
5. Plot the remaining depths of conduit storage above the mass runoff curve for the 10-min hydrograph; if these points coincide with the mass runoff curve for the 5-min hydrograph, the assumed 10-min hydrograph is correct; if not, plot another 10-min trial hydrograph and repeat the operations.
6. Having derived the correct 10-min hydrograph, assume a 20-min hydrograph, and repeat the operations, computing volume of conduit storage between 5-min and 10-min times of concentration, and between 10-min and 20-min times of concentration.
7. Repeat the operation for 10-min increments in time of concentration.

For illustrating the method, the 20-min runoff-in-conduit hydrograph is constructed using computed data in Tables 8, 9, and 10, and the graphs in Fig. 15. Tables 8 and 9 contain computations for the storage capacity of conduits lying upstream from points having times of concentration between 5 and 60 min. Table 10 is a multiple table with a common horizontal scale of clock times of points selected for computing volumes of instantaneous conduit storage. These values of conduit storage depth are plotted in Fig. 15 above the 20-min mass runoff curve. These points have been balanced with the 5-min mass runoff curve to a reasonable but not mathematical accuracy.

The results of these analyses are summarized in the table of basic peak runoff rates (Table 7) and in a chart of the time elements of the basic hydrographs (Fig. 16). With these basic data and charts of runoff factors (Fig. 13) for various rainfall intensities and physical characteristics of the drainage area, peak runoff rates and hydrographs can be computed for use in design. In Fig. 16, the time of drawdown (100% to 20% of the peak runoff rate) is equal to the time of concentration, t_c, for any time exceeding 20 min. A table for plotting the basic standard hydrographs for times of concentration of from 5 to 60 min is filed in the Engineering Societies Library. Examples are shown in Figs. 3 and 15.

Runoff Factors.—The derivation of runoff factors (F_{ro}) is based on the volume of mass runoff-to-gutter curve between 80 and 120 min clock time shown as intercepts for various hourly rates of rainfall in Fig. 17, which is constructed as follows: Using the standard pattern of mass rainfall curve with hourly intensities varying from 0.7 to 6 in. per hr, net runoff-to-gutter hydrographs are computed for sand, loam, clay, and impervious surfaces with loss rates for $M = 1$ from Fig. 4,[6] and with depression storage losses of 0.20, 0.15, and 0.10 in. for sand, loam, and clay.

[a] Total D_c available between times of concentration, in cubic feet.

Referring to Table 6, the rainfall on the pervious area is that falling directly upon it, plus 90% of that falling on impervious area and running on to pervious area. The runoff rate from pervious areas, which varies as $M^{0.59}$, is different for the different isohyetals (see Table 5 and Fig. 2). A sample computation of the runoff factor for an area in level residence classification, loam soil, on isohyetal 1.77, for an hourly rainfall rate of 1.77 × 10-yr factor 0.762 (Fig. 2) or 1.35 is as follows: Pervious area rainfall = 1.45 (Table 6) × 1.35 = 1.96, the converted hourly rate; intercept (Fig. 17) (hourly rate 1.35) for impervious area = 0.97; intercept (Fig. 17) (converted hourly rate 1.96) for pervious area = 1.02; and runoff factor

$$= \frac{(A_d \times \text{impervious intercept}) + (A_p \times M^{0.59} \times \text{pervious intercept})}{\text{Impervious intercept for basic hourly rate}}$$

$$= \frac{(0.40 \times 0.97) + (0.40 \times 0.755 \times 1.02)}{0.71} = 0.98 \text{ (see Fig. 13 for 40-2).}$$

The impervious intercept (0.71) for the basic hourly rainfall rate, 1.01 (10-yr B curve, Fig. 1) is used as a divisor in the foregoing equation for the runoff factor to make the results applicable to the basic runoff rates (Table 7). Runoff factors for various drainage area classifications are shown in Fig. 13.

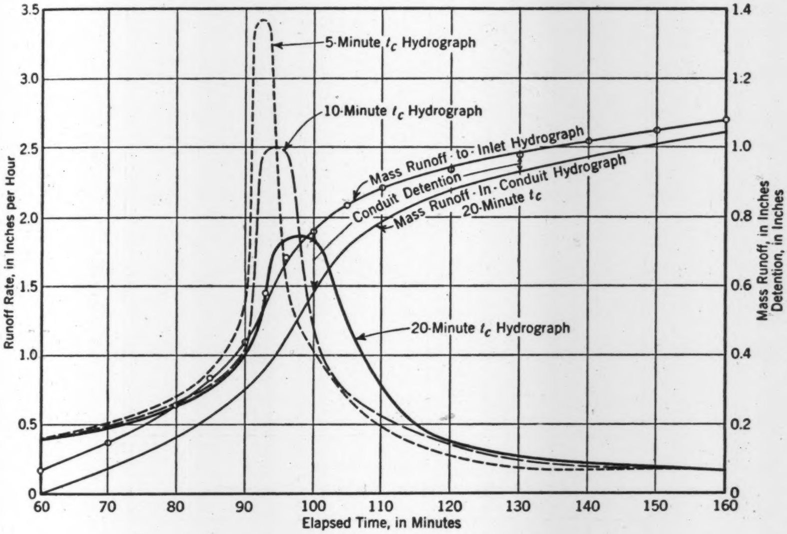

FIG. 15.—BASIC HYDROGRAPH FOR RUNOFF IN CONDUIT

A complete set of charts for the classifications listed in Table 6 has been filed with the Engineering Societies Library. The product of the runoff factor for a given area and the basic runoff rate for the time of concentration is the rate of runoff (q_c) in cubic feet per second per acre.

The values 1.12 and 2.65 in Fig. 13 indicate the 50-yr isohyetal on which the drainage area is located (see Fig. 2).

VII. HYDRAULICS OF THE PROCESS OF SUMMING HYDROGRAPHS

The process of summing hydrographs involves a hydrograph at point A on a drain being routed through a reach of conduit to point B where it is combined with a hydrograph from an incoming lateral and flows on to another junction point C, and so on.

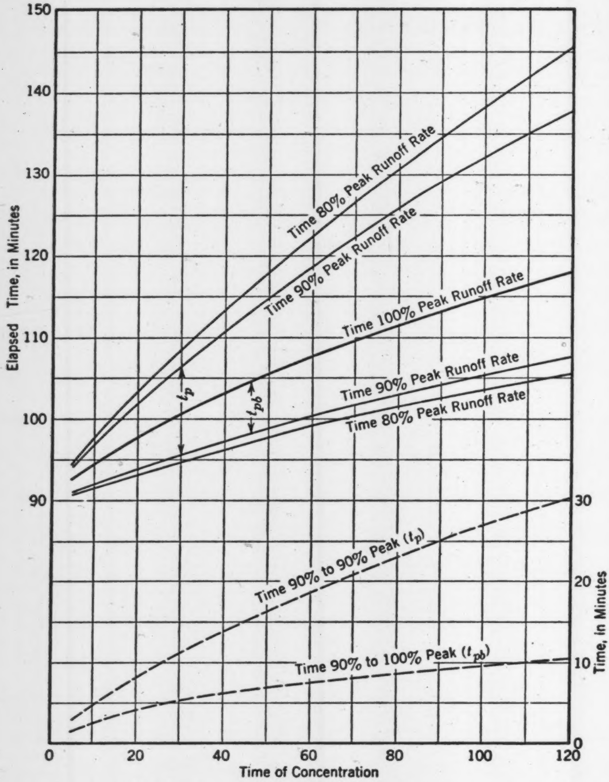

FIG. 16.—TIME ELEMENTS OF THE HYDROGRAPH

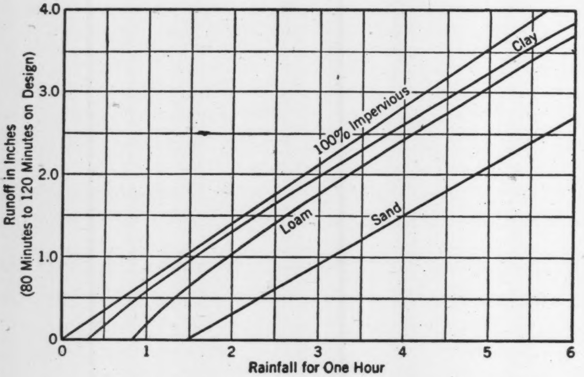

FIG. 17.—INTERCEPTS OF RUNOFF VOLUME, RUNOFF-TO-GUTTER CURVE

From studies of the basic hydrographs previously discussed, a method has been devised for transforming the rate hydrograph for the travel through a reach of conduit—first by a reduction of peak rate, and second by adjustment of the times of occurrence of various percentages of the new peak rate in the front and the back of the hydrograph.

Reduction of Peak Rate.—For this purpose, percentages of reduction of peak rate per minute of flow were computed for various times of concentration.

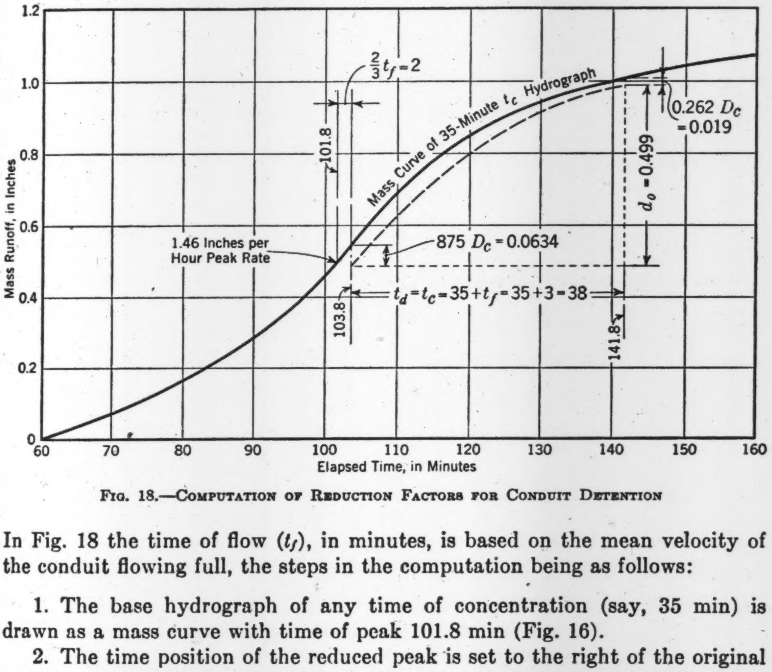

Fig. 18.—Computation of Reduction Factors for Conduit Detention

In Fig. 18 the time of flow (t_f), in minutes, is based on the mean velocity of the conduit flowing full, the steps in the computation being as follows:

1. The base hydrograph of any time of concentration (say, 35 min) is drawn as a mass curve with time of peak 101.8 min (Fig. 16).

2. The time position of the reduced peak is set to the right of the original peak by two thirds the time of flow (for a wave velocity 1.5 times the mean full-flow velocity) or at 103.8 min; the position of 20% peak is at 141.8 min or 103.8 min plus the time of drawdown (original t_c plus 3 min t_f).

3. The volume of available added conduit detention, in inches depth on the drainage area (D_c), is $(t_f \times 60 \times V)\left(q_c \frac{A}{V}\right)\left(\frac{12}{43{,}560\,A}\right) = 0.0165\,t_f\,q_c = 0.0724$ in. This volume, the product of the length of conduit and its cross-sectional area, is independent of both the velocity of flow and the drainage area.

4. As the flow in the drain is ordinarily free flow, the approximate added detention for peak flow is 87.5% of capacity or 0.0634 in., and for 20% peak, 26% or 0.0190 in.

5. Using $d_o = 0.499$, $t_d = 38$ min, and K for a t_c of 38 min = 106.9 in Eq. 4, a value for q_c of 1.40 is obtained.

6. The reduction for 3 min time of flow is 4.3% or 1.43% per min. Based on a series of similar computations, the values in Table 7, Col. B, were obtained.

Travel Velocity of the Flood Wave.—The velocity of travel of the front and peak of a flood wave is higher than the mean velocity computed for the peak depth while the velocity of the recession side recedes to less than the same mean velocity.

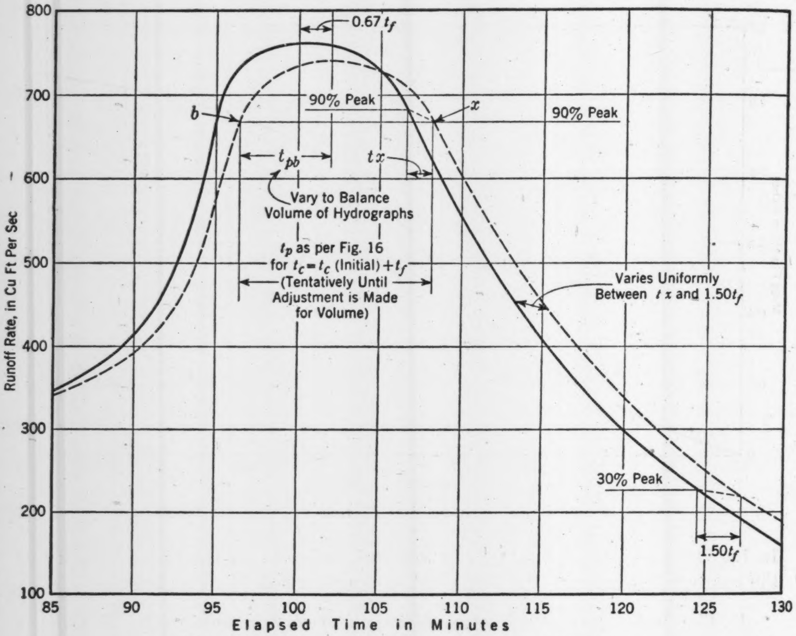

FIG. 19.—TRANSPOSITION OF A HYDROGRAPH FOR FLOW

An experiment along these lines by the Los Angeles County Flood Control District[11] was performed in an open rectangular channel 13,071 ft long between two reservoirs; the slope varied between 1.078% and 1.625%. Four releases of water were made, the last being in the form of a flood wave with a peak of 1,400 cu ft per sec. Gagings were made at five stations. In part the conclusions are:

> "7. For routing flood hydrographs down channels, a travel time based on a wave velocity affords a better approximation to true conditions than a travel time based on normal velocities. From the present test, the wave velocity ranges between 120% and 150% of the normal velocity for sudden changes of quantity."
>
> "11. The limitations of the data and conditions of flow must be kept in mind when applying these conclusions to other sets of conditions. * * *."

---

[11] "Field Test of Discharge from Puddingstone Dam and Flow in Puddingstone Diversion Channel," Los Angeles County Flood Control Dist. (unpublished).

In the experiment the normal velocity was based on open channel flow. If the percentages in conclusion 7 are expressed in terms of full-wetted perimeter, mean velocity, upon which time of flow is based in this paper, they become 140% to 175% (or 120% to 150% divided by 0.86).

From this experiment and a study of the time relations from rainfall-runoff records, the selection of 150% of mean full flow velocity of a closed conduit for the wave velocity of peak runoff rate at efficient free flow depth is reasonable and consistent with current engineering practice.

For the time movements of all phases of the hydrograph, the graph in Fig. 19 was developed from analyses of the time relations from rainfall-runoff records as recorded in Figs. 9 and 16.

Method of Summing Hydrographs.—This method is illustrated by an example. Two areas A and B have inlets 2 min time of flow apart. Area A has 700 acres of 50-2 development located on 50-yr isohyetal 2.22, $t_c = 40$ min; B has 300 acres of 40-2 on isohyetal 1.77, $t_c = 25$ min. A table filed in the Engineering Societies Library is used for plotting hydrographs.

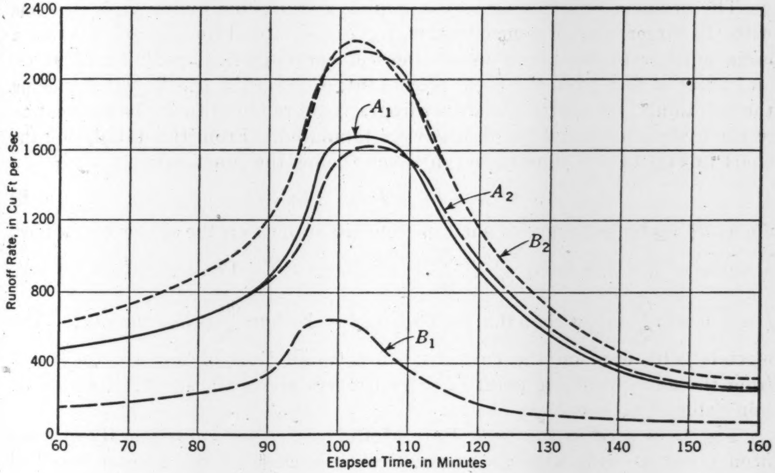

FIG. 20.—TRANSPOSITION AND SUMMATION OF HYDROGRAPH

For designing the conduit A to B, Q (peak runoff rate in cubic feet per second) = 700 acres × 1.80 (Fig. 13) × 1.37 (Table 7, Col. A) × 0.966 (Fig. 5) = 1,668 cu ft per sec. This quantity, applied to the 40-min basic hydrograph, yields hydrograph A_1 in Fig. 20.

For plotting hydrograph A_2 at the end of the reach A–B, the total reduction of peak for conduit detention is 2.45% (Table 7, Col. B), and the distribution factor becomes 0.954 because of the added 300 acres at point B; the peak rate for hydrograph $A_2 = 97.55\% \times \frac{0.954}{0.966} \times 1{,}668$ cu ft per sec = 1,607 cu ft per sec. Curve A_2 is plotted by the method of Fig. 19.

For plotting the hydrograph for area B, $Q = 300 \times 1.32$ (Fig. 13) $\times 1.68$ (Table 7) $\times 0.954$ (Fig. 5) $= 634$ cu ft per sec. The distribution factor is based on the combined areas A and B. Curve B_1 is the result.

Curves A_2 and B_1 are summed to form the tentative curve B_2. Because the mechanical process of summing does not evaluate the effects of hydraulic disturbances of the confluence, correction above 80% peak is made with the aid of Fig. 16:

1. By inspection of the uncorrected hydrograph at the points of 90% and 80% peak, select by trial a time position and value of 100% peak. Reconstruct the curve between points of 80% peak.

2. Check the revised curve against the original curve for agreement in volume between points of correction. The final value of Q for B_2 is 2,150 cu ft per sec.

Variation of Time of Concentration.—In summing hydrographs it is found frequently that the resulting hydrograph has time and peak characteristics materially different from those of either of the incoming hydrographs.

The problem was analyzed by summing a trunk-line hydrograph (the line with the larger time of concentration, t_{ca}) and a lateral hydrograph (t_{cb}) for a large number of combinations of times of concentration, peak runoff rates, and times of flow from the point of concentration on the trunk next preceding the junction. By trial, standard hydrographs were found to fit the summation of the hydrographs and the results were tabulated. From this tabulation the chart in Fig. 14 was constructed in which (below the junction):

$$t_{cx} = t_{cb} + f\,(t_{ca} - t_{cb}) \qquad (6)$$

To avoid undue influence of small increments of flow on the major trunk flow, a value of $f = 1$ is used when $\frac{Q_b}{Q_a}$ is less than 0.1. For $t_{ca} - t_{cb} = 40$ min, $f = 1$ when $\frac{Q_b}{Q_a}$ is less than 0.2; for 50 min, $f = 1$ when $\frac{Q_b}{Q_a}$ is less than 0.1. The legends 2-10, etc., on the curves mean a 2-min time of flow on the trunk from the next preceding point of concentration above the junction, and a 10-min value of $t_{ca} - t_{cb}$.

Fig. 14 is used in the Peak Rate Method described subsequently and has been given as wide a range as practicable because of the greater speed of operation of that method.

VIII. METHODS AND FORM OF RUNOFF COMPUTATION

Use of the Method of Summing Hydrographs described previously is confined to cases in which the Peak Rate Method is not applicable.

Peak Rate Method.—This method is subject to the following conditions:

1. When the hourly intensity of rainfall for the selected frequency is not constant over the entire drainage area (see Fig. 2), the hourly intensity for each point of concentration is computed by weighting the intensities within the drainage area by the effective areas to which they apply.

2. When a lateral and a trunk line combine with times of concentration and peak rates of runoff falling outside the limitations imposed by the notes

in the text, following Eq. 6, the Method of Summing Hydrographs is used for the continuation of the trunk line; the laterals to the continuation of the trunk are designed by the Peak Rate Method.

3. The outfall from a retarding reservoir is designed by the Method of Summing Hydrographs, after the inflow to the reservoir has been routed through by use of the reservoir formula (inflow = outflow plus storage).

4. Other limitations may be imposed by the judgment of the designer.

1. List the areas at their respective points of concentration (Cols. 1, 2, and 24).
2. Subclassify the areas (Table 6 and Cols. 4 to 11, Table 11).
3. Select the 1-hr rainfall rate from Fig. 2, with respect to the isohyetal and frequency (isohyetal 1.33 × 10-yr frequency factor 0.762 = 1.01, Col. 12).
4. When the gross drainage area exceeds 100 acres, adjust the 1-hr rate by the distribution factor (Fig. 5 and Cols. 13 and 14).
5. Determine the runoff factors from Fig. 13 in relation to the adjusted 1-hr rainfall rate and apply them to the base runoff rate for the time of concentration in Table 7 to derive runoff rate per acre (q_c in Col. 3).
6. Follow through with the routine tabling computations.
7. When a lateral is added, the time of concentration is adjusted in accordance with Fig. 14 (Col. 22).

IX. Comparison of Computed Runoff with Record Runoff

The methods of computation outlined herein are based on rather complete analyses of gagings taken in and near Los Angeles. Other records have become available, but have not been analyzed. Instead, runoff factors (F_{ro}) have been determined for the rainfall data of both local and outside records, both of the intense storm producing the runoff and of the antecedent precipitation, and these runoff factors have been applied to the basic runoff rates of Table 7 to produce computed values of runoff to compare with the actual values.

The runoff factor is based on surveyed percentages of the specific drainage area, namely A_i, A_d, and A_p. A series of curves is necessary to reflect the varying percentage of pervious runoff, which varies as $M^{0.59}$. A set of curves of runoff factors for Eastern Avenue (Station 3) is shown in Fig. 22.

Table 12.—Comparison of Computed and Actual Values of

No.	Date	Hour	Percentage of runoff	Time of concentration, in min (t_c)	Rainfall rate, in in. per hr (I)	Rainstorm shape factor (F)	Standard rainstorm shape factor (F_s)
1	1/ 5/35	3:44 a.m.	24.6	28.3	1.19	0.805[a]	0.767[a]

[a] Factors F and F_s are probably above average for area.

A set of computations for Station 3 is shown in Table 12, in which F_s = the standard rainstorm shape factor, which is the shape factor, F, for a standard shaped storm having a rainfall rate equal to that of the record storm for the specific time of concentration; F_s may be obtained by dividing the record intensity of rainfall (I) for this time of concentration by the rate for the same time duration on the standard 10-yr B curve (Fig. 1); I_H = the hourly rate of rainfall on the standard shaped rainfall curve corresponding to the rate for the specific time of concentration used, 1.01 $(F_s \times F_s)^{0.5}$, modified by the shape factor F, or 1.01 $(F \times F_s)^{0.5}$. The other headings have been defined or are self-explanatory.

The physical characteristics of local urban areas, Stations 3, 4, 10, and 11, are listed in Table 1; for Blocks A, B, and C, St. Louis, Mo., as reported[12] by W. W. Horner, M. Am. Soc. C. E., and F. L. Flynt, Assoc. M. Am. Soc. C. E., in Table 13. Record data, computations, and derived values of runoff, except for Station 3 (Table 12), are shown in tables filed in the Engineering Societies Library.

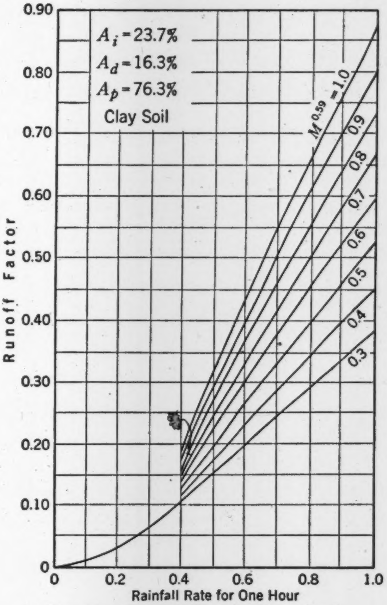

FIG. 22.—RUNOFF FACTORS, STATION 3

Record values of peak runoff rate for Stations 3 and 4 and for Blocks A and C have been corrected for overlap of preceding storms on the major storm (q_3). The hydrographs of the other areas were too irregular to justify this correction. In addition, the area for Station 4 has an inadequate lateral system

[12] "Relation Between Rainfall and Run-Off from Small Urban Areas," by W. W. Horner and F. L. Flynt, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 140.

which causes overflow into street channels leading to the gaging system at about 0.45 in. per hr runoff rate, and causes overflow into another drainage area at about 0.60 in. per hr; this condition distorts computed corrections of the peak runoff rate.

TABLE 13.—Characteristics of Urban Drainage Areas, St. Louis, Mo.

Station	Location	Area (acres)	Soil type	Improvement (%)			Channel type
				A_i	A_d	A_p	
A	Belt and Ridge avenues	2.3 to 1923 2.2 after	Clay	42.0 49.0	34.0[a] 38.0[a]	58.0 51.0	Gutter
B	City block No. 4841	3.27	Clay and loam	30.0	21.8[a]	70.0	Gutter
C	Ewing and Washington avenues	4.34	Clay	72.0	60.0[a]	28.0	Gutter, pipe, egg-shaped sewer

[a] Estimated.

Even with these deficiencies in the records, the comparison of the corrected record values of peak runoff rate with computed values (Fig. 12) shows a majority of the points lying within the lines of 20% variation. The mean of the points indicates that the computed values are a little below actual, especially when the correction for the preceding storm is considered.

Conclusions

1. The peak runoff rate for a given storm pattern is proportional to the volume of runoff resulting from the intense portion of the storm. The volume of runoff may be predicted—

(*a*) For pervious areas, by infiltration tests on small soil plots and by analyses of rainfall-runoff records from partly or fully pervious drainage areas;

(*b*) For impervious areas, by similar tests on impervious areas.

2. Rainfall-runoff records in which the high intensities of rainfall occur at or near the end of the storm (delayed pattern) disclose hydraulic phenomena and time relations which, when secured from drainage areas of various sizes and physical characteristics, enable the investigator to predict the approximate intensity and pattern of the runoff hydrograph that will occur under selected conditions of drainage area and rainfall.

When the method of computation derived from the delayed pattern storms is applied to the peak runoff rates for advance pattern storms, the approximate agreement obtained indicates that the same phenomena are present but are obscured by the runoff resulting from rainfall occurring after the peak of runoff.

3. The runoff hydrograph is the result of the travel and confluence of hydrographs from small units of area. As long as the urban drainage area is homogeneous in development and conforms to the topography of the natural drainage valley or swale, the hydrograph has a characteristic pattern of

smoothly varying rates; when hydrographs from dissimilar areas combine at a point of confluence, the outflow hydrograph has an irregular shape and a peak intensity unpredictable by a simple computation involving the size and physical characteristics of the drainage area and the intensity of rainfall. In such cases, the outflow hydrograph may be constructed by summing the hydrographs from each of the dissimilar areas.

4. Further accumulation of data is needed, emphasizing runoff records defining all stages of flow, accurate time correlation between rainfall and runoff, and experimentation on the storm flood wave.

5. For urban areas, in both Los Angeles and St. Louis, a comparison of actual runoff rates with those computed by this method from rainfall records (Fig. 12) shows most of the points falling within a 20% tolerance; agreement of points within the design range (above 1 cu ft per sec per acre) is more nearly perfect.

ACKNOWLEDGMENT

This investigation was conducted by the Bureau of Engineering, Department of Public Works, Los Angeles, under the direction of L. W. Armstrong, M. Am. Soc. C. E., principal civil engineer. Lloyd Aldrich, M. Am. Soc. C. E., is city engineer, and Merrill Butler, M. Am. Soc. C. E., is assistant city engineer (design). Prior to 1932, the work was supervised by F. L. Boyle, assistant civil engineer, and G. S. Tapley, Assoc. M. Am. Soc. C. E., civil engineering associate. At that time, the writer undertook the work, with H. W. Fraim, civil engineer, who supervised field and laboratory activities. Analyses and computations were performed by H. B. Brown and H. P. Larsen, civil engineering associates. Operation of automatic recording instruments was by F. J. Doran and A. A. Weston, civil engineering associates.

The Los Angeles County Flood Control District made its voluminous records and analyses available. Maxwell F. Burke, Assoc. M. Am. Soc. C. E., of that organization was very helpful in discussing the many phases of the problem.

The Water Department and the Engineering Bureau of the City of Pasadena cooperated in gaging rainfall and runoff in that city and by making available other records collected by them independently.

DISCUSSION

C. S. JARVIS,[13] M. AM. SOC. C. E.—The extensive plottings, analyses, and calculations presented by the author should insure more than a casual consideration of his contribution. The orderly arrangement in logical sequence, step by step, facilitates the understanding of both the objective and the scientific approach. After a careful reading of the paper, the writer's interest centered on Fig. 12, showing the computed and actual runoff rates, the computed quantities being plotted against the observed.

It is certainly gratifying to find that most of the plotted points fall within a 20% tolerance zone. Without intentionally detracting from this accomplishment, it seems necessary to observe the extreme range of variation—for example, using the ordinate value of 1.5. The envelope of plotted values extends from abscissa value 0.65 to 2.15, showing an actual range from 0.43 to 1.43, representing 43% to 143% of the actual runoff. Similarly, for the ordinate 0.8, the range of computed values extends from 0.30 to 1.50, or from 37.5% to 87.5% of the actual value. Concentrating on the symbols representing data from Station 3, shown in Table 12, the range between envelope curves at the ordinate value of 0.45 extends from about 0.33 to 0.59, or from 73% to 131% of the observed quantity.

In view of these fairly wide dispersions, it seems appropriate to inquire as to the advisability of adopting an average factor, say 40% or 50% in Table 12, by means of which the computed peak runoff rates might be derived directly from the recorded rainfall rates, in the sixth column, under (*I*). Exercise of the same ingenuity and personal judgment required in assigning appropriate values for the shape and moisture factors in Table 12 should insure as close agreement between computed and actual peak runoff rates as was attained in either Fig. 12 or Table 12.

Fortunately, reports on research projects need not include the explorations that end in blind alleys, unless a brief account of such fruitless endeavor will serve as a warning to others. It appears that full recompense in results of practical value has been realized for every operation thus far reported by the author. After setting up such definite forms and procedures, it is a simple matter to introduce refinements and revisions promptly after acquiring additional authentic data. Whether all new data shall be subjected to exactly the same processing or whether some abbreviated reductions shall be devised is relatively unimportant at this stage of development. However, with such a background of accomplishment as belongs to both the City and County of Los Angeles in the analysis and solution of flood and runoff problems generally, the conduct of operations from now on is practically assured as an example worth following under conditions largely comparable.

One of the greatest services that could be rendered by those inclined and equipped to make such elaborate analyses would be to render the results in the simple forms involving the proportion of rainfall amount as well as rate appearing with the runoff phenomena. Admitting that there is some reason for departing from the use of runoff coefficients and for adopting a more rigorously scientific approach, it does not seem to be too great a concession to those who have become accustomed to the simpler methods to translate results into the terms and expressions most familiar to them. Likewise, the use of some of the suggested scales for indicating the relative yields per unit of area would facilitate comparisons. Perhaps the author has some preferred method of rating the unit yield relation to drainage area, which would facilitate application of his method to much greater areas.

---

[13] Cons. Engr., Washington, D. C.

S. W. Jens,[14] Assoc. M. Am. Soc. C. E.—A very important contribution to the literature covering the application of the newer hydrology to practical design is contained in this paper. It is of particular significance as an indication of what a progressive municipal engineering organization can accomplish in the conduct and application of research to its design problems. The first few paragraphs of the paper present a very clear and succinct statement of the fundamentals involved.

The author rightly emphasizes the statistical meaning of the rainfall intensity-duration curves. It is easy to slip into careless thinking about this, with consequent erroneous use of the data. It seems preferable not to use the term "10-yr frequency storm" but rather "10-yr frequency rainfall rate" because the intensity-duration data merely give an average rainfall rate over the time of duration and may or may not represent the entire actual storm. In other words, the 10-yr, 30-min rainfall rate may actually be part of, say, a 60-min storm; and the 60-min average rainfall rate for that storm may be of a different frequency.

The techniques indicated by Mr. Hicks for the determination of the storm pattern and as a measure of the influence of antecedent precipitation are very interesting. Mr. Hicks states that the value of M determined by his studies applies to all rainfall frequencies. Can it be inferred that this value of M also applies to all durations? For areas having rains distributed throughout the year, it is presumed that varying values of M would need to be developed to reflect properly seasonal differences in antecedent precipitation.

The considerable importance of the factor expressed by the percentage of impervious area directly tributary to the collecting system is given proper emphasis but, if possible for the particular areas in Table 1, it would be of value to have the average slopes indicated for overland flow, gutters, and drains. In discussing lag time the author (see Section IV, heading, "Derivation of Time Factors") states "It is dependent on the shape and distribution of impervious development of the drainage area * * *." Surface slopes seem to be fully as important a determinant.

Recent studies in this office of actual open channel recession curves show a straight-line relationship between discharge rate in cubic feet per second and volume of storage in cubic feet. In view of Mr. Hicks' findings that the same general relationship holds for the composite storage involved in urban drainage, it may well be that all ordinary recession curves can be expressed in some such form as:

---

[14] Partner, Horner & Shifrin, Cons. Engrs., St. Louis, Mo.

$$q = K\,V^{n}{}_{L} \qquad (7)$$

in which q = rate of discharge or runoff in cubic feet per second or in inches per hour; V_L = volume of storage in cubic feet or in average inches of depth over the tributary area; K = a constant reflecting the physical characteristics of the area and the collecting system as well as the particular units being employed; and n = an exponent (found by the writer to be approximately 1). Additional similar study of rainfall-runoff data from a great number of different areas should be made.

In describing his technique of analyses, the author states that impervious surface loss has been experimentally determined as approximately 10% of the rainfall. It is difficult to understand why this should be so because analytical reasoning points to a fixed value for such loss for any particular surface. The amount of rainfall required to fill the undrainable depressions plus the surface film remaining after rainfall ceases would seem to be all the losses that can occur on impervious surfaces. Furthermore, both of these losses seem to be fixed amounts for any specific area, and all rainfall in excess of their sum should appear as runoff. It would be of interest if the author presented the experimental data that support his use of a constant percentage loss, irrespective of the rainfall intensity.

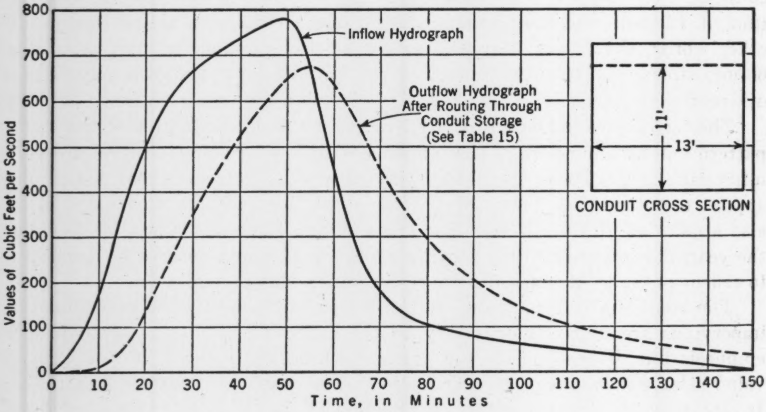

FIG. 23

For routing a known inflow through a conduit to determine the effect of conduit storage, the storage equation has been found applicable. The following example illustrates the technique: For a peak inflow rate of 780 cu ft per sec, a time of 49 min and a hydraulic slope of $S = 0.0003$, with $n = 0.012$, a box section 13 ft wide with free flow 11 ft deep is indicated. This section is shown in Fig. 23 and was chosen to keep the excavation as shallow as possible to minimize the extent of the trench in wet ground. The section prevails for $l = 5{,}585$ ft and serves as an outfall to a pump station.

Fig. 23 shows also the hydrograph of inflow at the upper end of the box. For a short finite increment of time, Δt, the equation can be written: Average inflow rate times Δt equals outflow rate times Δt plus or minus the change in storage in the time interval Δt. Let: I = average inflow rate in cubic feet per second for interval Δt; Q_1 = outflow rate at beginning of time Δt, in cubic feet per second; Q_2 = outflow rate at end of time Δt, in cubic feet per second; Δt = time interval, in minutes; V_{L1} = cubic feet of occupied volume in conduit at beginning of Δt; and V_{L2} = cubic feet of occupied volume in conduit at end of Δt. Then:

$$60\, I\, \Delta t = 60\, \frac{Q_1 + Q_2}{2}\, \Delta t + (V_{L2} - V_{L1}) \ldots\ldots\ldots\ldots (8)$$

Rearranging terms, Eq. 8 becomes

$$f Q_2 = I + f Q_1 \ldots\ldots\ldots\ldots (9a)$$

with

$$f Q_1 = \frac{V_{L1}}{60\, \Delta t} - \frac{Q_1}{2} \ldots\ldots\ldots\ldots (9b)$$

and

$$f Q_2 = \frac{V_{L2}}{60\, \Delta t} + \frac{Q_2}{2} \ldots\ldots\ldots\ldots (9c)$$

Table 14 gives the computations for the storage function curves shown in Fig. 24. Storage in the conduit has been assumed equal to the volumes under hydraulic gradients parallel to the flow line for varying depths of flow. This is not rigorously true, but, since change in storage is wanted, it is believed that the resulting curve represents the discharge-storage relationship with practical accuracy. The Manning formula has been used for discharge computations with n assumed as 0.012 for monolithic concrete. To catch the peak outflow more accurately, a curve for Δt equal to 1 min has been developed; for the remainder of the routing $\Delta t = 5$ min is used. As will be shown in describing the routing procedure, it is necessary to plot only the curve for fQ_2.

TABLE 14.—COMPUTATION OF STORAGE FUNCTIONS

Depth d (ft)	Area A (sq ft)	Wetted perimeter (ft)	Hydraulic Radius (Ft)		Flow (Cu Ft Per Sec)		$\Delta t = 5$		$\Delta t = 1$	
			R	$R^{2/3}$	Q	$\frac{Q}{2}$	$\frac{S}{300}$	fQ_2	$\frac{S}{60}$	fQ_2
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)
2	26	17	1.53	1.33	74.1	37.0	484.3	521.3	2,420.2	2,457.2
4	52	21	2.48	1.83	208.5	104.3	968.6	1,072.9	4,840.5	4,944.8
6	78	25	3.12	2.14	357.4	178.7	1,452.9	1,631.6	7,260.8	7,439.5
8	104	29	3.59	2.35	523.0	261.5	1,937.2	2,198.7	9,681.0	9,942.5
10	130	33	3.94	2.50	695.6	347.8	2,421.5	2,769.3	12,101.0	12,449.1
11	143	35	4.09	2.56	785.0	392.5	2,663.6	3,056.1	13,311.4	13,703.9

Table 15 gives the routing computations. Cols. 1, 2, and 3 are taken from the inflow hydrograph. It should be noted that Col. 3 is the average inflow rate for the period and that Col. 4 is the outflow rate at the end of the time interval read from the proper storage curve. These outflows are obtained as follows:

(*a*) The first average inflow is laid off on the horizontal scale and the outflow rate at the end of the first 5-min period is read on the vertical scale (using, of course, the fQ_2 curve for $\Delta t = 5$); and

(*b*) The value shown in Col. 8 for the preceding line is placed in Col. 5; to this is added the inflow for the period under consideration (Col. 6); then the outflow arrived at in the previous interval is inserted in Col. 7 and this is subtracted, resulting in the value given in Col. 8. This latter figure is laid off on the horizontal scale and the outflow read on the vertical.

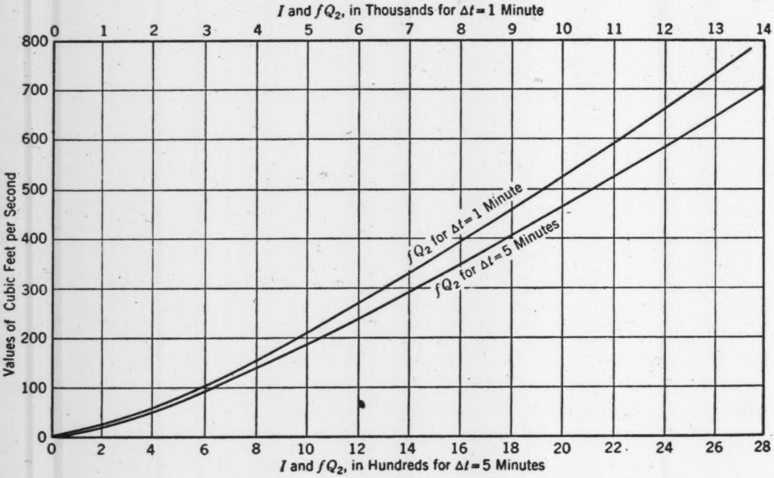

FIG. 24

The process is repeated throughout the hydrograph and is merely a combined graphic and arithmetic solution of the storage equation. Transition from a curve for one-time interval such as 5 min to that for another Δt is accomplished by selecting an abscissa value for the new Δt representing the same outflow value (Col. 4) as was obtained for the prior Δt; the procedure is then reversed upon changing back to the original Δt.

The foregoing computation suggests that, because of the peak reduction caused by the storage effect, the box section, 11 ft high by 13 ft wide, required for the inflow peak of 780 cu ft per sec could be replaced by an 11-ft by 12-ft box. A check routing through the smaller section is necessary to make sure that the lesser total storage accomplishes the requisite peak reduction.

Similar analyses were made of the storage effect for several other lengths and conduit sizes with various inflow peaks. These are shown in Table 16. These conduits all are in flat river bottoms and would be expected to exhibit more than ordinary storage effects. It seems significant, however, that only the extremely long, large box with a relatively short inflow hydrograph (49 min to peak inflow) gives an appreciable storage reduction. This is understandable from the viewpoint of the ratio of inflow volume to the available storage volume. The longer time hydrographs with greater volumes of inflow are more likely to fill the conduit before the occurrence of the peak.

[a] From the line preceding a given time interval.

All the foregoing leads to the conclusion that the effect of conduit storage must be evaluated for each specific reach, and it is difficult to understand how reductions accomplished by any particular system can be applied as indicated by the author to any other system with different conduit sizes, lengths, and times.

The author has kept to the basic fundamentals throughout his development of practical tools for use in urban storm sewer design. His fine paper should encourage others to analyze rainfall-runoff records in the light of the hydrologic knowledge of the past few years.

W. W. HORNER,[15] M. AM. SOC. C. E.—Within the limits of his allotted space, Mr. Hicks has attempted to present fundamental data that have been derived over a period of years; and he treats a wide variety of urban storm drainage design situations. As a result, the paper is too condensed to give the reader an adequate picture of the design methods developed by the Bureau of Engineering of the City of Los Angeles. It is extremely interesting to note that Mr. Hicks and his associates had anticipated the design procedure which the writer and Mr. Jens outlined in a previous paper.[4]

The writer has read Mr. Hicks' paper carefully several times and has discussed it, but he may not have fully appreciated all of the elements involved in the procedure. Accordingly, it would seem desirable for him to outline his understanding with the request that Mr. Hicks clarify certain of the matters that were presented much too briefly in the paper.

Mr. Hicks and his associates have apparently analyzed a great many actual runoff hydrographs in the Los Angeles storm drainage system, and have found that they could correlate certain of the parameters in a manner which would permit the preparation of a base hydrograph of correct form for any particular time of concentration.

Separately, extensive probability studies have been made resulting not only in the duration-intensity diagram of Fig. 1, but also in the determination of the most probable pattern of variation of rainfall intensity. The use of these studies permits the plotting of gross mass rainfall as indicated in Fig. 3.

The curve of mass rainfall is then modified through infiltration, surface detention, gutter storage, and finally conduit storage to a diagram of mass runoff in conduit, from which the runoff rate hydrograph can be derived. The writer understands that a large number of such hydrographs have been prepared and may be modified by the methods described to produce the actual hydrograph of runoff for any set of specific conditions.

---

[15] Cons. Engr. (Horner & Shifrin), St. Louis, Mo.

From the study of actual hydrographs and a correlation with the basic hydrographs, the author has been able to derive Eq. 5 and finds that this equation may be used satisfactorily as a basis for design in many instances. In actual practice it is understood that he uses either the summation of the derived hydrographs or Eq. 5, depending on certain limiting conditions.

From the foregoing, it would appear that, as the result of research work, the present actual design procedure may not be much more difficult or cumbersome than the sound application of the old rational method. If so, this answers one of the questions commonly raised; namely, can the engineer afford to take the time to evaluate infiltration, surface detention, gutter storage, etc., in the course of typical design practice. Apparently Mr. Hicks' research work makes it possible to evaluate all of these pertinent factors in an orderly manner and to reduce the procedure to a satisfactory working standard.

The writer would particularly like to have a more extended explanation of the moisture factor M. In part this factor as presented in Eq. 1 parallels somewhat the procedure, which the writer described,[16] in which he derived a moisture factor and gave it the same symbol M in order to relate infiltration capacity to antecedent precipitation. However, Mr. Hicks has introduced an evaporation factor which is fundamentally desirable. His value E apparently is not an evaporation rate, but some inverse function if the moisture factor is to increase with E. Further explanation of this factor would be desirable.

In recent design practice in the writer's office, particularly for the drainage of large airports, pattern storms or "design storms" have been derived very much in the manner Mr. Hicks describes. These are set up in hydrograph form and are routed successively from rainfall rate through surface detention to gutter inflow; then through gutter storage to inlet inflow; and finally through a process of routing through conduit storage and offsetting hydrographs to a determination of peak rates along the drainage lines. The writer has found, just as Mr. Hicks did, that, after a number of such designs had been prepared, correlations could be perfected which would give satisfactory, approximate values without going through the routing process for each particular subsection of the system.

Mr. Hicks is to be commended greatly for the fundamental work that he describes. This indicates that one city engineering department is now in a position to design storm drainage on the basis of a full evaluation of infiltration and detention of all classes.

W. I. HICKS,[17] ESQ.—The discussion of this paper includes commendation, requests for additional information and data, and constructive criticism. The writer is grateful for the commendation and will answer the queries and criticism to the best of his ability.

[16] "Rôle of the Land During Flood Periods," by W. W. Horner, *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 1269.

[17] Civ. Engr., Storm Drain Div., Bureau of Eng., Los Angeles, Calif.

Mr. Jarvis has noted certain divergences from agreement of the data plotted in Fig. 12. The writer selected data from seven drainage areas covering a wide range of urban development. As noted in the fifth paragraph of Part IX, there were irregularities in the records for Stations 4, 10, and 11, and Block B, which prevented full analysis of the peak runoff rates.

The record of Station 4, abscissa 1.50 and ordinate 0.80, is found on recheck of computations to be 1.33 and 0.80. As this drainage area is subject to heavy street flow at runoff rates greater than 0.45 in. per hr and to overflow from the drainage area at more than 0.60 in. per hr, agreement of record and computed flow would have been closer if the drainage system had been fully adequate to handle the storm.

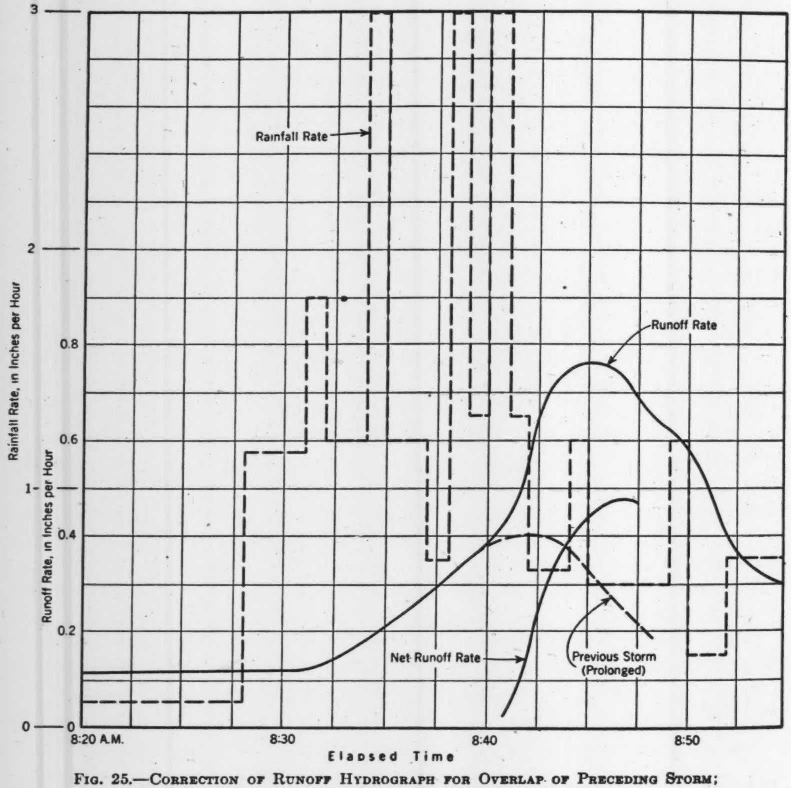

FIG. 25.—CORRECTION OF RUNOFF HYDROGRAPH FOR OVERLAP OF PRECEDING STORM; CITY BLOCK 4841, ST. LOUIS, MO., SEPTEMBER 28, 1919

Several of the records of Block B are subject to correction for overlap of preceding storms; one of these is analyzed in Fig. 25 for the point with an abscissa of 0.36 and an ordinate of 0.76. The peak at 8:45 a.m. is the result of rainfall from about 8:36 a.m. to 8:45 a.m. ($t_c = 9.2$); the rain prior to 8:36 a.m. would have caused a peak, if the rainfall had ceased at that time, with approximate shape and position as delineated ($t_c = 12 \pm$). Although no conclusive evaluation can be placed on its value nor on its recession curve, since no peak actually was formed in the record, it is apparent that the computed peak is more nearly in agreement than the plotted point indicates.

Station 11 is subject to heavier losses than would normally be expected on impervious areas, which accounts in part for the excess of computed peaks over actual peaks for that station. Although it may have been an error to include these divergent records in Fig. 12, they were included as being a part of the data; the writer considers that the computation method is substantiated by the predominance of points falling within the 20% tolerance zone and the possibility of explaining the divergence of some of the other points.

In compliance with Mr. Jarvis' suggestion of the possibility of computing a value of C from the data in Table 12 in the Rational Formula,

$$C = \frac{q_1}{I} \qquad (10)$$

Table 17 was prepared. It is largely self-explanatory: Cols. 1 to 5, inclusive, are prepared as Mr. Jarvis suggests, and the remaining columns are devoted to computation of a coefficient C_1 modified by the moisture factor M and the

Low values			72	....	....	....	....	....	....	85	....

shape factor F embodied in I_H (Col. 6, Table 17). The factor I_m (Col. 8) is the rainfall rate for the time of concentration (Col. 7) for the standard rainfall curve having an hourly intensity I_H. The modified C_1 is expressed in the equation,

$$C_I = \frac{q_3}{I_m\, M^{A_{px}}} \qquad (11)$$

The divergence between average high and average low ratios of q_c/q_1 in Table 12 is from about 118% to 87%; that for C is from 137% to 72%; and that for C_1, from 118% to 85%. Thus, for an area of stated physical and rainfall characteristics, Mr. Jarvis is correct.

However, to follow through with computation of runoff coefficients based on the ratio of observed runoff to observed rainfall without analysis and synthesis of the various factors affecting runoff, it will be necessary to gather and analyze data from a much greater number of drainage areas of different sizes, soils, and states of physical development. Although the possession of such data is greatly to be desired, it is doubtful whether personnel and money will be available to acquire it except through the passage of many years. In the meantime, the method of analysis and synthesis, refined and revised, as Mr. Jarvis suggests, by the accumulation of additional authentic data, holds forth the greater promise for current and future design. It is more flexible by reason of the use of the distribution factor (Fig. 5) and the factor for adjusting confluence of dissimilar areas (Fig. 14); when the designer has mastered its not too difficult method of operation, he will approach his problem with a clearer understanding of the fundamentals involved.

The area limitation in the paper has been set by the 120-min time of concentration set up in Figs. 5 and 16 and Table 7; larger areas can be handled by a reasonable extrapolation or by use of the Method of Summing Hydrographs.

In answer to Mr. Jens' questions on the factor M, the relations found by Eq. 5 led to the statistical analyses of rainfall data from the local Weather Bureau of the two composite factors, $I\ F$ and $I\ F\ M$. For loam or clay pervious areas, the maximum value of $I\ F\ M$ (not necessarily of $I\ F$) will cause the maximum runoff. Therefore, the seasonal variation of M is embodied in the data and need not be considered further in design. These analyses were made for several time durations and it was found that the resultant M was slightly greater for the short durations. On account of the small variation, it was ignored for the sake of simplicity in computations. However, in the analyses of individual rainfall-runoff records, M was computed from the data for each storm.

TABLE 18.—SLOPES FOR DRAINAGE AREAS IN FIG. 1 (PERCENTAGES)

Station No.	Overland			Gutter			Drain		
	Minimum	Maximum	Average	Minimum	Maximum	Average	Minimum	Maximum	Average
3	0.6	50.0	15.0	0.50	22.0	4.25	0.75	8.51	1.036
4	0.6	10.0	2.6	0.25	7.50	1.61	0.33	2.67	0.946
10	1.75	6.00	2.42	1.13	1.13	1.13	....	....	....
11	1.27	6.30	2.70	0.20	2.00	0.92	....	....	....

The additional slope data requested by Mr. Jens for drainage areas in Table 1 are given in Table 18. It is true that lag time is dependent on these slopes as well as on the shape of the drainage area and the distribution of impervious development therein. In Fig. 9(d), lag time is shown as a function of the time of concentration which in turn is a function of the slopes of the surfaces and the channels of flow. The shape of the area and the distribution of impervious development determine the point of the maximum quick concentration of runoff; the elapsed time between this point and the gaging station is the lag time.

It is gratifying to learn that Mr. Jens finds the straight-line relationship between volume of storage and rate of discharge in his study of open-channel recession curves. In Eq. 7, K corresponds to the inverse of $\frac{\Delta D}{\Delta q}$ in Figs. 8 and 9(a).

From a theoretical standpoint, Mr. Jens is correct in his contention that the loss of rainfall on an impervious surface is a fixed amount. On broad drainage areas, however, absolute imperviousness is a goal reached only in varying degrees of perfection. In determining the amount of loss of rainfall on impervious areas, data were used from impervious Stations 10 and 11, and from experiments on overland flow on impervious surfaces. In the case of Stations 10 and 11, analyses were made as in Figs. 6 and 7, and the amount of rainfall and of loss between control points was determined. The average rate of loss is plotted as an ordinate against the corresponding average rate of rainfall in Fig. 26. The results indicate an increase of loss rate with an increase of rainfall rate. The higher loss for Station 11 offers some possible explanation: Paving grades are flatter with a consequent wider spread of flow; the pavement is not fully impervious; numerous utility and sanitary sewer manholes furnish small avenues of escape; and sidewalks around basement openings and area lights allow leakage into the basements. These deductions are substantiated by the facts that street railways use ballast subdrains, that public utilities pump out their conduit systems and the city outfall sewer runs under heavy pressure for an extended period after heavy rains, and that numerous buildings use basement pumps. The use of 10% instead of the higher percentages indicated in Fig. 26 was determined by the smaller percentage of loss in the

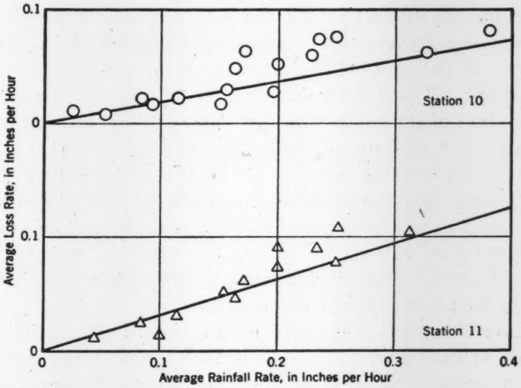

FIG. 26.—VARIATION OF LOSS RATES WITH RAINFALL RATES ON NOMINALLY IMPERVIOUS AREAS

overland flow experiments, the comparatively pervious soil under Stations 10 and 11, and the better surface drainage which an adequate storm drain system offers.

Mr. Jens' analysis of the storage equation is the most effective which the writer has encountered in that it avoids the tedious trial-and-error method so commonly used. Its use will furnish relief in reservoir problems where the inflow is translated to the gates and spillway of the dam by a high-velocity deep-water pressure wave. The complex pattern of velocities in the cross section of a conduit makes difficult the accurate determination of the changing shape of the hydrograph as it progresses downstream. In the studies leading to the method of peak-rate reduction used in this paper, investigations were made of a number of mathematical solutions of the storage equation; none seemed to fit the behavior of the hydrograph. The storage equation method, when applied to conduit flow, has the following inconsistencies: (*a*) It tends to shorten the near-peak-rate duration of flow instead of spreading the reduction in the vicinity of the peak; (*b*) computation for a 5-min reach of conduit shows much more than five times the reduction computed for a 1-min reach; and (*c*) the lag between the peaks of the inflow and the outflow hydrographs seems to bear no definite relationship to the time of flow in the reach of conduit selected. For example, in Fig. 23 the lag is about 5 min, whereas the time of flow is about 17 min in the 5,585-ft reach.

Hydrographs of storm drain flow, as gaged (Figs. 6 and 7) and as standardized for storm drain design (Fig. 15), are characterized by the sharp rate of rise on the accretion side of the curve and a comparatively short duration of near-peak rate, which duration increases with the time of concentration. These characteristics suggest a greater rate of peak-rate reduction for the slender hydrographs with small times of concentration than for the broader peaked, longer time hydrographs. The volume of available storage in a conduit t_f minutes long is the product of the length and the cross-sectional area, or $60\, t_f\, V \times Q/V = 60\, t_f\, Q$ cubic feet (see step 3 under the heading in Part VII, "Reduction of Peak Rate"). Since this volume of storage is independent of the slope or velocity of the conduit, the percentage of peak-rate reduction, computed by any method, remains constant regardless of the slope or slopes of the conduit. Based on these considerations and on the fact that Eq. 4 was derived from a study of the elements of actual hydrographs, the method of computing peak-rate reduction used in this paper was adopted.

The method of reduction is based on a standard shaped hydrograph. If, in the process of summing, the resultant hydrograph becomes so irregular as to not conform in shape to a standard hydrograph of any time of concentration, then Mr. Jens' objection to a standard method of reduction is correct. However, if the time of concentration is large, the percentage indicated in Table 7 is so small that no great error will be incurred by its use.

In discussing Eq. 5, Mr. Horner has assumed that either the summation of hydrographs or Eq. 5 is used in design practice. Under the heading, "VIII. Methods and Form of Runoff Computation," the Peak Rate Method is recommended for use except for stated conditions which require the Method of Summing Hydrographs. Eq. 5 has a limited special use on areas for which rainfall and runoff gagings are available.

Symbol M is an empirical factor derived from studies of rainfall-runoff data on pervious and partly pervious areas for the purpose of gaging the effect of antecedent precipitation, wind, temperature, etc., on the loss of storm precipitation into the soil. The writer also noticed its resemblance to the M derived by Mr. Horner.[16] Analyses of its effect on runoff were made with Eq. 5 for areas having different percentages of pervious area. It was used in the form M^{A_p} because, as A_p approaches 0 for impervious areas, M^{A_p} approaches unity.

The factor E is introduced to weight M for the seasonal variation in the amount of soil moisture loss. It was derived arbitrarily as follows: (*a*) Evaporation quantities for Fallon, Nev., California, Ohio, and Kingsbury, Calif.,[18] were averaged and summed for the calendar year; (*b*) the summation was converted into percentages of the total for the year; (*c*) for dates at regular intervals, the percentages covering 60 days antecedent were tabulated and plotted as ordinates on abscissas of the dates; and (*d*) these percentages, increased by a uniform 10%, were subtracted from 100% to form the E-curve.

In regard to the time required for design procedure by this method, the writer has encountered the same objections mentioned by Mr. Horner. In practice, the new method requires no more time than the Rational Method when applied to the routine peak-rate design which constitutes the bulk of municipal work, and it offers a comparatively simple method of solving special problems, such as retarding reservoirs, etc.

As the method of design in this paper was formulated for the solution of metropolitan Los Angeles drainage problems, informal discussion has raised the question of its applicability to other localities. The method is based on the following local fundamental data:

A. Rainfall
  1. Intensity-Duration Curves (Fig. 1)
  2. Variation of Rainfall Volume with Location (Fig. 2)
  3. Pattern of Major Storms (Fig. 3)
  4. Antecedent Precipitation (Moisture Factor M) (Table 5)
  5. Rainfall Distribution Factor (Fig. 5)

B. Soil Losses (Fig. 4)

C. Classification of Drainage Areas (Table 6)
  1. Percentages of A_d, A_i, A_p.
  2. Lengths and Slopes for Overland Flow
  3. Typical Block Dimensions

D. Climatic Conditions
  1. Temperature
  2. Humidity
  3. Frozen Ground—Snow
  4. Dry Weather Soil Cracking

Since these local data are used in constructing the table of basic peak runoff rates (Table 7), the charts of runoff factors (Fig. 13), and other tables and charts used in design, it is apparent that changes in the basic data would involve varying degrees of change in such tables and charts. The process of developing a runoff design method in another locality would be to analyze the data for that locality, derive the fundamental information indicated by the numbered figures and tables in the foregoing outline, and, by the methods of this paper and the previous paper by Messrs. Horner and Jens,[4] construct new tables and charts for design.

---

[18] "Handbook of Hydraulics for the Solution of Hydraulic Problems," by Horace Williams King, 3d Ed., McGraw-Hill Book Co., Inc., New York, N. Y., 1939, p. 444.

In other localities, use may be made of the charts and tables of this paper for peak runoff rates (not necessarily for shape of hydrograph, which is dependent on storm pattern) from areas having negligible or no percentages of pervious area (impervious business and manufacturing, apartment house, and bungalow court classifications, Table 6). As it is possible that intensity-duration curves for other localities will not have the same shape and pattern as those in Fig. 1, it will be necessary to use the following equation to secure the hourly rainfall rate for determining the runoff factor (Fig. 13):

$$\frac{I \text{ (for stated } t_c \text{ from their local rainfall curve)}}{I \text{ (for stated } t_c \text{ from 10-yr curve, Fig. 1)}} \times 1.01 = I_H \ldots\ldots (12)$$

The value of I_H will be amended by the distribution factor (Fig. 5), if the area exceeds 100 acres, before it is used to determine the runoff factor. The product of the runoff factor and the basic peak runoff rate (Cols. A, Table 7) is the peak rate of runoff, in cubic feet per second per acre. Because of possible variation of the shape of the intensity-duration curve and of the rainfall distribution factor, the solution will be subject to some error.

RÔLE OF THE LAND DURING FLOOD PERIODS

By W. W. Horner,[1] M. Am. Soc. C. E.

With Discussion by Messrs. L. K. Sherman, Raphael G. Kazmann, W. G. Hoyt and W. B. Langbein, Charlie M. Moore, Waldo E. Smith, P. B. Rowe, C. S. Jarvis, and W. W. Horner.

Synopsis

The rôle of the land discussed in this paper is that which determines, from any specific precipitation period, the stream-channel inflow, which will result directly therefrom, and which will occur during or immediately following that period. Stream-channel inflow of normal ground water, from the water table, is not discussed in detail. This paper recognizes that this "rôle" is not a matter peculiarly related to "flood" periods, but that the land effect during flood periods is merely a special case of its effect during any period of precipitation.

The rôle of the land is discussed in its abstractive or retentive effect, determining the volume of related runoff, and also in its detentive effect as a partial determinant of the shape and timing of the hydrograph of channel inflow.

The principal controls of the land are given as surface retention, infiltration capacity, surface detention, subsurface detention, subsurface storage, and the facility for quick subsurface return outflow to the stream. It is stated that for the greater part of the land area, infiltration capacity is the most important determinant, but that for other parts, subsurface retention and detention capacity may be the limiting element. Quantitative values are discussed and an illustrative example is presented; some space is given to the type of basic data needed for a true evaluation of the controlling elements, and the extent to which the data are becoming available is the subject of comment.

PART I.—INTRODUCTION

The objective of this paper is to discuss the manner in which a rainfall pattern, during a generally continuous period of precipitation, is modified and transformed by the land into a pattern of occurrence of stream-channel inflow

---

Note.—Published in May, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Cons. Engr. (Horner & Shifrin), St. Louis, Mo.

for a directly related rise of the hydrograph. For the sake of brevity, it is necessary to limit the scope of this paper to precipitation falling as rain, and to unfrozen ground.

The effects of the land with its vegetal cover fall into two general classes—(*a*) the retention effect, by which some or all of the rainfall is abstracted and stored and does not appear as stream-channel inflow or contribute to any directly related rise of the stream hydrograph, and (*b*) the detention effect through which the diagram of channel inflow is offset or delayed and modified with respect to the pattern of excess rainfall.

The paper traces the paths followed by water from its state as precipitation to its state as channel inflow, and the character of the controls that the land exerts on the water along these paths. It is recognized that the quantitative values of these controls, such as infiltration capacity, surface retention and detention, subsurface retention and detention, and subsurface return flow, are what they are, at the beginning of a storm period, because of the forces and effects that have been active during an antecedent period. During the antecedent period, the processes of evaporation, transpiration, and of percolation and subsurface discharge to the stream are the pumps which are evacuating ground storage space removing surface storage from the ground, and permitting, in varying amounts, changes in soil structure. These forces and effects are in a sense the "stagehands" which prepare the "setting," and what they accomplish prior to the rain has a very large relation to the type of performance which the principal "actor," precipitation, may produce with respect to storm runoff. Since this paper involves only the relationship between the precipitation and the channel inflow resulting from that precipitation, no consideration is given to channel inflow from the normal ground-water table, and the rise of the hydrograph is visualized as occurring from the excess channel inflow over and above normal ground-water inflow or base flow.

PRECIPITATION PATTERN

For the purpose of this presentation, it is assumed that precipitation occurrence may be treated in its pattern form. This pattern, depending upon the relative magnitude of the areas involved, preferably may be considered in intervals of 10 min, 1 hr, or even 3 hr. Mean values of precipitation for periods appreciably in excess of 1 hr are so different from the actual intensities that make them up, that their relation to controls, such as infiltration capacity rates, becomes obscured, and they may not be used except for generalization. This criterion becomes the more obvious when it is recognized that hydraulic procedures related to the flow in the streams must be based upon reasonably accurate patterns of inflow, and that only for the very large stream systems can mean inflow rates for periods greater than 6 hr be used to advantage in such procedures as flood routing, or in evaluating the effects of channel storage.

LAND CONTROLS

The effects of the land in modifying the amount and pattern of precipitation into an amount and pattern of channel inflow may be classified into five steps. There are two paths "a" and "b" which the precipitation at the soil surface may take in the direction of contributing to the stream-channel inflow, and along these paths the principal controls which the land exerts are:

I. Interception.—Storage, retention by and on vegetation, commonly referred to as interception. The precipitation not retained by vegetation will be referred to as rainfall at the soil surface.

II. Separation at the Soil Surface.—This is controlled by the relation between rainfall intensity at the soil surface and infiltration capacity. It divides the precipitation at the soil surface into (*a*) excess rainfall producing surface runoff and (*b*) accretion to soil moisture.

III. Storage.—

(*a*) The excess rainfall produced and remaining above the surface in Step II(*a*) may be retained in part in surface depressions, and is referred to as "depression storage." Excess rainfall minus depression storage becomes surface runoff as overland flow.

(*b*) That part of the rainfall at the ground surface which is infiltrated through the ground surface (Step II(*b*)) increases soil moisture initially up to the point of satisfying capillary deficiency.

IV. Detention.—

(*a*) Surface runoff in overland flow (Step II(*a*)) requires the detention of some part of the runoff in order to build up a film of water through which runoff can occur. Such surface detention does not of itself reduce the amount of channel inflow but modifies the time and rate of inflow occurrence. However, after the cessation of precipitation some water will infiltrate out of the surface detention film and surface runoff will be reduced further by the amount of such post precipitation infiltration.

(*b*) Accretions to soil moisture, in excess of capillary deficiency, represent free soil water and may be referred to as subsurface detention.

V. Runoff.—

(*a*) Surface runoff (Step II(*a*)) as reduced by infiltration out of surface detention (Step IV(*a*)) becomes channel inflow.

(*b*) Free soil water (Step IV(*b*)), when accumulated in sufficient amount and where the ground-water gradients are steep, may return to the surface, at stream margins or at the foot of steep slopes, in time to contribute to the rise of the hydrograph. For such conditions it may be referred to as quick subsurface return flow.

Values of these determinants are functions of soil surface, soil depth, soil composition and structure, and of soil slope; but they are also functions of the vegetal cover. Quantitatively they can be discussed only in terms of characteristic "complexes" or combinations of soil and cover.

SURFACE STORAGE OR RETENTION

The terms "surface storage" and "surface retention" in this paper include that part of the precipitation which does not appear either as surface runoff or as infiltration during the period of precipitation. It includes: (*a*) Interception by vegetal cover; (*b*) depression storage; (*c*) evaporation during storm period; and (*d*) surface retention.

(*a*) *Interception by Vegetal Cover.*—This item may be negligible with respect to major floods, but may affect the magnitude of minor floods appreciably.

Published values of interception generally are annual, seasonal, or monthly, but some information for precipitation periods is available. The areal holding capacity of the vegetation must vary with the density, percentage of canopy cover, character of leaf and stem surface, and similar factors. It is also subject to precipitation intensity and to wind effect. It will vary, therefore, with seasonal, crop, or vegetation conditions.

Interception for bare or fallow land, of course, is zero. Studies of interception by crop vegetation at Clarinda, Iowa, indicate that for corn, alfalfa, and clover, it may be as much as 0.5 in. for some types of storm and maximum vegetative development. It will generally range[2] from 0.05 in. to 0.20 in. when the precipitation in a storm period exceeds 0.5 in.

Studies at Bethany, Mo., indicate that for storms having a precipitation in excess of 0.5 in., and during a period of maximum vegetative development, alfalfa will intercept 35% of the precipitation, corn and soybeans from 13% to 17%, and oats 6%. Blue grass, exclusive of the holding power of the litter, seems to have a value between the latter two groups. Between the fallow and the maximum vegetative condition of the fields, the values probably would have a seasonal trend.[3]

TABLE 1.—PERCENTAGE OF RAINFALL INTERCEPTED BY TREES

2	Pines[a]............	0.09	0.13	0.19	0.24
3	Various trees[b].....	0.14	0.25	0.48	...

[a] Unpublished manuscript, Appalachian Forest Experiment Station. [b] "Rainfall Interception," by Robert E. Horton, *Monthly Weather Review*, September, 1919.

Studies by the Southern Appalachian Forest Experiment Station, shown in Items 1 and 2, Table 1, indicate the range of canopy interception, in inches of depth, for storms throughout the year. The values in Item 3 were determined by Robert E. Horton, M. Am. Soc. C. E., for summer and fall conditions in New York State; whereas Items 1 and 2, Table 1, are for the forest as a whole, Item 3 is for the projected area under the tree crowns.

(*b*) *Depression Storage.*—This represents water trapped on the surface in natural depressions, or artificial depressions, such as furrows under ordinary land management. When, in addition, water is trapped or stored by structures provided for that purpose, such as closed terraces, pasture furrows, or ridges, it is generally referred to as "mechanical storage." Water retained as depression storage at the end of the precipitation period is disposed of by evaporation and infiltration, and does not contribute to channel inflow during the "flood" period.

(*c*) *Evaporation During Storm Period.*—The definition of surface storage in this section includes evaporation during the precipitation period. In general, this is materially less than 0.01 in. per hr, and is of little importance even with respect to minor floods. For long rains and for heavy vegetal cover, evaporation from canopy interception may cause an appreciable apparent increase in interception losses.

[3] "Interception of Rainfall by Vegetative Canopy," by J. L. Haynes, Annual Meeting of the Am. Soc. of Agronomy, 1937 (unpublished).

(*d*) *Surface Retention; General.*—In the course of deriving infiltration-capacity values for small gaged watersheds, rainfall and surface runoff are segregated for separable portions of the hydrograph, calling Δt the mean time of infiltration opportunity for such a portion. Then infiltration capacity is

$$f = \frac{P - Q - s}{\Delta t} \qquad (1)$$

in which precipitation P, surface runoff Q, and the surface storage or retention s, are values for that portion. The retention is the sum of interception and depression storage during that portion. The quantities P, Q, and Δt are known; by trial and elimination, values of s may be obtained which will give a rational set of progressively reducing values of f for successive portions of the hydrograph. This procedure is quite sensitive to the value of s, and determines it within rather narrow limits for any storm period producing surface runoff. For the watersheds at Edwardsville, Ill., and Garland and Tyler, Tex., the value of s for crop land and ordinary meadow was between 0.05 in. and 0.15 in. and up to 0.25 in. for Bermuda grass pasture. There were characteristic variations depending on the extent to which interception was filled out of prior rain.

Interception represents a definite abstraction from precipitation and a small but definite reduction in channel inflow for good vegetal cover as compared to bare or fallow land. It appears to make little difference whether it is filled out of light, immediately antecedent rain, or out of the main body of flood-producing precipitation. In the first case, it prevents increase of soil moisture to the extent of its value, with a concurrent prevention of a decrease in initial infiltration capacity. In the second case, it is equivalent to a decrease in precipitation intensity at the ground surface.

Depression storage can appear only after surface runoff begins. For ordinary cultivation or pasture, it seems rarely to exceed 0.10 in. This value does not include surface runoff into large sun checks or shrinkage cracks which appear in clay soils with low moisture content. Such water is treated herein as infiltration, even though not immediately disseminated into the soil mass, thus leaving depression storage as a value related to the soil in its swollen or uncracked state.

INFILTRATION CAPACITY

The conception of infiltration capacity is relatively new in hydrology. It was defined by Mr. Horton in 1935 as—"The maximum rate at which the soil, when in a given condition, can absorb falling rain."[4] Thus it is seen that the term "capacity" in this connection has no relation to volume, but is a limiting infiltration rate.

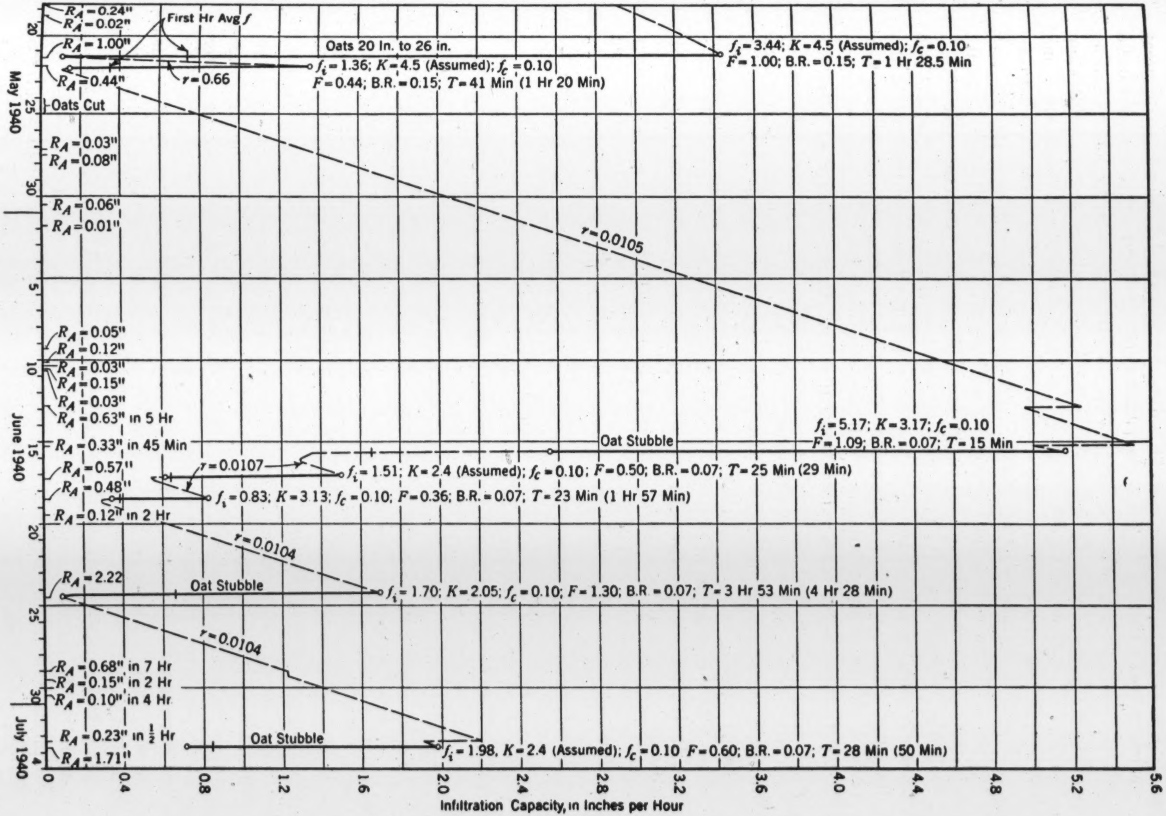

FIG. 1.—RECOVERY OF INFILTRATION CAPACITY BETWEEN RAINS, WACO, TEX. (EXPERIMENTAL WATERSHED SW 16), APRIL 6 TO JULY 3, 1940

Since 1935, infiltration-capacity values have been determined for a great variety of conditions. It seems clear that every soil and cover complex has a related characteristic curve of decreasing infiltration capacity values during a precipitation period. Mr. Horton also stated[4] that "as a rule, infiltration capacity of a given soil passes through a cycle from storm to storm," and illustrates the character of the recovery of infiltration capacity between precipitation periods; further "as the character of the soil and its moisture history are known for a time preceding a given rain, the infiltration capacity which it will have at the time of the rain can, in general, be closely predicted."

These conceptions have been verified by more recent investigations. The understanding of this writer with respect to the mechanics of infiltration and the elements which control infiltration capacity have been presented in another paper.[5] Much additional research will be needed for a complete understanding of the factors that control infiltration capacity. It is sufficient at this time to accept as a fact that each soil and cover complex has a related infiltration-capacity curve, that the values will follow a definite decreasing progression during a period of precipitation where intensities are in excess of infiltration-capacity values, and a somewhat modified curve during the period of precipitation where intensities are less than infiltration capacity.

Mr. Horton's statement with respect to the recovery of infiltration capacity between rains may be illustrated from Fig. 1, the results of a fragmentary study of one watershed at Waco, Tex. The symbols in this curve are defined as follows:

f_i = initial infiltration capacity, inches per hour;
f_c = minimum infiltration capacity, inches per hour;
F = mass infiltration in a storm, inches of depth;
T = compact time of storm (actual time shown in parentheses);
BR = basic retention, inches of depth;
r = rate of recovery, in inches per hour per hour;
R_A = rainfall, in inches of depth; and
K = constant in the equation.

$$f_1 - f_2 = K\,(\Delta F - f_c\,\Delta t) \qquad (2)$$

For lack of better knowledge, the rate of recovery r is shown as a uniform straight line between rains. Further studies will indicate the type of curve which this recovery really follows. It is interesting to note that these average rates of recovery are of the same general order as evaporation from water surface, and show the related seasonal change.

Characteristic curves of infiltration capacity which were derived in the course of investigations on the Trinity River basin in Texas (see Fig. 2) are shown in Fig. 3.

It will be noted that the original definition used the phrase "soil * * * can absorb." Mr. Horton undoubtedly referred to the actual absorption of precipitated water minutely into the soil mass. For certain soils which develop large cracks or sun checks when dry, it seems more convenient to treat infiltration as the disappearance of water below the general ground surface. This results in including, as part of the infiltration capacity, the rate at which surface water runs into open cracks. The effect of this inclusion produces relatively high infiltration-capacity rates at the beginning of the storm, decreasing sharply when the cracks are filled or become closed. However, this inclusion appears to be treated as part of depression storage, and this element would then be quite different in character for a particular ground surface in a normal uncracked condition, and for the same surface after large cracks have developed. The effect of this inclusion is particularly reflected in the high initial capacities and the rapid drop in capacities shown by the curves in Figs. 3(*a*) and 3(*b*).

FIG. 2.—LOCATION OF RAIN GAGES IN THE VICINITY OF THE EAST FORK OF TRINITY RIVER, TEXAS

SUBSURFACE RETENTION AND DETENTION

It is obvious that that part of the soil moisture which satisfies capillary deficiency is definitely held in the soil and cannot become an element of stream-channel inflow. Accretions to soil moisture in excess of this amount represent free water, subject to the laws of ground-water movement. If the ground-water gradients are sufficiently steep and the permeability relatively high, such water may pass laterally to the stream margins or back to the surface at lower

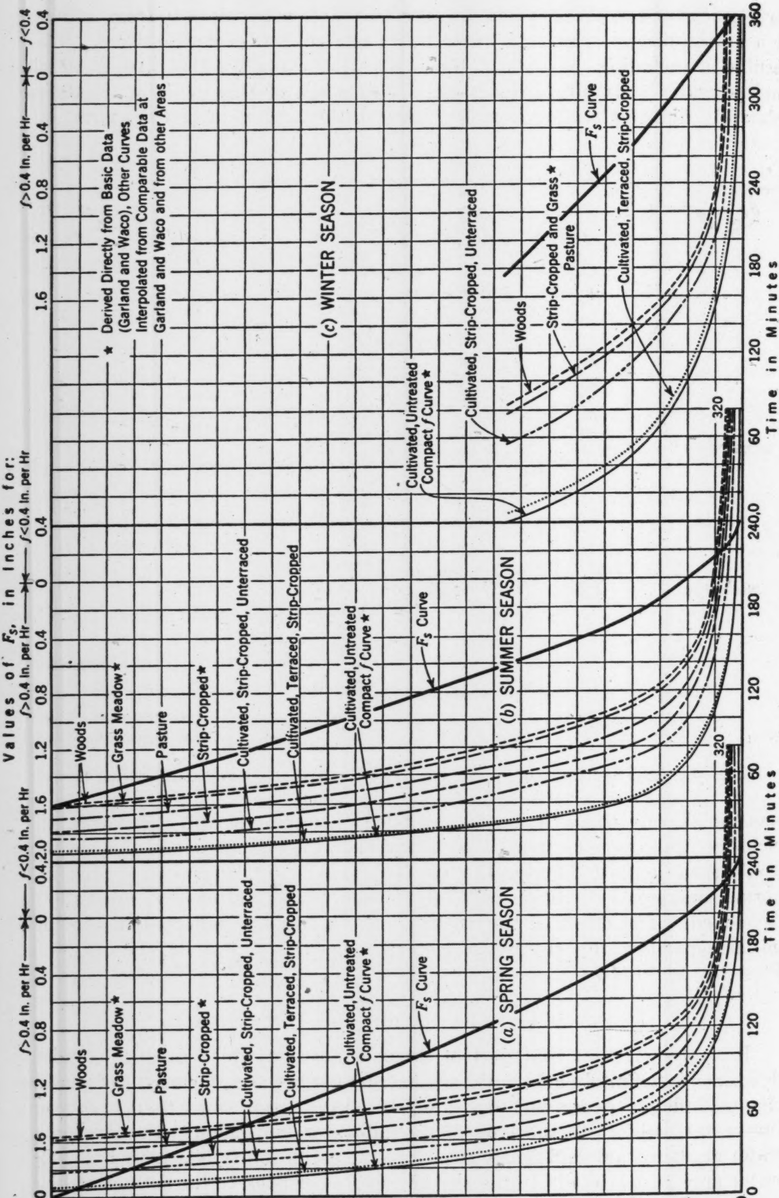

FIG. 3.—INFILTRATION CAPACITY AND CONTROL CURVES DERIVED DIRECTLY FROM BASIC DATA OBSERVED AT WACO AND GARLAND, TEX.; AND OTHER CURVES INTERPOLATED FROM COMPARABLE DATA

lying areas, and may become an important element of the stream channel inflow during the rise of the related hydrograph. On thin-soiled watersheds in mountainous regions a large part of the rise of the hydrograph may be produced by such "quick return subsurface flow." In some such areas, surface runoff may be extremely rare; in other cases where ground-water gradients are flatter, subsurface contributions to stream flow may come later than those from surface runoff resulting in an extended or possibly a double-peak hydrograph. Much information has become available with respect to characteristics of the hydrograph rise where inflow is largely "quick subsurface return water," but, as far as the writer is aware, no practical technique has been presented to the engineering profession that would permit quantitative evaluation of channel inflow from precipitation where subsurface inflow predominated, and for many drainage basins basic data are inadequate for this purpose. It is understood that basic data have been obtained and that such techniques have been developed by the flood control technicians of the U. S. Department of Agriculture. It is to be hoped some information of value in this field may become available in the course of the discussion of this paper.

ENGINEERING TECHNIQUE

As basic data have become available, engineering techniques have been developed for the evaluation of the flood flow which will result from specific precipitation occurrences; these utilize the quantitative values of the controls exercised by the land. In general, depending on the character the land controls, the techniques will fall into two classes.

Class 1.—Infiltration capacity is small to moderate in class 1, and stream-channel inflow occurs predominately as surface runoff. For this class a satisfactory technique is described in its application to the Trinity River basin in a succeeding section of this paper. This situation applies quite widely to cultivated and grass lands.

Class 2.—For class 2, infiltration capacity is generally large. Stream-channel inflow as surface runoff is a small part of the whole. Stream-channel inflow occurs predominately as "quick subsurface return flow." Infiltrated water is retained up to the amount of capillary moisture deficiency. This quantity has been referred to herein as "utilizable storage," but it may be retained also in part by percolation to deep water tables, and may arrive at the stream channel later as sustained base flow. Quantity and rate of stream-channel inflow also will be controlled by soil permeability and ground-water gradients. This situation is found principally in thin-soiled areas of steep topography. Many basic data are becoming available from which quantitative values of the land controls can be derived, but satisfactory techniques appear to be still in the process of development.

PART II.—THE RÔLE OF LAND IN DETERMINING STREAM-CHANNEL INFLOW WITHIN THE EAST FORK OF THE TRINITY RIVER DRAINAGE BASIN IN TEXAS

The physical conditions underlying the problem presented by the East Fork of the Trinity River drainage basin are typical of much of the land area which is susceptible to continuous agricultural use. Under these conditions, subsurface inflow to the stream channel is generally small during the rise of the hydrograph, and commonly constitutes less than 10% of the "flood" volume. Runoff is almost entirely surface runoff. The land abstracts a certain quantity of water above the ground surface—initially through interception and later through depression storage—and removes a considerable part of the precipitation into the soil through infiltration. For moderate storms producing small "floods," the effect of surface storage may be important. For great storms, the reduction effect of the land is determined almost entirely by the contemporary relative values of the ratio of precipitation "I" and infiltration capacity "f."

The drainage basin to which the application herein described was applied is outlined in Fig. 2, and has an area of 831 sq miles. The objective of the investigation was to determine the reduction in flood flow that would be expected to result in the application to this area of the Department of Agriculture program for change in land use and management. An investigation was conducted by the writer with the advice of the other members of the Engineering Consulting Board of the Department of Agriculture (R. E. Horton and L. K. Sherman, Members, Am. Soc. C. E.). The staff available for this work was furnished in considerable part by the flood control organization of that department under the supervision of Howard L. Cook, M. Am. Soc. C. E.

BASIC DATA

The basic data available consisted of (*a*) stream flow, (*b*) precipitation, (*c*) infiltration capacity and surface retention, and (*d*) soil and land use.

(*a*) *Stream Flow.*—The stream flow data consisted of a 16.5-yr record at Rockwall, Tex. The last 5.5 yr of this record was selected for the purpose of this study. During this period, 35 significant rises of the stream occurred; and these records then were found to represent, satisfactorily, the range of flood stages contained in the longer record.

(*b*) *Precipitation.*—Information concerning precipitation was available from the rain-gage stations indicated in Fig. 2. During the first part of the 5.5-yr period the only recording rain gages were those at Fort Worth, Tyler, Garland, and Dallas, Tex. During the latter part of the period, records were also available from the recording gages in Texas at Bonita, Denison Dam, Grant, Mount Pleasant, and Lindale. For many of the nonrecording gages the observers' records were adequate to determine the rainfall in periods of less than one day. On the whole, however, the precipitation information was much less adequate than was desirable, and this inadequacy accounts for some of the discrepancies in the results.

(*c*) *Infiltration Capacity and Surface Retention.*—Detailed rainfall and runoff records were available for several classes of land use at the experimental stations of the Department of Agriculture at Garland and Waco. From these could be derived the regression curves of infiltration capacity, relation of initial infiltration capacity to antecedent conditions and approximate values of "surface retention" taken to include interception and depression storage.

(*d*) *Soil and Land Use.*—Except for a negligible percentage of the drainage basin area the soil is typical of the Texas Blacklands. A detailed survey of the land use had been made and the Department of Agriculture had prepared each program for the revision of land use and management. The distribution of land use with respect to vegetal cover for "present" conditions and for "after" adoption of the Department's program is shown in Table 2. A study of the land-use survey and of the proposed program showed that the various classes of land use were reasonably well distributed throughout the basins and the percentages in Table 2 would apply equally well to each of the ten subdivisions.

TABLE 2.—DESCRIPTION OF LAND USE

Description	"BEFORE"		"AFTER"

Farmstead and non-farm	31,910	6	31,910	6
Total	531,840	100	531,840	100

METHODOLOGY

The methodology employed involved eleven steps, as follows:

1. Collection and correlation of all available precipitation data for each of the thirty-five storms;
2. Preparation of the most probable precipitation intensity patterns;
3. Derivation of infiltration capacity curves for the Blackland soil and various classes of vegetal cover;
4. Correlation of infiltration capacity with antecedent conditions;
5. Application of derived data to the evaluation of surface runoff;
6. Computation of the excess rainfall, hour by hour, throughout the storm;
7. Transformation of precipitation excess into mean values on each of ten sub-areas;
8. Comparison of mean computed surface runoff with actual surface runoff;
9. Determination of excess rainfall for "after" conditions;
10. Computation of flood-flow reduction resulting from the effective adoption of the program; and
11. Determination of flood-stage reduction, and reduction in area inundated.

Step 1.—The character of the available precipitation data has been described previously. The correlation from the information in the various standard gage stations with that at the available recording gage stations involved considerable tedious detail and some actual detective work in the interpretation of the cooperative observers' reports. Some of the observers made excellent records giving the time of the beginning and end of each such part of a storm period and the amount of precipitation in each part. Others gave only daily totals and the reports were often misdated.

Step 2.—The preparation of the most probable precipitation intensity patterns at each of the precipitation stations utilized for the specific storms (generally using five to eight stations) involved first, the plotting of the precipitation pattern by hourly intervals at the recording gage stations; and then the data given by the cooperative observers were placed in a similar pattern form. When the cooperative observers gave the time of the beginning and ending of each precipitation period, the shift in timing and in amount of each such period between the recording and cooperative station was evident. When this information was not available the timing was proportioned between recording gage stations or between stations where the timing was given on a basis of relative distance and position. For full-area storms it is believed that the resulting patterns are quite representative of the actual occurrence. For partial-area storms the problem was more difficult, particularly that of determining the total area covered by the storm. If two recording gage stations had actually been available within the drainage basin itself, the work required under Steps 1 and 2 would have been reduced by at least 75% and the significance of the resulting probable precipitation patterns would have been increased materially.

Step 3.—The problem of deriving infiltration-capacity curves for the Blackland soil and various classes of vegetal cover was simplified by the fact that, to all intents and purposes, only one soil type occurred in this basin, and that the variations in infiltration capacity were primarily those growing out of the difference in vegetal cover, and of antecedent conditions.

Infiltration-capacity curves were derived from the rainfall and runoff records available for a large number of small watersheds at Waco, and for several similar watersheds at Garland. The soils at both places were considered to be fundamentally the same. A review of the resulting infiltration-capacity curves, however, indicated a slight difference, between those from the two stations, which was adjusted in the final averaging.

The basic data were available for cultivated untreated land—that is, normal corn and cotton fields—for cultivation under the strip-cropping method and for grass meadow. Infiltration-capacity values were derived from all storms for a 2-yr period at Waco, and a 1.5-yr period at Garland. For some short storms, on some watersheds, only one point on an infiltration-capacity curve could be determined; but for many of the storms relatively complete curves could be derived. The derived curves were first condensed in time, to the form they would have if produced under continuous excess precipitation, on the hypothesis that

$$f_{t1} - f_{t2} = K\,(\Delta F - f_c\,\Delta t) \qquad (3)$$

in which f_t is infiltration capacity at time t_1, ΔF is mass infiltration in time $\Delta t = t_2 - t_1$, and f_c is the minimum final value of f. The condensed curves then were averaged by seasons for each station and then averaged for seasons for the entire data. Some information of value was also secured from infiltrometer runs.

The average curves were prepared directly from the basic data for the aforementioned three classes of cover. For those classes of cover which did not occur at the Waco or Garland stations, intermediate values were determined from the study of data on other experimental stations where records from such additional cover class were available and comparable. The curves for the remaining complexes were correlated in time with that for the "cultivated untreated" land by observing the time differences between occurrences of the same infiltration-capacity values under different vegetal covers, in each of the storms studied. The resulting curves for all classes of cover under consideration are shown in Fig. 3.

Step 4.—In addition to the derivation of the regression curve a correlation was developed between an index point ($f = 0.4$) on the master curve (that for "cultivated untreated" land) and the antecedent conditions which appeared to control the position of this curve at the beginning of the storm.

The correlation of antecedent conditions is an operation essential to the use of infiltration-capacity curves and is a matter which has been given too little attention.

For each of the storms studied the mass infiltration, occurring in the storm, prior to the time infiltration capacity reached a value of 0.4 in. per hr, was calculated. This is the value for F_s which for the average curves was later endorsed on Fig. 3. These values of F_s were plotted as ordinates on calendar paper for the full year, and a preliminary average curve was drawn through the resulting points.

The departure of the points from the average curve was then studied in terms of antecedent precipitation, and after a number of trials it was found that a new and much smoother curve would be produced if, to the values of F_s, a weighted value of precipitation was added during the antecedent thirty days. This weighted value took the final form of $M_a = \sum (F_a K_{t_d})$, in which F_a was the mass infiltration during a particular storm occurring t_d days prior to the storm under consideration; K varied from 100% for a time, t_d, of one day down to 10% for a period of thirty days.

This second correlation curve was quite significant. A study of the remaining departures from it indicated that these were primarily related to more general variations in soil moisture in different years, and could be reconciled by adding a final value, M_y, equal to 5% of the excess or deficiency of precipitation for ninety days preceding the aforementioned thirty days. The final M-curve in Fig. 4 has been referred to as an "effective moisture index." It is generally rational in form to the extent that it represents the antecedent accretions to soil moisture. It is theoretically defective in that it relates the loss of soil moisture only to elapsed time and does not reflect, directly, temperature or wind. However, these factors are involved in the seasonal position of the curve. Although the M-curve as a whole is entirely empirical in form, a test of its use indicated that it would place the infiltration-capacity curves quite accurately in the storms from which they were derived. It was used with confidence, therefore, in the application procedure described in the subsequent steps. Later studies have shown that, because of the small amount of data originally available for the midsummer and early fall periods, the position of curve should be revised for July, August, and September, and should be raised somewhat in these months. In particular, this reflects a sharp change in soil structure which occurs during these months and which produces excessive soil checking and aggregation.

Step 5.—For each of the thirty-five storms in the selected record for the Trinity basin, antecedent precipitation was reduced to antecedent infiltration and was weighted, as described in Step 4, to determine the value of M_a. The ninety-day value of M_y was taken also from the Weather Bureau records. Subtracting the sum of these two from the ordinate on the M-curve (Fig. 4) gave the value of F_s, or the mass infiltration which would have to occur during the storm period before the infiltration capacity reached the value of 0.4. With this information it was an easy matter to place the correct seasonal average infiltration-capacity curves in their proper position on the rainfall patterns. Highly variable or somewhat intermittent precipitation required the expansion of the infiltration-capacity curves, in time, reversing the procedure for condensing them, described in Step 3. Where there were gaps in the precipitation pattern of several hours or more, recovery of the infiltration capacity across the gaps had to be evaluated separately. An example of the resulting work diagram for the first 6 hr of a 7-hr storm is shown in Fig. 5, with computations for three of those hours in Table 3.

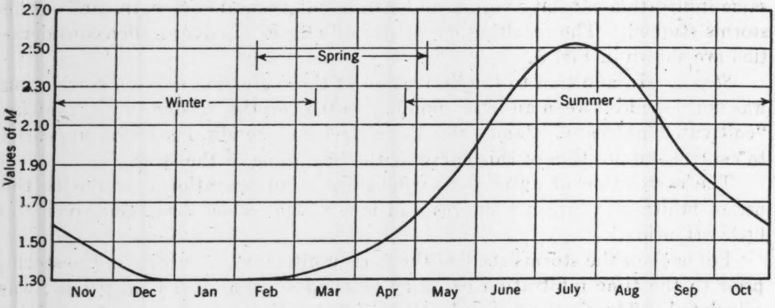

FIG. 4.—SEASONAL VALUES OF M, THE "EFFECTIVE MOISTURE" INDEX

Step 6.—From the related precipitation intensity rates and infiltration-capacity values, the excess rainfall was computed hour by hour throughout the storm. This excess rainfall for "present conditions" (conditions before adopting the land-use program) was modified by making deductions for interception and depression storage, the resulting net value being taken as equivalent to surface runoff.

Table 3 shows the values of surface storage in Col. 5, entitled "Retention," and the percentage of occurrence of various complexes in Col. 9 entitled "Weighted Values of Land Use." The values of surface runoff R_u by hours for each condition are shown in Col. 12, Table 3. This illustrative computation is for only one of the rainfall stations used in the basin. Similar computations were made for the remaining stations, and excess rainfall by hours, for the

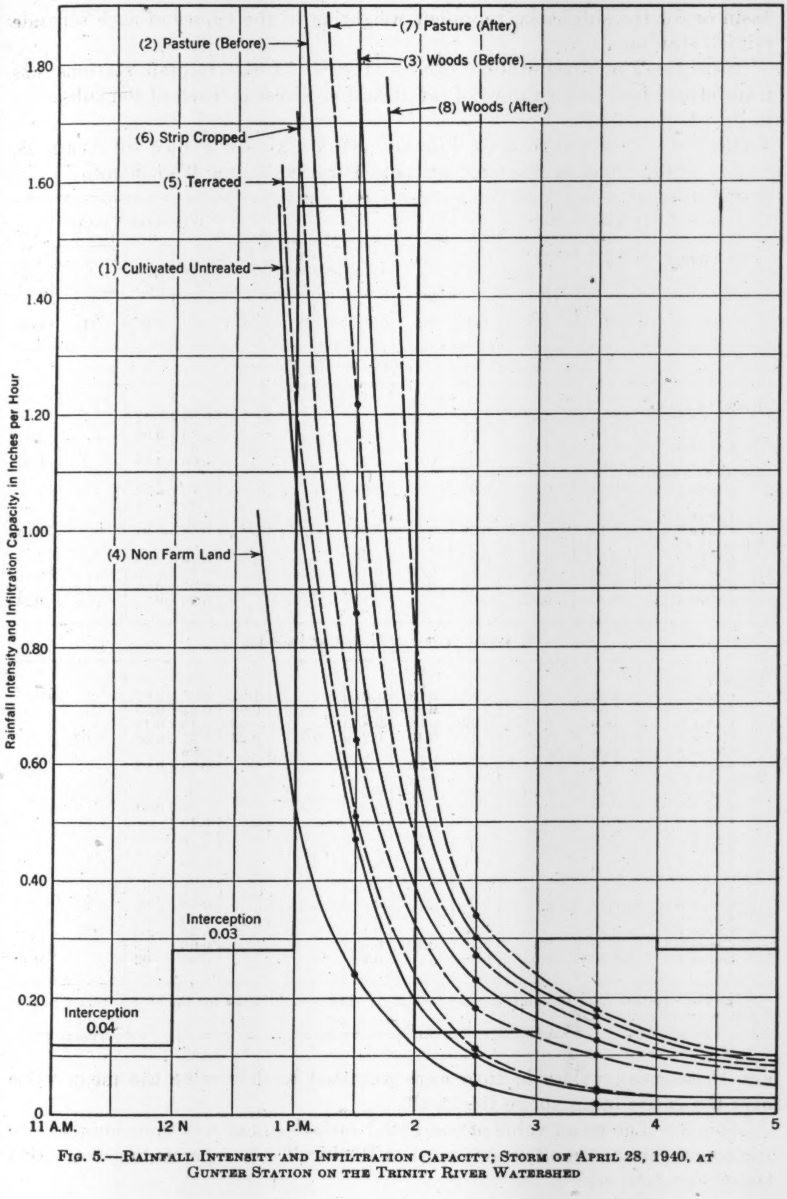

FIG. 5.—RAINFALL INTENSITY AND INFILTRATION CAPACITY; STORM OF APRIL 28, 1940, AT GUNTER STATION ON THE TRINITY RIVER WATERSHED

basin or for the sub-basin, represent weighting of the values of each separate rainfall station.

Step 7.—The precipitation excess at each of the rainfall stations was transformed into mean values of precipitation excess on each of ten sub-areas, and these mean values in turn were weighted to determine the mean value over the entire basin above Rockwall.

[a] The curve numbers refer to points plotted in Fig. 5. The computations for the excess from 4 p.m. to 5 p.m. were not included in the table.

Step 8.—The mean value of computed surface runoff was then compared to the actual surface runoff as measured at Rockwall, and a percentage correction factor was determined.

Step 9.—The parallel procedure for "after" conditions (after adopting the land-use program) results in a determination of excess rainfall for "after" conditions. This computed excess rainfall is modified, not only by making deductions for interception and depression storage, as in Step 6, but must be modified further by making deductions for storage in mechanical structures on the ground. The resulting value of surface runoff when thereafter revised, through the application of the foregoing correction factor, becomes comparable with the actual measured surface runoff under "present conditions" (Table 3(*a*)).

Step 10.—The difference between these values represents the calculated flood-flow reduction in inches, resulting from the effective adoption of the program, and the percentage relationship between the two represents the percentage of flood reduction produced by the program.

Step. 11.—For all of the thirty-five flood rises the actual stage hydrographs at the Rockwall Station were available. Through the use of hydraulic engineering procedure, involving distribution graphs, comparable hydrographs at Rockwall were prepared as representative of the stages at Rockwall.

Using cross sections, the stream slopes between them, and hydraulic factors derived from the Rockwall Station, and other pertinent records, distribution graphs were prepared for some eleven stations upstream from Rockwall.

General.—In the course of the procedure described in Steps 5 to 7, inclusive, surface runoff was evaluated hour by hour throughout the storm at each of the rainfall stations utilized. The values of excess rainfall in this pattern form were then transferred to mean values of excess rainfall not only for the basin as a whole but also on each of ten sub-areas. From these mean values for the sub-areas, mean values were determined for each hour for the area as a whole above each of the cross-section points. These records become the "excess precipitation patterns" which were applied to the appropriate distribution graphs in order to produce the most probable hydrographs of flood flow at each particular cross-section point.

In the subsequent step these discharge hydrographs are transformed to stage hydrographs, representative of the stages for both "before" and "after" conditions. A comparison between them results in an evaluation of flood-stage reduction at each of these stations.

In a later stage of this project "before" and "after" flood stages were utilized as a basis for determining the reduction of acreage inundated for each reach of the river and these figures were used as a basis for the determination of the reduction in flood damage.

PRESENTATION OF RESULTS

The results of the study for the thirty-five storms are presented in Table 4, which extends the study through to the evaluation of the reduction in flood flow as a percentage of volume. In order to obtain a reasonably accurate representation of both rainfall depth and area covered for partial-area storms (Table 4, Nos. 2, 3, 6, 7, 8, 9, 15, 18, 19, 32, 33, 34, and 35) the preparation of isohyetal maps was necessary. For several of the storms the rainfall information was fairly satisfactory for this purpose and resulting maps prepared entirely from rainfall information were adequate for the purpose of the study.

For storms 6, 7, 13, 34, and 35, however, the rainfall information was not adequate and the measured runoff was used as a guide in preparing the maps. For all except these five storms excess rainfall was computed from precipitation and infiltration-capacity information, and the resulting values, reduced to mean inches of depth, are shown in Cols. 4 and 5 for comparison with the measured runoff at Rockwall shown in Col. 3. Col. 6 shows the correction factor by which the computed runoff would have to be multiplied to make it equal to the measured runoff. This factor is the test of the validity of the procedure and has been restudied for the twenty-three storms having a volume of runoff of more than 0.25 in. For the purpose of such analysis the factors have been grouped by seasons and by amounts of runoff, and results are shown in Table 5.

[a] Both Thiessen and proportional weightings shown if computed. [b] Surface runoff only. [c] Base flow included.

In general, it appears that the use of the derived infiltration-capacity and surface storage data, applied in this manner, will reproduce the measured flood flow to a reasonable degree and can be made equal to it through the use of a rather uniform correction factor. For this project the rainfall data were relatively unsatisfactory, particularly in the first part of the 5.5-yr period. No recording gage was within the basin, and considerable use had to be made of the timing shown on the observers' reports.

It is interesting that the computed values were less than the actual stream flow during the winter and spring months, and exceeded the actual stream flow during the summer and fall months. The most probable explanation is that the watersheds for which infiltration-capacity values were determined were largely on the uplands, and that during the winter period a part of the drainage area located on the lower slopes of the bottom lands had a higher average moisture content, a lower infiltration capacity and consequently a greater amount of excess rainfall than that reflected in the computations. The reverse difference for the summer and the fall storms probably reflects the generally

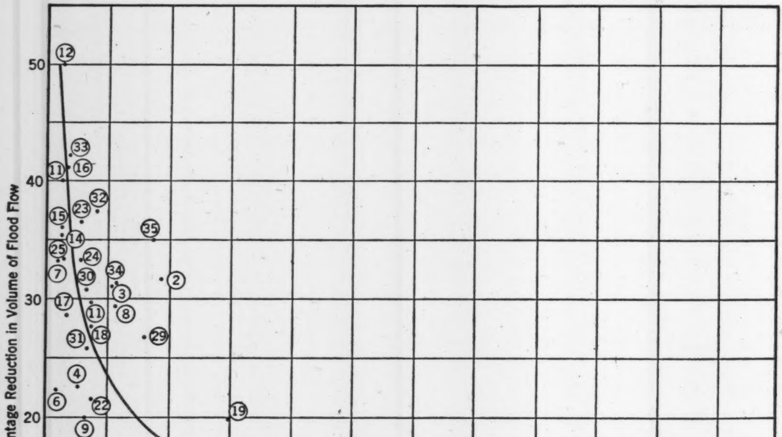

FIG. 6.—FLOOD REDUCTION CURVE, EAST FORK OF THE TRINITY RIVER NEAR ROCKWALL, TEX.

Referring to the infiltration-capacity curves in Fig. 3(b), it will be noted that they are similar in shape, that they are offset in time, and that they have a small but appreciable difference of infiltration-capacity values at the end of several hours. For the shorter storms, the difference in time position probably accounts for the major part of the difference in runoff—as, for example, between grass lands and "cultivated untreated" lands. For the long storms, the relatively small differences in the lower part of the curve account for material difference in total runoff.

The relation of flood reduction to the size of the storm is shown by Fig. 6. In this diagram no effort has been made to distinguish between storms of different seasons. Storm 13 was omitted because the precipitation was partly snow and sleet.

It is of speculative interest to determine from these data what the relative difference in runoff would be if the entire drainage basin had been uniformly in one type of vegetal cover. As an illustration, the values of excess rainfall or total runoff for one storm have been summarized separately for each class of cover. The results of this illustrative computation for the East Fork of Trinity River at Rockwall (storm of April 28, 1940) are as follows:

Discharge, in Cubic Feet per Second:	
Crest	9,850
Bank full	1,500
Rainfall-Runoff Depths, in Inches:	
Weighted rainfall	2.38
Measured runoff	0.78
Computed runoff, P_e	0.96
Correction factor to be applied to all computations (%)	81

The computed and corrected volumes of runoff are:

Present conditions	0.78
Department of Agriculture program	0.57
Entire Basin:	
Cultivated untreated	0.89
Present pasture	0.45
Managed pasture	0.16
Present type woods	0.12
Managed woods	0.08

Undoubtedly a similar computation for the larger floods would show somewhat less difference between runoff under the different types of cover. The foregoing is illustrative of the effect of cover on the retention of the water, for one single soil type.

TRANSLATION TO CREST RATE AND STAGE REDUCTION

The procedure described in Step 11 is outside of the scope of this paper since it is in the field of the channel phase of runoff and not of the land phase. It has been described merely to show the continuity of the technique and the relationship of the end-point results to the objective of the particular study. As a matter of interest the summary of the results of the applications under Step 11 are shown in Fig. 7 in terms of the reduction in crest-discharge rate at Rockwall for storms having the average recurrence intervals indicated as abscissas. Comparing Fig. 7 with Fig. 6 it will be noted that there are material differences in the position of the individual points, as would be expected from the differences in the shape of different hydrographs. The resulting mean curves, however, on the two figures are quite similar. For the larger storms the percentage reduction in crest rate is a little greater than the reduction in flood volume; whereas, for the smaller storms, the reverse is true.

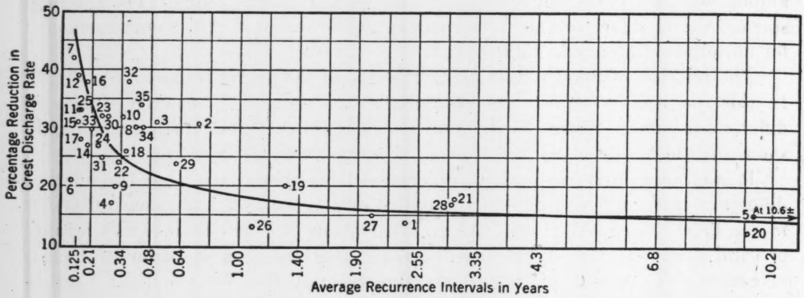

FIG. 7.—REDUCTION IN CREST-DISCHARGE RATE

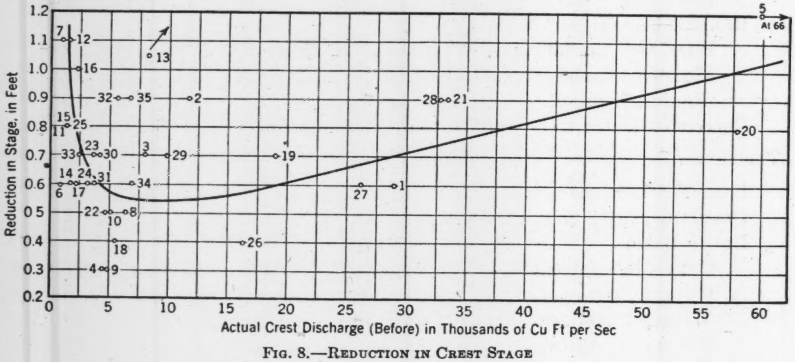

FIG. 8.—REDUCTION IN CREST STAGE

The application of the Rockwall rating curve to the "before" and "after" crest rates produces the values in crest stage reduction shown in Fig. 8. Similar determinations were made at other cross sections along the stream.

PART III.—RÔLE OF THE LAND DURING FLOOD PERIODS

GENERAL

All of the land controls have a common background and a characteristic related to the geology and the climate of the region, which has been well stated[6] by W. G. Hoyt, M. Am. Soc. C. E., and Walter Langbein, Assoc. M. Am. Soc. C. E.:

> "The ability of the soil and vegetation to serve as agencies for the disposal of potential flood-water is in a large sense a climatic factor. It depends

---

[6] "Some General Observations of Physiographic and Climatic Influences on Floods," by W. G. Hoyt and W. B. Langbein, *Transactions*, Am. Geophysical Union, Vol. 20 (1939), p. 166.

> not only upon the composition and gradation of the soil and the density and type of the vegetation, but also upon the degree to which their absorptive capacity has been utilized. All of these factors are largely reflections of their particular climatic environment experiencing seasonal changes in accordance with the established climatic regimen. Two principal factors that influence the soil and vegetal characteristics are those of precipitation and temperature. Thus it is observed that not only do precipitation and temperature affect the supply but also the ability of the soil to serve as a vehicle for its disposal."

It is necessary to recognize that "outstanding flood periods" are the result not only of great storms, but of the coincidence of great storms, and sometimes lesser storms, with the occurrence of either low infiltration capacity or small utilizable storage condition. In the Trinity basin of Texas (not in the semi-arid section) autumn storms of 7 in. often produce a fraction of an inch of runoff. In the southern Appalachian forest region it is reported that heavy storms, in July and August, of from 8 in. to 10 in. sometimes have not satisfied field moisture deficiency.

Studies restricted to "major flood periods" disregard the potential flood-producing storms that have not produced major floods. Only by studying the mechanics of storm runoff at all levels of flood magnitude separately by climatic provinces, and more definitely by soil and cover complexes, can the hydrologist begin to isolate the controlling factors and their quantitative ranges.

A system of bookkeeping is needed that will reveal the values of infiltration capacity and of utilizable soil storage capacity in their occurrence pattern over a considerable period of years. When these have been disclosed from studies of uniform areas, and sufficiently recorded by complexes, engineers can match them with storm precipitation of magnitude and pattern related to specific frequency, and thus use a sound hydrologic basis for the evaluation of storm runoff. In no other way can the effect of vegetal cover be recognized. The results will be helpful also in rationalizing statistical records of "flood" occurrence, many of which must reflect the nonuniform soil and cover conditions throughout their period.

Recent Investigations

During the ten years since 1933, basic precipitation and stream-flow data have been becoming available in a steadily increasing volume and in improving detail. This has inspired engineers and hydrologists to new efforts toward correlating cause and results, particularly in the flood phase of the hydrologic cycle. For example, the U. S. Geological Survey has presented an increasing number of Water Supply Papers of a descriptive and analytical character. Analyses are disclosing quantitative values of retention, in terms of subsurface storage capacity utilized, for particular basins of different general character. The quantitative values of storage capacity utilized, however, are mean values for complete drainage basins and rarely disclose the storage quantities that may be related to particular complexes. To permit the identification of the various controlling elements, particularly infiltration capacity and subsurface retention values with specific soil and cover complexes, they must be studied for areas where they are relatively uniform throughout. This may restrict the investigations to the smaller drainage basins, to the so-called small control watersheds and the small control plots, under either natural or artificial rainfall. For such areas, a wealth of fundamental data has been accumulated through the research work of the Soil Conservation Service and Forest Service of the U. S. Department of Agriculture, and some of the smaller scale investigations of the U. S. Geological Survey.

The new basic data which have been collected by the research agencies are becoming available rather slowly in compiled form. Some of them have been published. From them, essential secondary data reflecting the elements of control by the land are being derived, and satisfactory methodologies for this purpose have been described in departmental bulletins and in the *Proceedings* of the American Geophysical Union. A tremendous further program of analytical work will be needed before the data collected will all be in shape for widespread use in hydrologic engineering practice; and, although some of this work may be done under research programs in engineering schools, and some of it by engineering offices under pressure of specific need of information, the great bulk must be done by the federal bureaus—either those which have collected the basic data or those charged with programs to which the derived data are essential.

Although flood flow cannot be unscrambled from large basins, the engineer can reverse the process and use measured flood flow as a check on synthetic computations. When the values of infiltration capacity or of subsurface storage capacity are determined for the commoner soil and cover complexes, when these are applied to a series of actual precipitation patterns, and when the excess water is weighted in proportion to the distribution of the complexes in a basin, a synthetic value of retention by the land and vegetation, and of the complimentary runoff, can be obtained. If these computed values reproduce, significantly, measured flood flows over a sufficient range of storm and antecedent conditions, then both the unit values for the complexes and the propriety of the methodology used would appear to be sufficiently confirmed.

Thereafter, both the derived data as to controlling elements and the form of procedure may be re-used, for example, to evaluate:

(1) The changes in flood-flow characteristics which probably have occurred during the duration of a gaging station record on account of changes in land use and cover;

(2) The changes in flood flow that would occur under an expected future plan of land use and management; and

(3) The most probable flood-flow values for a basin for which no stream-flow records are available, either with regard to some specific storm or in the form of values for storms of various frequencies.

Lack of space precludes the use of illustrative material, other than the technique applied to the Trinity River; it may be hoped that other applications will become available in the course of the discussion. It is also to be hoped that at a later time the somewhat different effect of the land under snow and ice conditions will be presented in some detail.

ACKNOWLEDGMENT

The writer wishes to express his appreciation to the U. S. Department of Agriculture for permission to present certain heretofore unpublished material.

DISCUSSION

L. K. SHERMAN,[7] M. AM. SOC. C. E.—The subject of applied hydrology has been advanced appreciably by the publication of this paper. The writer has worked for several years along similar hydrologic lines relating to the measured effect of land, soil moisture, and vegetal cover on runoff and infiltration from natural rainfalls. His researches have been conducted independently of those made by Mr. Horner and on some basins differing materially in location and physical character from the basins described in the paper. The agreement between the two studies, as well as the lack of agreement, therefore, serves as a check or as a measure for the adoption of findings and procedures. The author's introduction gives a concise statement of the concepts and findings now generally approved in the science of hydrology.

Under "Infiltration Capacity" Mr. Horner defines the curve of infiltration capacity (sometimes called f-curve). This diagram is one of the most useful devices in the realm of hydrology. Rainfalls on the same basin or plot, occurring in the same month or season, will not give identical curves or parts of curves. However, these curves are generally in such agreement that they will furnish a composite f-curve which is sufficient for all practical purposes. A composite f-curve is more reliable than any curve from a single storm. The author assembles the curve at the point $f = 0.4$ to draw the average. The writer starts with a curve for a high value of f and successively moves the curve of next high f_o to the average point until the curve of lowest f_o is included. Tests made by the writer indicated that both methods furnish composites in close agreement. The important thing is to assemble all f-curves so as to maintain all of the highest f-values (f_o) at their original value on the f-scale. Vertical movement of position is not allowable. The writer finds that averaging f-curves by placing f_o at time zero, and then deriving average values at time intervals, is irrational and gives meaningless results. The same statement applies to the averaging of f_a-values.

Many infiltration-capacity curves have been derived from infiltrometers. The ultimate minimum values of f_c on "wet" runs agree well with f_c-values from natural rainfall. The agreement on the f-curves is not very good. In the final analysis, field comparisons must be based on natural rainfalls.

Time condensation is mentioned by Mr. Horner, but its importance in the derivation of infiltration-capacity curves from natural rainfalls deserves re-emphasis. By definition, during a short time interval, the infiltration-capacity curve gives the infiltration volume at the "capacity rate." Frequently, in nature, the rain intensity may fall below the capacity rate. The rain during a certain hour may be only 0.25 in. per hr, whereas the infiltration capacity f at that hour may be 0.75 in. per hr. To meet the f-curve requirement of capacity, this hour of 0.25-in. rain must be shown on the f-curve as 20 min. The latter is condensed time—symbol T.

---

[7] Cons. Engr., Chicago, Ill.

The procedures for deriving curves of infiltration capacity from natural rainfall include the following:

1. The Horner method, mentioned in the paper. Requires hydrographs of runoff closely synchronized with rain sequences or pattern. The method applies to plots and small basins.
2. The Sharp and Holtan method.[8] Requires hydrographs of runoff. Applies to small plots and large basins. First, the mass curve of infiltration is derived, and, from this, the f-curve is found.
3. The Sherman and Mayer method.[9] Requires the derivation of f_a (average infiltration capacity for the storm) and f_c. Requires only the total volume of surface runoff. The f-curve is found first, and the mass curve of infiltration is derived from it. Applies to small plots and large basins.

All methods require the sequence of rain intensities in time periods of one hour or less. All of the foregoing methods give f-curves that are in fair agreement.[10] (This applies to the Sharp and Holtan method after time condensation is applied. This was not done in their examples.[8])

The writer has compared Eq. 3 with the type of f-curves used in the Sherman and Mayer diagram. The term $\Delta F - f_c\,\Delta t$ represents the volume of infiltration under an f-curve and above the horizontal line of f_c. Eq. 3 therefore may be written:

$$\text{Volume above } f_c = V_f = \frac{f_{t1} - f_{t2}}{K} \dots\dots\dots\dots\dots (4a)$$

In the Sherman and Mayer type of f-curve the volume above f_c between f_1 and f_c is:

$$V_f = (f_1 - f_c - 0.01)C_b \dots\dots\dots\dots\dots\dots\dots (4b)$$

in which C_b is a constant. When Eq. 4b is applied to a segment of the f-curve between f_{t1} and f_{t2}, it becomes:

$$V_f = (f_{t1} - f_{t2})C_b \dots\dots\dots\dots\dots\dots\dots\dots (4c)$$

Equating Eqs. 4a and 4c, the author's ratio $\frac{1}{K}$ is equal to C_b introduced by Messrs. Sherman and Mayer.

The Sherman and Mayer type of f-curve originally was derived graphically to conform to the requirement that, at any point on an f-curve, the hypotenuse of a triangle with $f - f_c$ as altitude and C_b (constant base) as base on the f_c-line was tangent to the curve at that point. The type of f-curve to fit the given data of f_a and f_c is selected by the equation:

$$C_b = \frac{f_a - f_c}{f_a} \dots\dots\dots\dots\dots\dots\dots\dots\dots (5)$$

[9] "Application of the Infiltration Theory to Engineering Practice," by L. K. Sherman and L. C. Mayer, *ibid.*, Pt. III, 1941, p. 666.

[10] Paper by L. K. Sherman, presented at the meeting of the Section of Hydrology, Am. Geophysical Union, April, 1943.

There appears to be a definite relation between the f-curve arcs in the paper and those introduced by Messrs. Sherman and Mayer. The composite f-curve is generally used in practical applications.

The author's M-curve and his stress upon the importance of considering antecedent soil moisture are of prime importance. Runoff from rainfall is meaningless if this factor of initial soil moisture is not specified.

Attention is directed to Table 6, containing data on brown loam soil in the basin of the Little Tallahatchie River of northeastern Mississippi.[11]

TABLE 6.—RUNOFF, IN INCHES, AT INITIAL SOIL MOISTURE; GROWING SEASON IN THE BASIN OF THE LITTLE TALLAHATCHIE RIVER

Cover	Rain	Very dry	Medium	Very wet
Bare	2.5	0.5	1.2	2.0
	3.5	0.8	1.9	2.6
Cultivated corn cotton	2.5	0.2	1.1	1.8
	3.5	0.4	1.7	2.4
Native grass	2.5	0.0	0.4	1.0
	3.5	0.0	0.7	1.4

The M-curve, as shown by Mr. Horner, is probably the most accurately devised scale or index of initial soil moisture yet presented. It may be susceptible of simplification, especially for purposes of comparing runoffs from different cover complexes on the same basin. The writer has used the following procedure with satisfactory results: Derive a mass curve of infiltration from the composite f-curve of the basin for a particular cover, season, or month. The base or time scale is the same as the composite f-curve. The volume of infiltration scale, or ordinates, in inches, is at the left. Zero of this scale corresponds to the point of tangency of the f-curve at f_c. The scale shows the capacity for absorbing infiltration; hence it is expressed in terms of soil moisture deficiency. The deficiency is 0 at f_c when the soil is very wet. The deficiency is greatest at an f_o for which the soil is very dry. The range on the mass scale between very wet and very dry runs from about -2.0 in. for bare soil, 3.0 in. for grass, and -4.0 or -5.0 in. for old forest cover. Points above zero, on the f_c-line are marked $+1.0$, $+2.0$, etc.

"Medium" initial soil moisture is halfway between 0 or very wet and the maximum or very dry. "Wet" and "dry" are the quarter points. "Medium" is used generally for cover comparisons of runoff. It has a different initial soil moisture for different covers. This is as it should be. Different vegetal covers evaporate and transpire different amounts of soil moisture for identical antecedent meteorological conditions. This scale was used in the foregoing tabulations of initial soil moisture and runoff. When the observed runoff is known, the numerical figure for initial soil moisture can be determined. This, as the author states, is simply the reverse case of computing runoff. With either scale, correlation with antecedent meteorological conditions (used in forecasting runoff) has not yet been accomplished.

In line with the author's findings on the Trinity River basin of Texas, the writer presents the following for the Little Tallahatchie River basin of Mississippi:

---

[11] "Manual on Reduction of Runoff and Floods Through Agricultural Operations," by L. K. Sherman, 1942 (unpublished).

Description	Hudson Creek basin	Cane Creek basin
Drainage area, in miles	9.35	23.8
Soil	Brown loam	Pontotoc and Flatwoods
Initial soil moisture	Medium+14% toward dry	Medium
Date of observation	June 17, 1939	June 17, 1939
Basin f_c	0.17	0.11
Rainfall, in inches	1.34	3.11
Observed runoff, in inches	0.285	1.81
Computed runoff, in inches	0.26	1.86
Correction factor	1.09	0.97

A comparison of conditions, before and after certain assumed cover changes and gully controls, is as follows:

Description	Hudson Creek basin	Cane Creek basin
Medium Initial Soil Moisture Conditions:		
Rainfall, 2.70 In.—		
Runoff before assumed changes	1.09	1.46
Runoff after assumed changes	0.53	1.16
Rainfall, 4.35 In.—		
Runoff before assumed changes	2.40	2.52
Runoff after assumed changes	1.48	2.14

Some of the complexes used, like increased crop acreage, may increase the "after" runoff. The benefits under some plan designed by the U. S. Department of Agriculture may exceed this showing materially.

RAPHAEL G. KAZMANN,[12] JUN. AM. SOC. C. E.—The words "permeability" and "porosity" are sometimes used interchangeably by engineers. As this is incorrect, it may be of general interest to differentiate between these concepts and illustrate the difference by concrete examples. The porosity of a material is no indication of its ability to transmit water through its interstices. The ability of a material to function as a "conduit" for the transmission of water generally is known as the material's permeability.

As used by the Geological Survey, U. S. Department of the Interior, the coefficient of permeability of a water-bearing material is defined as the rate of flow of water, in gallons per day, through a cross-sectional area of 1 sq ft under a hydraulic gradient of 100% at a temperature of 60° F.

The porosities of water-bearing materials bear little relationship to their permeabilities. This is illustrated by Table 7, adapted from *Water-Supply Papers Nos. 596-F* and *887*[13,14] of the Geological Survey. Table 7 demonstrates that the water-transmitting properties of materials generally are not related directly to their porosities. The materials listed in Table 7 were obtained in various sections of the country and at various depths below the land surface. The coefficients of permeability were determined in the laboratory by passing water through samples of the material by means of techniques which are described in detail in *Water-Supply Paper No. 887*.[15]

[14] "Methods for Determining Permeability of Water-Bearing Materials," by L. K. Wenzel, *Water-Supply Paper No. 887*, U. S. Geological Survey, 1942, pp. 13–14.

Mr. Horner's paper would have been strengthened by including a treatment of the movement of ground water. In dealing with the problem of subsurface retention and detention, there is no reference to the rise and fall of the water table during or following any of the storms; nor does any attempt appear to have been made to obtain data of this sort. Furthermore, a study of the trends and magnitudes of ground-water fluctuations would have corroborated or disproved a fundamental assumption upon which the paper is based—that the infiltration capacity of the Trinity River basin is small to moderate. Inasmuch as this is a qualitatively determinable factor, a generalization based on observations of water level should have been substituted for this assumption. In the absence of such observations it would appear impossible to evaluate the technique described in this paper.

TABLE 7.—POROSITIES AND PERMEABILITIES OF WATER-BEARING MATERIALS

Description of material (1)	Porosity (%) (2)	Coefficient of permeability (3)
Terrace gravel	23.6	1,230
Gravel mixed with some coarse sand	24.1	4,500
Gravel	25.1	20,000
Alluvium gravel (gravel and silt)	29.3	70
Sand and gravel	29.7	1,820
Sand	35.8	2,600
Fine gravel, coarse sand mixed with clay balls	37.0	30
Glacial gravel	38.0	90,000
Washed gravel	38.5	10,500
Red clay	42.4	20
Sand	44.4	1,100
Sand	44.8	560
Silty sand	45.1	6
Sand	45.8	410
Loess	53 2	7
Subsoil	54.2	20
Subsoil	55.5	0.2

W. G. HOYT,[16] M. AM. SOC. C. E., AND W. B. LANGBEIN,[17] ASSOC. M. AM. SOC. C. E.—With the passage of the Flood Control Act of June 22, 1936, an obligation was imposed on the engineering and associated professions to determine the magnitude of reduction in flood stages and discharges that could be effected through changes in land use. The author describes a technique for evaluating the rôle of land during flood periods with no snow or ice, and limited to areas where (see heading, "Part I.—Introduction: Engineering Technique") "Infiltration capacity is small to moderate * * *, and stream-channel inflow occurs predominantly as surface runoff," a situation which the author indicated "applied quite widely to cultivated and grass lands."

Through the use of infiltration-capacity curves for small experimental catchment areas, homogeneous in soil, cover, and cultural treatment, surface runoff volumes as the result of changes in land use are determined, and finally the runoff volumes are translated into river stages and discharges. To the extent that flood rises caused by rain are composed of surface runoff only and to the extent that "correct seasonal average infiltration curves" can be derived and placed "in their proper position on the rainfall patterns," the method enables one to evaluate a reduction in surface runoff through changes in land use. Such quantitative determinations are necessary if the feasibility of flood control through treatment of land is to be evaluated.

[15] "Methods for Determining Permeability of Water-Bearing Materials," by L. K. Wenzel, *Water-Supply Paper No. 887*, U. S. Geological Survey, 1942, pp. 50–71.

[16] Hydr. Engr. (Prin.), Water Resources Branch, U. S. Geological Survey, Washington, D. C.

[17] Associate Hydr. Engr., U. S. Geological Survey, Washington, D. C.

Flood control operations of any nature involve the expenditure of millions of dollars, and it is essential that the degree of control to be effected should be well demonstrated. The hydraulics of flood control through the use of engineering structures can be evaluated by verifiable and comparatively well-founded technical processes. The evaluation of the hydraulics of land use during flood periods is accomplished by techniques that are quite complex and speculative. This is true because of (1) a lack of basic knowledge concerning the land phase of runoff, (2) wide variations in infiltration capacity and other hydrologic conditions within a drainage basin, and (3) a lack of demonstrated beneficial change in flood-runoff régime of any large stream because of a change in land use.

The author attempts to supply the first deficiency and is to be congratulated for breaking down[18] the process by which rainfall is translated into runoff, for outlining the manner in which meager observational data may be used to give quantitative expression to the factors involved, for computing the runoff for a typical drainage basin in Texas in accordance with the concepts outlined, and for comparing it storm by storm with the measured volumes and rates. This comparison between computed and observed results may be necessary, but is it sufficient to prove the correctness of the postulates? The derived relations may furnish good empirical working tools, but the writers suggest that other postulates may evolve equally good checks.

The author presents curves of infiltration capacity for soils typical of the Texas Blacklands that show marked differences in position, and, therefore, for a given rainfall pattern and antecedent conditions, marked differences in surface runoff for different kinds of land use These curves are based on measurements of runoff on small homogeneous catchment areas at the Waco watershed and the Garland Runoff Studies Project. There is no reason to believe that these curves do not reflect the qualitative effects of cover on the surface runoff of the small homogeneous areas for which they were derived. There is nothing in the report, however, to demonstrate that a river such as the Trinity River would respond to changes in land use in the same way as the small homogeneous plots. Thus, although the author has devised a technique which will show quantitative difference in surface runoff (the immediate task before him), there is still lacking a process for evaluating the effect of land-use change on flood stages and flows which is not open to considerable doubt.

Some may feel, as do the writers, that the author has placed too much dependence on the concept of "infiltration capacity," arrived at, as it is, indirectly through the measurement of surface runoff on small experimental areas in a procedure designed to simulate flood rises from large natural drainage basins under assumed combinations of land use.

---

[18] "See also "Hydrology," Physics of the Earth—IX, edited by Oscar E. Meinzer, McGraw-Hill Book Co., Inc., New York, N. Y., 1942, pp. 507–513.

In so far as the engineering technique is concerned and as the author quite clearly implies, an expanded title for the paper might well read, "Rôle of the Land During Flood Periods in Those Areas Where Infiltration Capacity Is Low to Moderate, Where Infiltrated Water Does Not Appear in the Stream as 'Quick-Subsurface Return Flow,' and Only During Periods of No Snow, Ice, or Frost." These restrictions in the use of the technique impose quite serious limits on described procedures from the viewpoint of practical application to general flood problems. They do not necessarily detract from the author's conclusion with respect to the East Fork of the Trinity River provided that its basin characteristics can be definitely determined to be such that the foregoing limitations apply. Apparently, at one time, conditions in the Trinity River basin were such that the author's technique would not apply. It is stated in the final report on the Trinity River watershed:[19]

> "There is evidence that floods occurred on the Trinity before settlement but they were vastly different from the present floods. Water rose and receded so slowly that many streams which are now intermittent then flowed all year."

This description implies an area with large infiltration capacity, much groundwater storage, little surface runoff, and a slow release of infiltrated water to the stream as sustained flow—conditions that in the main are seemingly inherent to a basin and not modified so materially by human occupation.

The writers know of no simple method to determine, on an areal basis, whether subsurface inflow constitutes less than 10% of flood volume. Although the author may be correct in his assumption that 90% of the present flood volume in the East Fork of the Trinity River is surface runoff, no basic data have been submitted to prove it. The total runoff (surface) at the Rockwall gaging station for the thirty-five storms, May 3, 1935, to July 3, 1940, as reported in Table 4 is 31.29 in. The total flow past the Rockwall gaging station for the same period is about 40 in. In other words, 78% of the total runoff that appeared at Rockwall is assumed by the author to be surface runoff. The difference between these two amounts (8.7 in.), except for a few flood rises not included and which approximate 0.70 in., is presumed to represent all the infiltrated water that reached the stream channel at Rockwall.

Based on an extensive knowledge of hydrologic conditions at the North Appalachian Experimental Watershed near Coshocton, Ohio, a research project of the Hydrologic Division, Office of Research, Soil Conservation Service, U. S. Department of Agriculture, H. S. Riesbol, Assoc. M. Am. Soc. C. E., concluded[20] substantially as follows: Extensive study of ground-water levels, percolation rates, hydrograph recessions, and normal ground-water depletion curves should lead to dependable and practical knowledge concerning when and where infiltrated water joins channel flow as seepage and spring flow from perched water tables, temporary zones of saturation, or from deep seepage. No such basic information is submitted for the Trinity River basin.

---

[19] *H. R. Doc. No. 708*, 77th Cong., 2d Session (letter from the Secretary of Agriculture transmitting a report of a survey of the Trinity River watershed based on an investigation authorized by the Flood Control Act of June 22, 1936).

[20] "Some Aspects of Subsurface Water in Hydrologic Research Agricultural Watersheds," by H. S. Riesbol, *Proceedings* of the Hydrologic Conference, Pennsylvania State College, State College, June 30 to July 2, 1931, p. 107.

The writers do not question the accuracy of the various infiltration-capacity curves shown in Fig. 5 in which infiltration capacity is shown to increase progressively from untreated farm land to well-managed forests. Through the use of such a family of curves under any given rainfall pattern, computed reductions in surface runoff as a result of betterment in cover or land use are obtained. Whether or not these computed reductions in surface runoff can be assumed to be equivalent to reduction in the flood runoff of the stream draining the particular area, however, seems open to question. The writers believe the author fully understands this situation, but he fails to delineate or give an expression to the area where his technique would apply except the broad statement (see heading, "Part I.—Introduction: Engineering Technique") that the "situation applies quite widely to cultivated and grass lands." It would seem quite the contrary with respect to much of the cultivated land in the United States since the agriculturist would tend to select, among other factors, soils that combine high infiltration capacities with satisfactory moisture-retention properties. The real criterion underlying the author's technique is not so much whether the cover is cultivated or in grass but rather, the subsurface storage characteristics. Will the subsurface storage spaces retain the infiltrated water, or are they of such limited extent that infiltrated water passes into stream channels where it forms a part of the direct flood runoff of all stream rises?

The author suggests that the ratio between observed surface runoff and computed rainfall excess is a test of the validity of his procedure. It is stated that for five storms the rainfall data were inadequate and that measured runoff was used as a guide in the determination of rainfall excess. Examination of the author's unpublished reports on his study as a consultant to the Department of Agriculture indicates that the computation of rainfall excess in the other thirty storms was influenced to a considerable extent by knowledge of the actual volume of runoff as measured at the gaging station maintained by the U. S. Geological Survey at Rockwall. Some of these influences included reinterpretations of the rainfall patterns, adjustments in the position of infiltration-capacity curves, and deviation from the seasonal *M*-curve values. The correction factor (Col. 6, Table 4) therefore reflects the errors that remain after all readily explainable adjustments have been made. It is obvious that wide departures from observed runoff have been adjusted in order to arrive at a result more closely in conformance with observed runoff. The test is not the same as would be met by a forecaster who has no knowledge of the runoff to be produced by the storm other than that provided by his working formulas. If partial advantage is taken of the runoff as it was, why not take full advantage? The technique might not be so different. If the author had wished, he might have continued his adjustments until conformance of computed and observed runoff was obtained. Perhaps a method varying the *M*-curve or other factor to this end can be devised. Whether or not the author's procedure can be considered practicable for ordinary engineering practice will depend on the man-hours involved in its application. Some idea as to the number of man-hours required to simulate the thirty-five flood peaks would be enlightening.

An examination of Fig. 5 and a study of the method by which the family of infiltration-capacity curves was placed on the rainfall graphs suggests that the results are highly sensitive to rainfall intensity. Hourly rainfall amounts were estimated from data so scant as to be almost nonexistent; but, assuming that the hourly pattern shown in Fig. 5 is correct, minute-to-minute variations in intensity necessarily have been neglected. For example, consider the hour interval, 1 p.m. to 2 p.m., during which there was 1.56 in. of rainfall: Suppose 0.20 in. of this amount fell during the first 20 min, 0.52 in. during the middle 20 min, and 0.84 in. during the last 20 min; then the amount of mass infiltration that occurred prior to rainfall reaching the infiltration capacity would be increased by 0.20 in., and the initial infiltration capacity on curve (1), Fig. 5, would be 0.80 in. per hour instead of 1.09. The net result would be that the rainfall excess during this hour would be 1.03 in. for cultivated untreated land and 0.91 in. for strip-cropped, both important land classes. The author's values are 1.09 in. and 0.92 in., respectively. It is significant that, by assuming a different rainfall distribution, the computed reduction in runoff is less. The author's difference between the two values is 0.17 in.; that computed for a possible distribution of rainfall assumed by the writers is 0.12 in. Seemingly, the effect of any error that would advance the period of intense rainfall would increase the computed difference between "before" and "after"; an error that would retard the period of intense rainfall would diminish the effect.

The report explains the influence of antecedent conditions as they affect soil moisture on the infiltration capacity during a storm. Increasing the volume of infiltration prior to a storm decreases the capacity of the basin to retain water. Therefore, under the changed conditions, to what extent would the presumed increase in infiltration operate adversely to lower infiltration capacities during subsequent storms? Moreover, are there not economic implications of the reduction in flood runoff, particularly with respect to the rights of downstream riparian owners or appropriators? In this particular case, using the values given in Col. 13, Table 4, the 20.4% reduction in total surface runoff means a reduction of 16% in total stream flow.

The annual runoff in inches at the Rockwall gaging station is greater than that at other stations in the upper Trinity River basin.[21] It is much greater than at any of the basins at the Waco Experiment Station.[22] Does this difference in annual runoff indicate difference in land types or land use or does it conform to differences in rainfall?

Query is raised as to the use of the term "regression curves." Apparently this term as used refers to the die-away curves of infiltration capacity shown in Fig. 5. Lines or curves of "regression" are statistical terms devised by Sir Francis Galton[23] to describe lines or curves of best fit between a single independent variable and one or more dependent variables. In this sense the die-away curves of infiltration capacity may be regression curves; but, then, so are all the other empirical lines or curves shown. A more descriptive term should be devised.

The *M*-curve shows that the spring season overlaps the adjoining winter and summer seasons. This is understandable, but what procedures are used to determine which seasonal curve shall govern in a particular condition?

CHARLIE M. MOORE,[24] JUN. AM. SOC. C. E.—The actual application of a method for determining the measured effect of land, soil moisture, and vegetal cover on runoff and infiltration from natural rainfall is presented in this enlightening and interesting paper.

In discussing Step 1 (heading, "Methodology") the author has applied rainfall data collected by the writer at Lindale and Mount Pleasant, Tex., during the 5-yr period from 1935 to 1940. At each of these locations the federal government installed three Ferguson recording gages, and five standard gages within demonstration project areas of some 23,000 acres. The recording gages were supervised by junior engineers, whereas it was necessary to rely upon cooperating farmers to measure and record the precipitation collected by the standard gages. A diligent effort was made to keep the recording gages in good operating condition and to obtain records as accurate as possible for all gages. Cooperative observers were selected carefully in almost every instance before installing the gages. However, some of the original observers moved or became disinterested after a period of 2 yr or 3 yr. Where they were interested it was not difficult to obtain a satisfactory record that could be depended upon. In the monthly collection of data from cooperative observers, it was often necessary to redate the reports and to compare the recorded amounts of the rains with the nearest recording gages. Quite often several hours would elapse before the observer would remember to measure the rain. At times, after small rains, the precipitation would be evaporated before measurements were made. This fact, no doubt, made it difficult to analyze the data at a later date.

As illustrated by the author, the application of the method to drainage basins as large as 831 sq miles gives some valuable information to engineers interested in the determination of maximum runoff to be expected from watersheds, and the reduction that can be expected from the application of the Department of Agriculture program, as related to erosion control, land use, and management.

The engineers of the Soil Conservation Service, in Region Four, of necessity use the rational method in determining the runoff to be expected for a given frequency of rainfall. This method, which is based on the formula—

$$Q = C\,I\,A \qquad (6)$$

—is used for comparatively small agricultural areas and is limited to a maximum of approximately 1,000 acres. It is realized by engineers that some such method as the author has given is needed to evaluate properly the rôle of the land and the part that it plays in reducing the runoff where proper land use and management are employed. Also, a method similar to that of the paper, which can be applied to larger watersheds, is needed.

In the application of Eq. 6, a constant runoff factor is generally chosen and assigned to certain land-use groups within a soil group. However, it can be seen that such a procedure does not take into account the effect of previous rainfall, type of cover, condition of cover, degree of erosion, or variations in soils within a soil group. The method presented by the author will evaluate most of these factors and their effect upon the runoff.

---

[24] District Engr., SCS, Crockett, Tex.

It is noted in Step 3 that the problem of deriving infiltration-capacity curves for the Blackland soil and various classes of vegetal cover was simplified in that, to all intents and purposes, only one soil type occurred in the basin, and in that the variations in infiltration capacity were primarily those growing out of the difference in vegetal cover and of antecedent conditions. This problem would be very acute in the sandy lands of eastern Texas, and other areas, where some sixty to seventy soil types occur, ranging from deep sands to very heavy, almost impervious, clay soils. Many of these soils occur within very small drainage basins in the eastern Texas area.

The writer agrees with the statement that a system of bookkeeping is needed that will reveal the values of infiltration capacity and of utilizable soil-storage capacity in their occurrence pattern over a considerable period of years. This will help to form a sound hydrologic basis for the evaluation of storm runoff.

In considering the rôle of the land and its effect upon runoff, the writer has found that, by treating drainage basins properly with sound conservation practices, such as terracing, contour cultivation, contour ridges, retiring steep slopes to grass and woodland, controlling gullies with dams, and sloping and sodding gullies, considerable expense can be saved in the capacity of bridges, culverts, spillways, etc., in the lower reaches of the watersheds. These practices help to retain the water on the land for a period sufficient to cause most of it to be absorbed. By proper land use and management in a drainage basin, the reduction of runoff, as illustrated by the author, can well be expected. The mere changing of a system of cultivated rows by a farmer can cause almost total runoff as compared to a very small amount of runoff if the rows are laid off on the contour. The writer has observed that flood flows on drainage basins ranging in size from 100 to 1,000 acres or more—on which the Department of Agriculture program had been applied almost 100%—were reduced considerably. On one of these basins it had been impossible for the county government to construct semipermanent bridges across the main channel without having them overflowed or washed out. County officials have been troubled very little with this problem since the watershed has been treated.

The writer is anticipating the time when sufficient information is compiled and made available to engineers for use in the application of this method to various sizes of watersheds or drainage basins. The author has advanced this method appreciably by the publication of this paper.

WALDO E. SMITH,[25] M. AM. SOC. C. E.—Many questions that hitherto have been raised concerning the infiltration approach have been answered in this paper, the most notable of which is perhaps the placing of the infiltration curve in proper time position with reference to the rainfall. To the writer's knowledge, this is the most definite work of this sort yet published. The setting down of the step by step procedure clarifies still other questions. A related question that the author himself inspired in a previous paper[26] that yet remains unanswered is the validity of the use of average hourly intensities in the face of the great normal variations in intensity from the hourly average. About one half of the rain within the hour normally falls at two times or more the average hourly intensity, and about one fourth falls at three times or more the average hourly intensity. Thus, the actual pattern of the rainfall that is shown only in terms of hourly averages in Fig. 5 would normally result in decidedly different amounts of rainfall excess. The writer feels, however, that the development of the infiltration technique has been advanced considerably in this paper. An attempt should be made to test this technique as soon as possible, utilizing better basic data.

---

[25] Head, Section of Hydrology, Div. of Water Conservation & Disposal Practices, Soil Conservation Service, Washington, D. C.

It is unfortunate that the data for the testing of this method and for this extensive work using the infiltration approach were so inadequate. As the author states, only daily records of precipitation, some of doubtful validity, were available on the watershed for the storms studied. There was no recording rain gage on the area and, for that matter, none was very close to the area until the Garland gage was established in the latter part of the period. Streamflow records consisted generally of twice daily visual observations which, on the watershed of 831 sq.miles, do not define the hydrograph very well. The writer would like to see the author's technique tried with more adequate data, such

Water" in the Upper 40 In. of Soil Mantle

as those that are available concerning the basin of the Licking River above Zanesville, Ohio. On this basin there are quite a number of recording rain and stream gages with records of 3 yr or 4 yr or longer. These data would afford a much more satisfactory test of the adequacy of this method. Attempting to establish refinements in records, such as hourly values from already uncertain daily amounts of rainfall and such as the sketching in of the gaps between the twice daily stream gaging observations, seems questionable indeed for the uses of the author's analysis.

Inasmuch as the derivation of infiltration curves is by no means standardized and, furthermore, is largely an unknown technique to many hydraulic engineers, a repetition of the citations on the procedure for their derivation presented in the earlier paper,[26] and the addition of more recent ones, is in order. A list, in so far as the writer has it at hand, is appended to this discussion.

The author may have a file of infiltration curves that he has derived for various soil-cover complexes for various seasons, but as yet such curves are not generally available. Derivation is laborious and within the writer's experience there is frequently little uniformity in product as derived by the different methods for the same single watershed complex and storm.

With regard to the author's discussion of outstanding flood periods in Part III of this paper and to his statement that floods are usually caused by the coincidence of storms and low infiltration rather than by either of these things alone, a paper by F. R. Dreibelbis and F. A. Post [27] should be called to the attention of hydraulic engineers. Messrs. Dreibelbis and Post showed that the "active soil water" in the upper 40 in. of the soil mantle that they studied varies as much as 9.39 in. in depth of water in a year. Three curves of the "active soil water" prepared from their data [28] are shown in Fig. 9. On this illustration also is given the mass curve of precipitation. Volume-weight soil samples were taken at intervals of a week to a month on the dates generally shown by the break points in the curves, and the actual quantity of water in each sample was determined. That water greater than the minimum for the year was defined as "active soil water." There was still considerable moisture in the soil at the time of the minimum value. which, in the case of watershed 109 (cultivated), was 6.28 in.[29] of depth. The "active soil water" in the graphs shown is probably considerably more than the subsurface retention (capillary and pellicular water) in the 40-in. layer, and includes subsurface detention (gravitational water). The soil probably approached saturation at the wettest time of the year. Infiltration values are low at such times in these soils and those of the Texas Blacklands. This method may possibly be used as a quantitative indicator of low infiltration rates and approach of the soil to saturation and thus of incipient flood conditions. More detailed information on the vertical distribution of the water in the 40-in. layer might prove helpful.

It is interesting to note that in general the mass curve shows light precipitation during periods of decreasing active soil moisture, and heavy precipitation during periods of increasing active soil moisture. This is a logical deduction supported by the data. Furthermore, due to high evapo-transpiration in the summer and due, perhaps in part, to the usual nature of many summer storms (high intensity and short duration), much more precipitation is necessary to support a constant value of active soil moisture in summer than in winter. Still a further fact is worthy of note—namely, that the greatest depth of active soil moisture occurred on woodland (9.39 in.), next on pasture (8.36 in.), and lowest on cultivated land (7.82 in.). (In the paper cited,[29] this value is given as 7.09 in., but the period used ended August 7, 1940. Extending the period to September 12 gave a new low value for the cultivated watershed, increasing the range between lowest and highest values of soil moisture to 7.82 in.) Data on retention and detention will probably prove to be very useful in analyses made using the infiltration approach.

[29] For information concerning the watersheds involved, and for much of the data used by Messrs. Dreibelbis and Post, see "Hydrologic Data," *Hydrologic Bulletin No. 1*, North Appalachian Experimental Watershed, Coshocton, Ohio, 1939, and "Hydrologic Data," *Hydrologic Bulletin No. 4*, North Appalachian Experimental Watershed, Coshocton, Ohio, 1940.

It is further interesting to note that the active soil moisture fluctuations for the 13-month period conform to the trend of precipitation-evaporation ratios in so far as evaporation data are available for their determination. These ratios, the usefulness of which were established by C. W. Thornthwaite,[30] are simply the monthly precipitation divided by corresponding monthly evaporation. They may also be derived by empirical means from the data on temperature and precipitation. This was not done. The ratios for the available data might have been added to Fig. 9 but were omitted to avoid confusion. For the months for which they can be found they are given below:

Month	Precipitation-evaporation ratio
1939	
August	0.20
September	0.18
October	0.76
1940	
April	1.34
May	0.71
June	1.34
July	0.57
August	1.44
September	0.42

The ambiguity of the term "infiltration capacity" is indicated in the closing paragraph of the "Synopsis" of the paper in which "infiltration capacity," a rate, is compared with "detention capacity," a volume. As a substitue for the confusing term "infiltration capacity," the writer proposes the term "potential infiltration rate" as being more descriptive of this phenomenon. Furthermore, in the place of "infiltration regression curve," the simple term "infiltration curve" might well be used; or, if one must be more explanatory, the term "the curve of potential infiltration" could be used.

P. B. Rowe,[31] Esq.—The hydrologic literature concerned with evaluating land effects on stream flow is measurably enhanced by this valuable and stimulating contribution. An approach developed by the California Forest and Range Experiment Station,[32] similar to that presented by Mr. Horner, has been used in the hydrologic analyses of some of the U. S. Department of Agriculture Flood Control Surveys in California. Because of variations in procedures used and in the watershed conditions encountered, a comparison of the two methods and of the results is of interest.

---

[31] Silviculturist, Div. of Forest Influences, California Forest and Range Experiment Station, maintained by the U. S. Dept. of Agriculture, Forest Service, in cooperation with the Univ. of California, Berkeley.

[32] "A Method of Hydrologic Analysis in Watershed Management," by P. B. Rowe, Twenty-Fourth Annual Meeting, Am. Geophysical Union, April, 1943 (in process of publication).

In the Horner method an average (f_a) infiltration-capacity curve of each infiltration "complex" was derived from the rainfall and runoff records of small watersheds. In the California approach, infiltration-capacity curves of the complexes were obtained from small plot (infiltrometer) measurements. These permitted—

(*a*) Reliable determinations, not only of the relative differences of infiltration capacities of the different complexes but also of the range of infiltration capacities within complexes; and

(*b*) Computation of surface runoff from individual complexes by use of the individual f-curves or of a series of f_a-curves representing the full range of the infiltration capacities of the complex. The use of such infiltration-capacity curves has proved important in making possible the calculation of surface runoff (often of considerable volume in large complexes) from rainfall at rates below the average infiltration capacity of the complex. Before being used in computing surface runoff the infiltration-capacity curves were adjusted to measured rainfall and runoff of representative sub-drainages comprising single or similar complexes, and the adjusted curves, in turn, were checked against measured rainfall and runoff relations of the watershed as a whole.

In Mr. Horner's analysis, stream-channel inflow was visualized predominantly as surface runoff. After deductions were made for such factors as interception and depression storage, this assumption permitted the direct computation of surface runoff from the infiltration-capacity curves and storm precipitation patterns. In the watersheds studied in California more than 10% of the flows at flood crest during major storms, and much higher proportions during minor storms, were composed of "quick subsurface storm flow." Further, under watershed conditions with an assumed improved land-use program in operation, the proportion of channel flow at flood crest composed of quick subsurface storm flow was normally much greater than under present watershed conditions.

TABLE 8.—COMPUTED SURFACE RUNOFF AND FLOOD CREST DISCHARGES FOR PRESENT AND ASSUMED LAND-USE CONDITIONS, SANTA YNEZ RIVER DRAINAGE, CALIFORNIA

Watershed land-use conditions	3.50-IN. STORM		6.00-IN. STORM	
	Runoff[a]	Discharge[b]	Runoff[a]	Discharge[b]
Present observed	1.08	51,600	2.15	105,000
Assumed without program	1.17	55,700	2.27	110,200
Assumed with program	0.89	43,600	1.77	90,000

[a] Surface runoff, in inches of depth. [b] Crest discharge, in cubic feet per second.

In some watersheds considerable amounts of surface runoff were also yielded to channel inflow from complexes of shallow soils that, owing to impervious or partly impervious soil and rock formations or limited water-storage capacities of the substrata, became saturated during the storm. In applying the infiltration-capacity curves to the computation of surface runoff from these complexes, it was necessary to determine not only the rates of the quick subsurface storm flow throughout the course of the storm but also the depletion rates in storage capacities of the soil and substrata of the complexes reaching saturation. This was accomplished largely by analysis of rainfall and runoff records of subwatersheds composed of representative complexes and by establishing correlations between rates of quick subsurface flow and the total amounts of water retained within the soil and substrata.

In both the Horner and the California methods the infiltration-capacity curves were correlated with soil moisture and other antecedent watershed conditions to determine the correct position of the curves with respect to the storm rainfall patterns used in the surface runoff calculations. Mr. Horner wisely stresses the importance of this operation and, for analyses in which storm patterns are fitted to average watershed conditions, presents a very workable method for accomplishing it. Of equal importance in California is the placement and use of the correct infiltration-capacity curves in complexes comprising large areas of recently cultivated or freshly burned-over lands. On such lands the infiltration capacities may be decreased rapidly by changes in the physical properties of the soil through exposure to the beating effects of rain, surface runoff, and soil erosion.

Table 8 presents a comparison of the computed surface runoff and flood crest discharges during mid-winter storms in the Santa Ynez River drainage under present and assumed land-use conditions, with and without a remedial program. The Santa Ynez watershed comprises an area of 790 sq miles in the chaparral (brush) type of the Coast Range Mountains in Santa Barbara County, California. Owing to the high soil-moisture content and comparatively low rate of water use by vegetation during the winter flood periods, the computed reductions in surface runoff were accompanied by almost equivalent increases in subsurface and ground-water flows. The reduction in flood crest discharges expected from the proposed remedial land-use program results, therefore, not so much from a reduction in total water yield as from the more equable distribution of the yield.

C. S. JARVIS,[33] M. AM. SOC. C. E.—It is much more satisfactory to peruse the report of a consulting engineer on the results actually achieved and recorded than to scan the prospectus of intended goals in soil and water conservation. Many of the technical papers thus far dealing with the rôle of the land in regulating runoff in general and flood flow in particular have perforce depended on assumptions, estimates, and specifications which may or may not represent the changed conditions after the contracts are approaching completion. The author has carefully presented his official observations and interpretations in such a manner as to convince the most skeptical of the following facts:

1. The East Fork tributary of the Trinity River above Rockwall—not specially favored as to topography, soil, natural vegetative cover, rainfall distribution, and other significant elements of the geologic and climatic background, but somewhat deficient in some of the characteristics that would assist

---

[33] Cons. Engr., Washington, D. C.

in conserving moisture where it falls—is apparently amenable to the improved land use and management, with a corresponding reduction in peak discharge ranging usually from 10% to 40%.

2. With such beneficial disposal of considerable percentages of the most notable storms of record during the past few years, the conclusion is inescapable that greater percentages of retention and infiltration would occur with the more numerous storms of less severity.

3. Contrary to the conservative forecasts of prominent hydrologists (who claimed to be friendly toward conservation principles, yet disavowed any hope of influencing the catastrophic severity of the flood by the surface treatment and land-use changes included in the conservation program), it appears that measurable reduction can be assured in the event of long-period maxima, with correspondingly greater effect on flood happenings of greater frequency and less intensity.

4. Wherever the geologic and climatic background is more favorably inclined for response to conservation measures, correspondingly greater reduction of flood crests may result from comparable treatment, as estimated for the North Concho River, Texas,[34] according to preliminary studies and the actual behavior of several thousands of acres of newly treated valley lands. After additional months of study involving the use of infiltrometer equipment of various types on many sample areas throughout the valley, the conclusion was reached by the consultants in charge that the preliminary estimates were conservative as to assumed infiltration capacities and rates that would prevail. The later findings would have supported a more liberal estimate of flood-peak reduction, as well as the decrease of total volume, than that shown under the hydrographs presented by the writer on a previous occasion.[34]

W. W. HORNER,[35] M. AM. SOC. C. E.—The discussion of this paper is extremely interesting both with respect to the corroborative data presented and with respect to pertinent questions raised. Some of the discussers allowed their curiosity to carry them beyond the scope of the subject matter in the paper, and many of the questions relate to other phases of hydrology.

Mr. Kazmann suggests that the paper could be strengthened by including a treatment of the relation of infiltration to ground-water movement, particularly to changes in water table elevation. Such a study would undoubtedly have been extremely interesting. At one phase of the investigation the writer made a quick review of observation well data available at the Black Lands Experiment Station at Waco, and found that water table elevations could not be correlated satisfactorily with changes in infiltration capacity.

The writer's detailed presentation was restricted to surface runoff and related stream flow. The quantitative value of the infiltration capacity of the soil surface seems to be related to the rise and fall of the water table only when the water table is high enough to bring the surface soil within the capillary fringe. Undoubtedly, an investigation such as Mr. Kazmann suggests would be of real value to the general knowledge of hydrology, and possibly sufficient data are now available at Waco and Coshocton to justify such an undertaking.

---

[34] "Analysis of Run-Off Characteristics," by Otto H. Meyer, *Transactions*, Am. Soc. C. E., Vol. 105 (1940), p. 132, Fig. 13.

[35] Cons. Engr. (Horner & Shifrin), St. Louis, Mo.

Messrs. Hoyt and Langbein ask a number of questions, some of which are pertinent to the subject matter of the paper. These questions are discussed herein in the order of their appearance and with reference to the paragraphs.

In the seventh and eighth paragraphs Messrs. Hoyt and Langbein offer an expanded title for the paper, part of which is "Where Infiltrated Water Does Not Appear in the Stream as 'Quick-Subsurface Return Flow,'" and suggest that basic data might have been presented to prove that "subsurface inflow constitutes less than 10% of the flood volume." Both of the foregoing facts were stated by the writer in the course of a general description of the basin; in the methodology used and described in the paper, ground water was separated out from the hydrographs of flood rises. An inspection of these hydrographs affords an approximate verification of the statements quoted.

The writer has no responsibility for the statement quoted by Messrs. Hoyt and Langbein.[19] Their interpretation of that statement might apply to parts of the Trinity basin outside the Blacklands, but not the East Fork above Rockwall.

In the ninth paragraph Messrs. Hoyt and Langbein make their own computation that 78% of the total runoff at Rockwall was surface runoff. The writer made no assumptions or computations of the percentage of total surface runoff at Rockwall. Surface runoff was determined for each rise of the hydrograph for the thirty-five storms through the elimination of base flow by generally accepted methods.

In the tenth paragraph Messrs. Hoyt and Langbein seem to question the results of the writer's presentation because it did not include research studies similar to those carried out at Coshocton. Undoubtedly such a research study can be made from data available at Waco; but it is entirely outside the scope of the subject matter presented.

In the eleventh paragraph the first question raised by the discussers, if properly related to the Trinity basin and to the material presented in the paper, is whether reduction in surface runoff can be assumed to be the equivalent of the reduction in flood runoff of the stream when there is no considerable subsurface return flow. With regard to the use of cultivated lands, if agriculturalists restricted their operations to "soils that combine high infiltration capacities with satisfactory moisture-retention properties," the nation would probably be on the verge of quite a famine.

The questions raised in the twelfth paragraph and thereafter are directly pertinent to the paper, but they also reflect the natural difficulty of fully understanding new methodologies and their implications until after a personal effort has been made to apply them. Messrs. Hoyt and Langbein state that they reviewed the writer's report as consultant to the Department of Agriculture, but apparently they did not distinguish between the two principal parts of the methodology as related to the objectives of that investigation. For each storm the report contained discussions of the probable reasons for differences between computed surface runoff and the surface runoff in the actual hydrograph. To clarify the natural resulting confusion, the following more extended discussion of Steps 7 and 8 is presented:

The hourly pattern of excess rainfall was computed for each rainfall station in the manner indicated in Table 3. These patterns then had to be transferred to patterns for each of the ten sub-basins. These in turn were weighted to produce the average hourly excess for the basin as a whole. The values of excess rainfall for most of the storms varied materially between rainfall stations. Many of the storms were actually partial-area storms. Initially the pattern transfer was made on the basis of Thiessen area weighting. Later, it was made on the basis of inverse distance ratios which seemed more nearly to reflect the actual variation across the basin. The latter method was adopted for determination of the correction factors and gave reasonable results for all the more uniform storms.

For the more highly varying and for some of the partial-area storms, neither of these arithmetical procedures could give a satisfactory indication of the actual distribution of excess rainfall over the sub-areas, and for such conditions the drawing of isohyetal maps was essential. The use of such maps throughout the study would have appreciably increased the significance of the results.

In all cases, excess rainfall was computed initially and transferred to a mean value for the entire basin by the proportional method. It was then compared to the measured surface runoff as determined from the Rockwall gage. Although this gage was a chain gage read twice daily, and, although for one or two of the greater floods the record included estimated values of discharge, it was necessary to assume that the complete record was valid and it was so accepted as a basis for comparison.

If the computed excess rainfall was greatly different from the measured runoff, this fact was taken as a "red flag" and the possible reason for the difference was explored and discussed. The same procedure was followed if the later computed hydrograph was seriously out of phase with the recorded hydrograph. Restudies of this kind resulted in several revised computations for some of the storms—for example, such a comparison served to clarify ambiguities of dating the cooperative observers' rainfall reports. For some of the storms the discordance could be largely accounted for by the method of transfer of values to the sub-basins; in others, the drawing of isohyetal maps giving rational consideration to the distribution of rainfall between stations quite generally produced weighted values for the basin having closer accord with the measured values. For those storms in Table 4, which were selected for inclusion in Table 5, isohyetal maps were initially made up on the basis of rainfall information only. For use in the second steps, such maps were in some instances readjusted to produce excess rainfall exactly equal to the measured runoff. This procedure was in lieu of the use of a correction factor.

For example, for storm 2 under the initial procedure the weighted excess was 1.77 in., requiring a correction factor of 0.91, but the later computed hydrograph was somewhat out of phase. Thus, a revision of the interpretation of dates on certain ambiguous rainfall reports was indicated. On this basis the recomputed weighted excess was 1.83 in.; and the correction factor, 0.88. This factor is shown in Table 4 and is based on transference by isohyetal map. This second computation was not influenced by the measured amount of runoff. For the succeeding "before and after" study, the pattern was shifted to produce better conformance with the shape of the hydrograph.

Table 5 is the compilation for those storms where excess rainfall was computed on the basis of the *M*-curve and transferred to the sub-areas either by the proportional method or by isohyetal maps. The only influence of the known "measured" runoff on this procedure was the indication of the possibility of error in the proportional method of transference. If (as was later concluded) such maps could have been used to advantage throughout this study, no reference whatever to measured values would have been involved.

A recheck of the data used in Table 5 discloses that one additional flood (No. 9) was excluded from this table besides those stated. Also one flood indicated in the range from 0.5 to 1.0 in., in the December 1 to March 15 period, was incorrectly included in that range. This table therefore is based on twenty-two floods for which the computation of excess rainfall and the indicated correction factors were completed before any comparison was made with measured runoff.

With respect to the question about the *M*-curve, the initial *M*-curve was developed from a study of the small watershed data from which the infiltration-capacity curves were derived.

Subsequent to the analysis of the thirty-five storms above Rockwall, determinations were made of the *M*-values (assuming all other data valid), the use of which would have resulted in reproducing the value of surface runoff taken from the hydrograph at Rockwall. This series of *M*-values departed somewhat from the *M*-curve shown in Fig. 4, placing this curve somewhat lower during the winter season and somewhat higher in July and August. Some composite of these two *M*-curves undoubtedly can now be used in this basin for forecasting the flood flow from any specific storm pattern.

Table 5 is the test of the ability of the described method to produce values of flood flow in fair conformance to measured values. Messrs. Hoyt and Langbein confuse the character of the data in Table 5 with the procedure in the succeeding stage. They ask, "If partial advantage is taken of the runoff as it was, why not take full advantage." This is exactly what was done in the second stage of the study in which the original computed values are adjusted by use of the correction factor or by revised or original isohyetal maps to an exact equality with the actual surface runoff. The reweighting of excess rainfall in accordance with the proposed program of land-use revision then produces "after" values of flood runoff. Thus, the present or "before" value having been adjusted to the measured value, the "after" value resulting from a computation identical in every respect (except for the land program) makes possible the determination of the reduction in flood flow which that land program would cause.

The writer is in full agreement with the questions concerning the use of hourly rainfall values. The procedure is quite sensitive to rainfall intensity. Mean rates for, say, 30 min could have been used to advantage if they had been generally available. It is interesting, however, that, even with only hourly values of rainfall derived from poor precipitation data, the results are generally consistent. In this investigation the objective is the determination of the average flood reduction with relation to flood magnitude. Possibly the poor rainfall data explain some of the scatter of points in Fig. 6; but nevertheless a rather significant trend is indicated.

In the fourth paragraph from the end of their discussion Messrs. Hoyt and Langbein state:

> "The report explains the influence of antecedent conditions as they affect soil moisture on the infiltration capacity during a storm. Increasing the volume of infiltration prior to a storm decreases the capacity of the basin to retain water. Therefore, under the changed conditions, to what extent would the presumed increase in infiltration operate adversely to lower infiltration capacities during subsequent storms?"

This question appears to be answered by the actual data presented. Infiltration-capacity curves, for each separate complex, were derived from small watershed data taken under a natural sequence of precipitation periods. Therefore the curves for pasture, for example, indicate the value of infiltration capacity for pasture when the soil moisture is related to antecedent infiltration for pasture. Since the infiltration for pasture is higher than for cultivated lands subjected to the same rains, the soil surface under pasture grass, and among other things protected from the effect of rain impact, seems to retain a higher capacity even though the moisture content be greater than that for adjacent cultivated fields.

The economic implications again are beyond the scope of the paper. However, the paper did not cover the subject of flow reduction as a whole, but only the "reduction in flood flow." Any adverse effect would seem to apply only to consumptive use of impounded flood waters. This, eventually, conceivably might be offset in some part by improvement in base flow.

Mr. Sherman's discussion presents the results of similar investigations in which he has used a methodology paralleling in many respect that which the writer applied to the Trinity River study. Mr. Sherman appears to be in thorough agreement with the practice of time condensation by which infiltration-capacity curves derived from natural rainfall data may be reduced to the approximate equivalent of curves that would have resulted from rainfall-intensity rates which exceeded infiltration-capacity rates in every case. This method permits a correlation between the infiltration-capacity curves derived from the two types of data. If such a condensation of the original derived curves is satisfactory, the condensed curves could, with some assurance, be expanded in the same manner, in order to be matched appropriately with any particular rainfall-intensity pattern.

Mr. Sherman also independently relates infiltration capacity to soil moisture through a compilation of antecedent infiltration. In his practice he has developed a somewhat simplified procedure as compared to the writer's *M*-curve, by relating infiltration-capacity values to three conditions of soil moisture deficiency.

It is of interest that, since the presentation of his discussion in May, 1943, Mr. Sherman has made a much more detailed analysis of the mechanics of infiltration and has developed a relationship between infiltration-capacity values and soil moisture deficiency as separated into capillary and noncapillary deficiency.[36]

As stated in the paper and in connection with the discussion by Messrs. Hoyt and Langbein, a second series of M-values was determined for the whole of the East Fork of the Trinity basin above Rockwall. On the basis of these additional values, a modified M-curve was developed. All of the data and the original and modified M-curves are shown in Fig. 10. The placing of the original M-curve, in the period from July to November, was based on a relatively few infiltrometer runs. Using the basin-wide data, satisfactory results cannot be secured from an infiltrometer during the period when these black soils are extensively cracked. Therefore, probably much of the applied water leaves the area of the infiltrometer plot through wide cracks and supplies noncapillary deficiency over a large area around the plot.

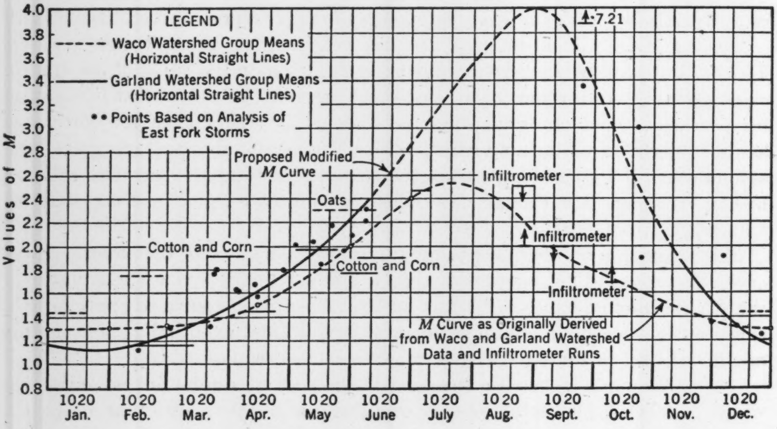

FIG. 10.—VARIATION, DURING ONE YEAR, OF THE VALUE OF M REQUIRED TO PRODUCE AN INFILTRATION CAPACITY OF 0.4 IN. PER HR

An inspection of the modified M-curve, even though it is sketched in, indicates that M-values of between 3 and 4 in. would control surface runoff for the months of July to October, inclusive, and further indicates that the probability of a major flood during those months is extremely remote. For example, for normal precipitation conditions in the three months prior to the last 30 days before a storm, infiltration capacity would not drop to 0.4 in. per hr until either—

(*a*) Infiltration in the storm had exceeded about 3.5 in.; or

(*b*) Some combination as, for example, 4 in. of infiltration from the preceding 30 days plus 1.5 in. of infiltration in the specific storm period had occurred.

[36] "Infiltration and the Physics of Soil Moisture," by L. K. Sherman, presented at the regional meeting of the Am. Geophysical Union in Berkeley, Calif., on February 15, 1944.

A study of the 5-yr record indicates a number of excessive precipitation periods that produced only insignificant rises of the hydrograph of stream flow. One such period involved about 7 in. of rainfall within 3 or 4 days.

Mr. Moore presents an interesting account of the difficulty in maintaining adequate supervision over a large group of rainfall gage observers. The writer made an analysis of some of the small watershed and runoff plot records at the Tyler Station, involving certain of the east Texas sandy soils. Infiltration capacity was determined for these soils for a number of complexes but the results were not used in the Trinity River investigation, since it was found that a negligible percentage of the soils in the basin above Rockwall was of that type. Out of these studies, however, some tentative conclusions were reached. One of these was that the infiltration capacity of terraced watersheds was not appreciably higher than that for watersheds having the same type of cover but without such structures. The greatly increased infiltration in the terraced channels probably resulted in a generally higher moisture content which offset the other advantages of the treatment. Another interesting result of these studies was finding that the terraced watershed in Bermuda grass and another watershed in native protected forest rarely produced any surface runoff.

Mr. Moore refers to the use of the rational formula by the Operation Division of the Soil Conservation Service with the choice of a constant value of *C* for each land use and soil group. The procedure which the writer has outlined would permit the choice of a value of *C* for each such group. This would properly reflect maximum soil moisture conditions and consequently would probably produce maximum values of runoff. Such an application may be justified where the ultimate purpose is to design structures of adequate capacity, as, for example, outlet channels for terraced areas.

Mr. Smith again raises the question of the use of average hourly rainfall intensities and comments further on the unsatisfactory character of the data. Apparently he would like to see an investigation of this type in which all the desirable data are of a highly accurate character. Such a study would then fall into the field of a high-grade research project. The investigation reported by the writer was one which needed to be made and had to be made on the basis of the data available. The results appeared to be highly significant, probably more so than any one would have anticipated before the effort was undertaken. It is to be hoped that at some future time, when technical personnel again becomes available for extensive hydrologic research, the methodology may be applied to some such basin as that of the Licking River in Ohio.

Mr. Smith's presentation of the data in Fig. 9 is extremely interesting. The use of information of this kind when properly correlated with corresponding infiltration-capacity curves would probably permit further material improvement in controlling soil moisture factors such as the *M*-curve which the writer has used. Mr. Smith has performed a real service in bringing up to date a brief bibliography for deriving infiltration-capacity curves.

The writer is highly gratified with Mr. Rowe's discussion. In a first draft of the paper the writer made an attempt to include a discussion of the analysis of drainage basins in which stream flow was materially affected by "quick subsurface return flow." He reviewed some of the excellent information which has become available from the Southern Appalachian Experiment Station of the Forest Service, U. S. Department of Agriculture, but was unable to cite good examples of the use of these data in the quantitative determination of the relation of stream flow to land factors. For this reason, the writer found it necessary to restrict his detailed presentation of methodology to the situation in which stream flow resulted primarily from surface runoff and in which infiltration capacity of the soil surface was the primary control. Under the heading, "Subsurface Retention and Detention," the writer expressed the hope that information might be presented with respect to a satisfactory methodology in which quick subsurface return flow represented a material part of stream flow.

Mr. Rowe has described briefly the approach in California to an analysis of this latter situation. He states that infiltration-capacity curves are derived from small plot infiltrometer measurements. Such derivations must be used with extreme caution. The writer has seen infiltrometer runs made on shallow surface soils and steep slopes where no surface runoff whatever was produced, and yet the streams in this area were subject to floods of considerable magnitude. In one particular instance, further investigation indicated that subsurface flow was preceding down slope through the porous surface soil at extremely high rates and that this flow generally came to the surface at the margins or banks of the small streams or gullies. Recently the writer analyzed infiltrometer runs on a deep fill of clean sand with practically no lateral slope but with a water table 5 ft to 6 ft below the surface. An analysis of these runs showed that they made possible a determination of infiltration capacity for only a few minutes after surface runoff began. Thereafter a mounded water table was flushed to the surface and the infiltrometer record showed merely the rate at which subsurface water was transmitted away from the vicinity of the plot. Both of the foregoing are unquestionably extreme cases. Many situations have been recognized in which surface runoff was produced and controlled by the infiltration capacity of the soil, but at the same time infiltration capacities continued at high values, soil-storage capacity became filled, and subsurface return flow occurred at high rates. A methodology that would recognize all of these conditions and permit the reproduction of flood flow in the streams on the basis of precipitation intensity and land factors will be much more complex than that presented by the writer. Such methodologies have been devised in connection with certain flood control surveys of the U. S. Department of Agriculture. It is hoped that some of these may be presented in detail to the engineering profession.

The remarks of Mr. Jarvis are particularly interesting. The writer is in agreement with his conclusion 3. With respect to the fourth paragraph, the writer would also anticipate that, for a watershed such as the North Concho in Texas, a revised program of land use and management might well result in a greater reduction of flood flow than was found for the Trinity basin.

STRENGTH OF SLENDER BEAMS

BY GEORGE WINTER,[1] ESQ.

WITH DISCUSSION BY MESSRS. T. MCLEAN JASPER, C. M. GOODRICH, J. P. WADLECK, H. D. HUSSEY, AND GEORGE WINTER.

SYNOPSIS

Slender beams loaded in the usual manner tend to fail laterally at stresses often far below the yield point of the material. This fact is provided for in design specifications by reducing the basic allowable stress in the extreme compression fiber for beams in which the ratio of length to width is greater than a prescribed maximum. The specified reduction is based more or less on semi-empirical considerations rather than on strict analytical study.

In this paper the ultimate strength of slender beams is determined by rational methods similar to those generally accepted in column design, due consideration being given to highly probable imperfections in loading and beam shape. It is shown that these methods, whose value in column analysis is well established, can be applied with comparative ease to the fundamentally more complex beam problem.

Beam curves, similar in character to the well-known column curves, serve to illustrate the influence on the ultimate strength of such factors as slenderness ratio, shape of cross section, and degree of imperfection. In addition, a discussion is given of the influence of the character of the load, of intermediate bracing, and of elastic restraint at the end connections.

GENERAL

It has long been recognized that transversely loaded slender beams may fail by lateral buckling at stresses far below the yield point or the ultimate stress of the material (1).[2] In recent years considerable attention has been devoted to investigating the magnitude of those loads (critical loads) which cause beams of given shapes and dimensions to become unstable. These investigations apply only to very slender beams which buckle at stresses below the proportional limit. Therefore, their application to structural design is limited to very long

---

NOTE.—Published in June, 1943, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[2] Numerals in parentheses, thus: (1), refer to the corresponding items in the Bibliography (Appendix I).

and narrow beams, just as the Eüler column formula gives reliable information on the carrying capacity only of very slender compression members. The designer, however, needs to know the allowable working stresses, with a given factor of safety, for beams of any dimensions. To meet this need, in the absence of more reliable information pertaining to beams of moderate slenderness, semi-empirical design specifications have been developed in various ways (2). Thus, the compression flange of a steel beam is frequently regarded as a strut free to buckle laterally, and the supposedly safe extreme fiber stress for this flange is obtained by applying a suitable column formula to the imaginary strut. It is evident that such a procedure represents, at best, a rather crude approximation, since the effect of the joint action of the compression flange with the remainder of the section, and particularly the influence of the torsional rigidity of the beam, are neglected entirely.

The situation is comparable to that which, years ago, prevailed in column design when the Eüler formula was accepted for columns of great slenderness and different kinds of semi-empirical transition curves were recommended for columns of moderate slenderness. In the field of compression members, considerable progress toward a more rational design has been made in recent years through acceptance of the secant formula or similar approaches (3)(4), as a criterion for the design of columns of any slenderness ratio. These methods have in common that they are based on a definite degree of inaccuracy of loading or of crookedness of the column. They allow a rigorous determination of the magnitude of that compression stress, $\frac{P}{A}$, which, for the given imperfections, will stress the outer fiber to the yield point or to any other given maximum stress. Column design curves and formulas are now generally based on this $\frac{P}{A}$-value.

This paper attempts to develop a similar rational basis for the design of slender beams. Paralleling the column methods, it assumes a given amount of inaccuracy of loading and proceeds to determine the magnitude of that applied stress, $\frac{M\,c}{I}$, which will stress to the yield point or any other given maximum value that point of the section farthest removed from the centroid of the section (for example, for I-beams the edges of the flanges). This applied stress can serve as a reliable design criterion just as the $\frac{P}{A}$-value obtained from the secant formula does in column design.

An analysis of doubly symmetrical solid and hollow sections, like rectangular or box-beams, is made first. This analysis is then extended to include the more involved symmetrical I-beam sections. From the resulting data, curves are drawn for various degrees of inaccuracy of loading and for different shapes of cross sections. These curves show the relation between the magnitude of that applied stress $s = \frac{M\,c}{I}$ which results in yield point stress s_y on the most remote points of the section and the slenderness ratio $\frac{L}{b}$ (L = span, b = width). By applying a given factor of safety, these curves can be redrawn to give the allowable bending stress directly as a function of the slenderness ratio.

In addition to this part of the study, several other related factors are investigated. One of these is the influence of the character of the load. For beams stressed below the proportional limit, the critical moment M_c which causes the beam to buckle laterally depends not only on the shape and material of the beam but also on the type of loading (5). Although a complete treatment of this question is beyond the scope of this paper, a brief discussion of the magnitude of its effect is given.

The critical loads and ultimate stresses for slender beams are derived for freely supported ends, just as the Eüler and the secant formulas apply only to pin-ended columns. Most beams, however, are restrained elastically at their ends, in various degrees. The influence of such end restraints may be provided for in the same manner as for columns—namely, by introducing an equivalent reduced length instead of the actual span.

Notation.—The letter symbols in this paper are defined where they first appear (unless the definition is self-evident) and are assembled for convenience of reference in Appendix II.

STRESSES IN SLENDER BEAMS

In determining stresses in beams subject to transverse loading, generally it is assumed that the loading plane coincides with one of the principal planes of the beam. If the loading plane is inclined with respect to one of the principal axes, the moment is resolved into two components, M_x and M_y (see Fig. 1(*a*)) and the maximum stress is computed from the equation

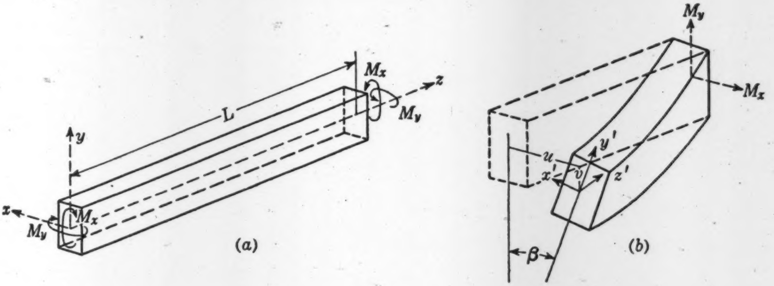

FIG. 1

$$s_m = \frac{M_x c_{x'}}{I_{x'}} + \frac{M_y c_{y'}}{I_{y'}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

This formula is reasonably accurate for rather short beams with small ratios of $\frac{L}{b}$. However, for slender beams the actual maximum stress is larger than that given by Eq. 1, because a beam so loaded twists as it bends (see Fig. 1(*b*)). The principal axes x' and y' of the cross section anywhere along the span are no longer parallel to the x-axis and y-axis, respectively, the inclination between these two sets of axes changing along the length of the beam. Consequently, the bending moments about the principal axes of the section are no longer M_x and M_y, but are the projections of these moments in the x' and y' directions. Therefore, they are dependent on the angle β. It will be shown that the increase of s_m due to the twist becomes very significant for slender beams; and, in fact, it may be regarded as the principal factor in relating allowable stresses to slenderness ratios $\frac{L}{b}$.

Inaccuracies of loading or shape are inevitable in beams just as they are in columns. In view of the influence of β on s_m it is proposed to assume that the plane of loading is slightly inclined with respect to the y-axis (Fig. 1(a)) and to investigate the effect of such inaccuracy of loading on beams of any slenderness in pure bending.

To determine the stresses in a section subtending the angle β with the y-axis it is necessary to project M_x and M_y into the x' and y' directions. With u and v representing the displacements of the centroid in the x-direction and y-direction, respectively, the direction cosines between the two sets of axes (5a) are as given in Table 1. In computing the values of this table advantage was taken of the fact that u, v, and β are small quantities. For this reason terms above the first order are negligible. In addition to the values for the x'-axis and y'-axis, cosines are also given with respect to the z'-axis (see Fig. 1(b)), since these will be used subsequently.

TABLE 1.—DIRECTION COSINES BETWEEN TWO SETS OF AXES

Axes	x	y
x'	1	β
y'	$-\beta$	1
z'	$\frac{du}{dz}$	$\frac{dv}{dz}$

With the vectors of M_x and M_y as shown in Fig. 1(b) the moments about the principal axes are

$$M_{x'} = - M_x + \beta M_y \tag{2a}$$

and

$$M_{y'} = \beta M_x + M_y \tag{2b}$$

The absolute magnitude of the maximum stress is obtained from the equation

$$s_m = \frac{M_{x'} c_{x'}}{I_{x'}} + \frac{M_{y'} c_{y'}}{I_{y'}} \tag{3a}$$

in which $I_{x'}$, $I_{y'}$, $c_{x'}$, and $c_{y'}$ are, respectively, the moments of inertia about, and the distances to the outer fiber from, the x' and y' axes of the section. Substitution of Eqs. 2 in Eq. 3a gives

$$s_m = \frac{c_{x'}}{I_{x'}} (M_x - \beta M_y) + \frac{c_{y'}}{I_{y'}} (\beta M_x + M_y) \tag{3b}$$

For deep beams ($I_{x'} \gg I_{y'}$) with but slightly inclined loadings ($M_x \gg M_y$), the term $- \frac{\beta M_y c_{x'}}{I_{x'}}$ is of higher order than the remainder of the terms. Consequently, for such conditions (of primary interest) this term can be neglected.

Then

$$s_m = \frac{M_x\, c_{x'}}{I_{x'}} + \frac{M_y\, c_{y'}}{I_{y'}} + \beta\, \frac{M_x\, c_{y'}}{I_{y'}} \tag{3c}$$

A comparison of Eq. 3*c* with the usual approximate Eq. 1 shows that the two differ by the term $\frac{\beta\, M_x\, c_{y'}}{I_{y'}}$ which is due to the twist β. To determine s_m it is necessary first to compute β.

THE SECANT FORMULA FOR RECTANGULAR AND BOX-BEAMS

For small angles β, neglecting terms of higher order, the curvature $\frac{d^2u}{(dz')^2} = \frac{d^2u}{dz^2}$ and the curvature $\frac{d^2v}{(dz')^2} = \frac{d^2v}{dz^2}$. Consequently, resolution of the applied end moments M_x and M_y in the x', y', and z' directions yields the three simultaneous equations of equilibrium (6):

$$M_{y'} = \beta\, M_x + M_y = E\, I_{y'}\, \frac{d^2u}{dz^2} \tag{4a}$$

$$M_{x'} = -\, M_x + \beta\, M_y = -\, E\, I_{x'}\, \frac{d^2v}{dz^2} \tag{4b}$$

and

$$M_{z'} = -\, \frac{du}{dz}\, M_x + \frac{dv}{dz}\, M_y = G\, K\, \frac{d\beta}{dz} \tag{4c}$$

in which K is the torsional constant of the section (7). To eliminate u and v, Eq. 4*c* is differentiated and $\frac{d^2u}{dz^2}$ and $\frac{d^2v}{dz^2}$ substituted from Eqs. 4*a* and 4*b*. Thus,

$$\frac{d^2\beta}{dz^2} + \left(\frac{M^2_x}{R_{y'}} + \frac{M^2_y}{R_{x'}}\right) \beta = M_x\, M_y \left(\frac{1}{R_{x'}} - \frac{1}{R_{y'}}\right) \tag{5}$$

in which $R_{x'} = E\, G\, K\, I_{x'}$; and $R_{y'} = E\, G\, K\, I_{y'}$, E being Young's modulus and G the shearing modulus. With

$$\alpha^2 = \frac{M^2_x}{R_{y'}} + \frac{M^2_y}{R_{x'}} \tag{6a}$$

and

$$\gamma = M_x\, M_y \left(\frac{1}{R_{x'}} - \frac{1}{R_{y'}}\right) \tag{6b}$$

the general solution of Eq. 5 is

$$\beta = C_1 \cos \alpha\, z + C_2 \sin \alpha\, z + \frac{\gamma}{\alpha^2} \tag{7}$$

in which the constants C_1 and C_2 are determined from the end conditions. If the beam is "freely supported" (that is, if the ends are free to rotate about the x-axis and y-axis, while rotation about the z-axis is prevented), the end conditions are: $\beta_{z=0} = \beta_{z=L} = 0$; or—

$$\beta = \frac{\gamma}{\alpha^2}\left[1 - \left(\cos \alpha\, z + \sin \alpha\, z \tan \frac{\alpha\, L}{2}\right)\right] \tag{8a}$$

From the coefficient

$$\frac{\gamma}{\alpha^2} = \frac{M_y}{M_x} \frac{\dfrac{I_{y'}}{I_{x'}} - 1}{\left[1 + \left(\dfrac{M_y}{M_x}\right)^2 \dfrac{I_{y'}}{I_{x'}}\right]} \qquad \text{(8b)}$$

it is seen that any symmetrical beam, subject to unsymmetrical bending, twists as it bends. In fact, $\beta = 0$ only if $I_{x'} = I_{y'}$. The physical significance of this result is this: It is well known that the direction of the deflections of beams subject to unsymmetrical bending is different from that of the applied bending moment. Consequently, the normal to the plane of any cross section is not perpendicular to the vector of the applied moment. The projection of this vector in the direction of the section-normal is equal to the twisting moment at that particular section. It vanishes only if $I_{x'} = I_{y'}$, as, for example, for quadratic or circular sections, since beams of such shape deflect in the plane of the applied moment.

In practical applications the influence of β becomes important only for deep beams $\left(\text{that is, when } \dfrac{I_{y'}}{I_{x'}} \ll 1\right)$. Eqs. 6 may be rewritten in the form

$$\alpha^2 = \frac{M^2{}_x}{R_{y'}} \left[1 + \left(\frac{M_y}{M_x}\right)^2 \frac{I_{y'}}{I_{x'}}\right] \qquad \text{(9a)}$$

and

$$\gamma = \frac{M_x\, M_y}{R_{y'}} \left[\frac{I_{y'}}{I_{x'}} - 1\right] \qquad \text{(9b)}$$

If terms of the order $\dfrac{I_{y'}}{I_{x'}}$ as compared with 1 are neglected,

$$\beta = \frac{\gamma_1}{\alpha^2{}_1} \left[1 - \left(\cos \alpha_1 z + \sin \alpha_1 z \tan \frac{\alpha_1 L}{2}\right)\right] \qquad \text{(10)}$$

in which,

$$\alpha^2{}_1 = \frac{M^2{}_x}{R_{y'}} \qquad \text{(11a)}$$

and

$$\gamma_1 = -\frac{M_x\, M_y}{R_{y'}} \qquad \text{(11b)}$$

Eqs. 10 and 11 also can be obtained directly if, in Eq. 4*c*, the influence of v on β is omitted (it actually is negligible in deep beams). Then, instead of the three Eqs. 4 one has simply Eq. 4*a* and the modified expression (see Eq. 4*c*),

$$M_{z'} = -\frac{du}{dz} M_x = G\, K \frac{d\beta}{dz} \qquad \text{(12)}$$

Eq. 4*b* represents the curvature in the direction of the main bending moment and is independent of Eqs. 4*a* and 12. The simultaneous solution of Eqs. 4*a* and 12 is identical with Eq. 10. From the comparison of the approximate coefficient

$$\frac{\gamma_1}{\alpha^2_1} = -\frac{M_y}{M_x} \quad \text{.......................} (13)$$

for deep beams with the exact expression Eq. 8*b*, it is seen that in fact only terms of order $\frac{I_{y'}}{I_{x'}}$ have been neglected.

The maximum value of β occurs at $z = \frac{L}{2}$ and it is consequently at this place that the third term in Eq. 3*c* becomes most important. From Eq. 10, with $z = \frac{L}{2}$,

$$\beta_m = \frac{\gamma_1}{\alpha^2_1}\left(1 - \sec\frac{\alpha_1 L}{2}\right) \quad \text{.................} (14a)$$

or, with Eq. 13,

$$\beta_m = -\frac{M_y}{M_x}\left(1 - \sec\frac{\alpha_1 L}{2}\right) \quad \text{................} (14b)$$

Substitution of this value of β in Eq. 3*c* yields

$$s_m = \frac{M_x c_{x'}}{I_{x'}}\left(1 + \frac{M_y c_{y'} I_{x'}}{M_x c_{x'} I_{y'}} \sec\frac{\alpha_1 L}{2}\right) \quad \text{............} (15)$$

On the other hand

$$s = \frac{M_x c_{x'}}{I_{x'}} \quad \text{........................} (16)$$

is the direct bending stress for the ideally straight beam loaded exactly in the y-direction; that is, for vertically loaded beams it is the only stress usually considered by the designer. Also, with $(s)_y = \frac{M_y c_{y'}}{I_{y'}}$ —

$$k = \frac{M_y c_{y'}}{I_{y'}} \frac{I_{x'}}{M_x c_{x'}} = \frac{(s)_y}{s} \quad \text{..................} (17)$$

is a convenient measure of the inaccuracy of loading, comparable to $\frac{e\,c}{r^2}$ in column design (3)(4). Finally, from Eq. 11*a*,

$$\frac{\alpha_1 L}{2} = \frac{L}{2}\frac{M_x}{\sqrt{R_{y'}}} = \frac{L\, s\, I_{x'}}{h\sqrt{E\,G\,I_{y'}\,K}} = \frac{L}{b}\frac{s}{\sqrt{E\,G}}A' \quad \text{.........} (18)$$

in which A' is a non-dimensional characteristic of the cross section

$$A' = \frac{I_{x'}}{\sqrt{I_{y'}\,K}}\frac{b}{h} \quad \text{.......................} (19)$$

With these simplifications Eq. 15 may now be rewritten as follows:

$$s_m = s\left[1 + k\sec\left(\frac{L}{b}\frac{s}{\sqrt{E\,G}}A'\right)\right] \quad \text{..............} (20)$$

For a deep rectangular section with $I_{x'} = \frac{b\,h^3}{12}$, $I_{y'} = \frac{b^3\,h}{12}$, $K = \frac{b^3\,h}{3}$, A' has the particularly simple value

$$A' = \frac{h}{2\,b} \quad \text{(21)}$$

For other types such as box-beams, expressions for A' are obtained easily from Eq. 19.

The practical problem, then, is to use Eq. 20 for finding pairs of values s and $\frac{L}{b}$ such that the maximum stress s_m has a prescribed value. In particular, the ultimate strength of a steel beam will be reached when s_m is equal to the yield point s_y. (Actually the carrying capacity of a beam is not yet reached when the diagonally opposite edges are stressed to the yield point. The main part of the section is then still stressed to a smaller amount and the beam will sustain a further load increase (8). For this same reason the secant formula for columns gives values somewhat below the ultimate capacity of the strut, especially for small $\frac{L}{r}$-values (4). It is customary, however, to disregard this strength reserve and to consider as the limiting load that load at which yield-point stresses occur in any portion of the section. This is particularly justified for dynamic loading.) To make $s_m = s_y$, Eq. 20 is conveniently written as

$$s = \frac{s_y}{1 + k \sec\left(\frac{L}{b}\frac{s}{\sqrt{E\,G}}\,A'\right)} \quad \text{(22)}$$

which, in form, is analogous to the secant formula for columns. Thus, using Eq. 22, it is possible to plot s versus $\frac{L}{b}$ for any given yield point s_y and any degree of inaccuracy of loading k. It is seen that in addition to s_y and k, the $\left(s - \frac{L}{b}\right)$-relation also depends on the characteristic A' of the cross section. For rectangular beams, with $A' = \frac{h}{2\,b}$, the following particularly simple formula is obtained:

$$s = \frac{s_y}{1 + k \sec\left(\frac{L\,h}{2\,b^2}\frac{s}{\sqrt{E\,G}}\right)} \quad \text{(23)}$$

Just as in the case of columns, any desired factor of safety is easily applied to these secant formulas, and results in curves giving the allowable working stress as a function of $\frac{L}{b}$ for given k and A'.

THE SECANT FORMULA FOR I-BEAMS

The formulas discussed in the preceding section apply only to doubly symmetrical solid or hollow cross sections. In deriving similar equations for symmetrical I-beams account must be taken of the additional torsional resistance of such beams due to lateral bending of the flanges. Instead of Eqs. 4, one has then (6):

$$M_{y'} = \beta\, M_x + M_y = E\, I_{y'} \frac{d^2u}{dz^2} \qquad \text{(24a)}$$

$$M_{x'} = -\, M_x + \beta\, M_y = -\, E\, I_{x'} \frac{d^2v}{dz^2} \qquad \text{(24b)}$$

and

$$M_{z'} = -\frac{du}{dz} M_x + \frac{dv}{dz} M_y = G\, K \frac{d\beta}{dz} - E\, I_{y'} \frac{h^2}{4} \frac{d^3\beta}{dz^3} \qquad \text{(24c)}$$

in which the second term on the right side of Eq. 24*c* represents the contribution of the flanges to the torsional rigidity.

The end conditions for the freely supported beam are

$$\beta_{z=0} = \beta_{z=L} = \left(\frac{d^2\beta}{dz^2}\right)_{z=0} = \left(\frac{d^2\beta}{dz^2}\right)_{z=L} = 0 \qquad \text{(25)}$$

The last two conditions express the fact that the longitudinal stresses due to warping of the beam vanish at the free ends. The solution satisfying Eqs. 24 and 25, as derived jointly by D. F. Gunder and the author, is

$$\beta = q \left[p_2 \left(-\sin m_1 z \tan \frac{m_1 L}{2} - \cos m_1 z \right) + p_1 \left(\sinh m_2 z \tanh \frac{m_2 L}{2} - \cosh m_2 z \right) + 1 \right] \qquad \text{(26)}$$

in which

$$q = -\frac{\dfrac{M_x M_y}{E} \left(\dfrac{1}{I_{y'}} - \dfrac{1}{I_{x'}} \right)}{\dfrac{M^2{}_x}{E\, I_{y'}} + \dfrac{M^2{}_y}{E\, I_{x'}}} \qquad \text{(27a)}$$

$$m^2{}_1 = -\frac{2\, G\, K}{E\, I_{y'}\, h^2} + \sqrt{\frac{4\, G^2\, K^2}{E^2\, (I_{y'})^2\, h^4} + \frac{4}{h^2} \left[\frac{M^2{}_x}{E^2\, (I_{y'})^2} + \frac{M^2{}_y}{E^2\, I_{y'}\, I_{x'}} \right]} \qquad \text{(27b)}$$

$$m^2{}_2 = \frac{2\, G\, K}{E\, I_{y'}\, h^2} + \sqrt{\frac{4\, G^2\, K^2}{E^2\, (I_{y'})^2\, h^4} + \frac{4}{h^2} \left[\frac{M^2{}_x}{E^2\, (I_{y'})^2} + \frac{M^2{}_y}{E^2\, I_{y'}\, I_{x'}} \right]} \qquad \text{(27c)}$$

and

$$p_1 = \frac{m^2{}_1}{m^2{}_1 + m^2{}_2}\,; \qquad p_2 = \frac{m^2{}_2}{m^2{}_1 + m^2{}_2} \qquad \text{(27d)}$$

Since, as before, $M_x \gg M_y$ and $I_{x'} \gg I_{y'}$, the expression for q simplifies to

$$q = -\frac{M_y}{M_x} \qquad \text{(28)}$$

For the same reason, in Eqs. 27*b* and 27*c*, $\dfrac{M^2{}_y}{E^2\, I_{y'}\, I_{x'}}$ is negligible when compared with $\dfrac{M^2_x}{E^2\,(I_{y'})^2}$. Multiplying and dividing $\dfrac{4}{h^2}\dfrac{M^2_x}{E^2\,(I_{y'})^2}$ in Eqs. 27*b* and 27*c* by $h^2\,(I_{x'})^2$ and factoring,

$$m^2{}_1 = \frac{2\,G\,K}{E\,I_{y'}\,h^2}\left[\sqrt{1+\left(2\,\frac{s}{G}\,\frac{I_{x'}}{K}\right)^2} - 1\right] \ldots\ldots\ldots\ldots (29a)$$

and

$$m^2{}_2 = \frac{2\,G\,K}{E\,I_{y'}\,h^2}\left[\sqrt{1+\left(2\,\frac{s}{G}\,\frac{I_{x'}}{K}\right)^2} + 1\right] \ldots\ldots\ldots\ldots (29b)$$

in which, as before (see Eq. 16), $s = \dfrac{M_x\,h}{2\,I_{x'}}$ is the applied direct bending stress.

The maximum stress s_m is again computed from Eq. 3*c* by introducing the maximum value for β. From Eq. 26, for $z = \dfrac{L}{2}$, and with q from Eq. 28,

$$\beta_m = -\frac{M_y}{M_x}\left[1 - p_2 \sec\frac{m_1\,L}{2} - p_1 \operatorname{sech}\frac{m_2\,L}{2}\right] \ldots\ldots\ldots\ldots (30)$$

Substitution of this expression in Eq. 3*c* gives for the maximum stress

$$s_m = \frac{M_x\,c_{x'}}{I_{x'}}\left[1 + \frac{M_y\,c_{y'}\,I_{x'}}{M_x\,c_{x'}\,I_{y'}}\left(p_2 \sec\frac{m_1\,L}{2} + p_1 \operatorname{sech}\frac{m_2\,L}{2}\right)\right] \ldots (31)$$

or, with s and k from Eqs. 16 and 17

$$s_m = s\left[1 + k\left(p_2 \sec\frac{m_1\,L}{2} + p_1 \operatorname{sech}\frac{m_2\,L}{2}\right)\right] \ldots\ldots\ldots\ldots (32)$$

Convenient forms of the arguments are obtained by multiplying and dividing by b^2 the factor in front of the brackets of Eqs. 29, and by making use of the relation $G = \dfrac{E}{2\,(1+\nu)}$. Then

$$\frac{m_1\,L}{2} = \frac{L}{2\,b}\sqrt{\frac{1}{1+\nu}\,B'\left\{\sqrt{1+\left[\frac{4\,(1+\nu)\,s}{E}\,C'\right]^2} - 1\right\}} \ldots (33a)$$

and

$$\frac{m_2\,L}{2} = \frac{L}{2\,b}\sqrt{\frac{1}{1+\nu}\,B'\left\{\sqrt{1+\left[\frac{4\,(1+\nu)\,s}{E}\,C'\right]^2} + 1\right\}} \ldots (33b)$$

in which ν is Poisson's ratio and B' and C' are two non-dimensional characteristics of the cross section:

$$B' = \frac{K\,b^2}{I_{y'}\,h^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34a)$$

and

$$C' = \frac{I_{x'}}{K} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34b)$$

Also, using Eqs. 33 in Eq. 27*d*, the following simple expressions are obtained for p_1 and p_2:

$$p_1 = \frac{\sqrt{1 + \left[\frac{4\,(1+\nu)\,\bar{s}}{E}\,C'\right]^2} - 1}{2\sqrt{1 + \left[\frac{4\,(1+\nu)\,\bar{s}}{E}\,C'\right]^2}} \tag{35a}$$

and

$$p_2 = \frac{\sqrt{1 + \left[\frac{4\,(1+\nu)\,\bar{s}}{E}\,C'\right]^2} + 1}{2\sqrt{1 + \left[\frac{4\,(1+\nu)\,\bar{s}}{E}\,C'\right]^2}} = 1 - p_1 \tag{35b}$$

If, for abbreviation, Eqs. 33 are rewritten in the form

$$\frac{m_1 L}{2} = \frac{L}{2\,b}\,D'_1; \qquad \text{and} \qquad \frac{m_2 L}{2} = \frac{L}{2\,b}\,D'_2 \tag{36}$$

then from Eq. 32, by making $s_m = s_y$, the secant formula for I-beams is obtained:

$$\bar{s} = \frac{s_y}{1 + k\left[p_2 \sec\left(\frac{L}{2\,b}\,D'_1\right) + p_1 \operatorname{sech}\left(\frac{L}{2\,b}\,D'_2\right)\right]} \tag{37}$$

It is seen from Eq. 37 that, as in the case of rectangular or box-beams, the direct bending stress $\bar{s}$ which produces yield-point stress in the most remote fiber depends not only on k and the slenderness ratio $\frac{L}{b}$, but also on additional characteristics of the cross section, B' and C'. In fact (compare Eqs. 33 and 35), p_1, p_2, D'_1, and D'_2 all depend upon these characteristics.

Eq. 37 is not very convenient to evaluate and can be solved numerically by a cut-and-try process only. However, considerable simplification can be made in most cases. From Eqs. 33 it is seen that $\frac{m_1 L}{2} < \frac{m_2 L}{2}$. Consequently $\sec\frac{m_1 L}{2} = \sec\left(\frac{L}{2\,b}\,D'_1\right) > \operatorname{sech}\left(\frac{L}{2\,b}\,D'_2\right) = \operatorname{sech}\frac{m_2 L}{2}$. In addition, from Eqs. 35 it is seen that $p_1 < p_2$. Consequently,

$$p_2 \sec\left(\frac{L}{2\,b}\,D'_1\right) \gg p_1 \operatorname{sech}\left(\frac{L}{2\,b}\,D'_2\right) \tag{38}$$

and therefore, in most cases, the last term in the denominator of Eq. 37 is negligible. The simplified form of the secant formula for I-beams is then

$$\bar{s} = \frac{s_y}{1 + k\,p_2 \sec\left(\frac{L}{2\,b}\,D'_1\right)} \tag{39}$$

For beams of medium and large slenderness the error so introduced is entirely negligible. Only for beams of rather small slenderness does the term

$p_1 \operatorname{sech}\left(\frac{L}{2\,b}D'_2\right)$ become significant. For such short beams s approaches $\frac{s_y}{1+k}$. Numerical computations for various rolled steel I-sections showed that for $\frac{L}{b}$ corresponding to about $s = 0.9\,\frac{s_y}{1+k}$ the error caused by omitting the hyperbolic term amounts to from 2% to 5%, and increases for still larger values of s $\left(\text{smaller values of } \frac{L}{b}\right)$. Since, for such beams, the hyperbolic term is no longer negligible, as a first approximation $\frac{L}{b}$ is computed from Eq. 39. The value so obtained is somewhat too large. Therefore, a smaller value is

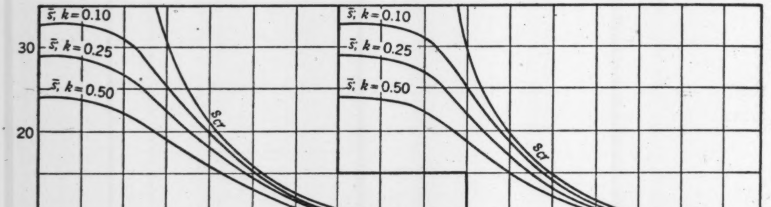

Fig. 2.—Ultimate Stress $\bar{s}$ for a Yield Point of 36,000 Lb per Sq In. and for Various Degrees of Imperfection k; and the Theoretical Buckling Stress s_c for an Ideally Perfect Beam (See Fig. 3 for Dimensions of Beams)

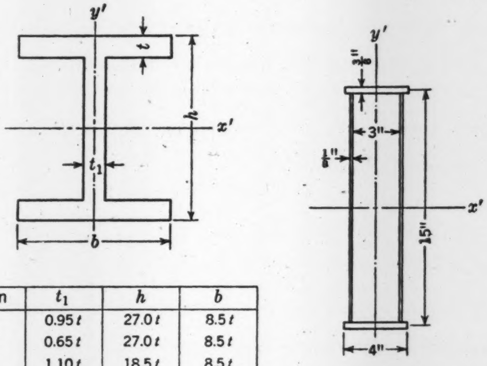
substituted in the accurate Eq. 37 and the process is repeated until satisfactory accuracy is obtained. This method of successive approximation requires not more than two or three trials to give $\frac{L}{b}$ correct within a fraction of 1%.

BEAM CURVES

For columns, the influence of eccentric loading on the strength is demonstrated most easily by plotting s versus $\frac{L}{r}$ for given magnitudes of eccentricity (3)(4)(5). Design curves or formulas are then established by selecting a definite eccentricity most likely to fit practical conditions and applying a given factor of safety to the curve corresponding to that eccentricity (3)(9).

To allow for a similar approach in regard to beams, curves of the same nature for structural I-beams are drawn in Fig. 2. These curves were computed by means of Eqs. 37 and 39 for a yield-point stress s_y = 36,000 lb per sq in. Since, in the case of beams, s depends not only on the slenderness ratio $\frac{L}{b}$ but also on the characteristics B' and C' of the cross section (see Eqs. 34), it is not possible to draw a single set of curves for I-beams of any shape. For this reason, curves are given for four different I-beams, the dimensions of which are indicated in Fig. 3. These dimensions were chosen to cover, as far as possible, most of the range of standard rolled sections. Thus, the dimensions of beam A are approximately those of large heavy beams like 24-in., 100-lb I-beam or 18-in., 94-lb I-beam; those of beam B correspond to the lighter sections of the same depth such as 24-in., 79.9-lb I-beam or 18-in., 54.7-lb I-beam. The dimensions of beam C are approximately those of small, heavy beams like 15-in., 75-lb I-beam or 8-in., 25.5-lb I-beam, whereas those of beam D correspond to the lighter sections of the same depth, such as 15-in., 60.8-lb I-beam or 8-in., 18.4-lb I-beam. In Fig. 2 curves are drawn for three values of the degree of imperfection—k = 0.10, 0.25, and 0.50.



Beam	t_1	h	b
A	0.95 t	27.0 t	8.5 t
B	0.65 t	27.0 t	8.5 t
C	1.10 t	18.5 t	8.5 t
D	0.65 t	18.5 t	8.5 t

FIG. 3.—DIMENSIONS OF BEAMS WHOSE $\bar{s}$-CURVES ARE GIVEN IN FIGS. 2 AND 4

In addition to the s-curves the critical buckling stresses s_c are plotted for the four beams. The stress s_c is the maximum bending stress at which an ideally straight beam bent exactly in the plane of the web buckles laterally.

This s_c is easily computed from (10*a*):

$$M_c = E\frac{\pi^2}{L^2}\sqrt{I^2_o h^2 + 2\,C\,I_o\frac{L^2}{\pi^2}} \quad \text{(40)}$$

From this equation, by simple transformation, the critical stress is found to be

$$s_c = \frac{E\,\pi^2}{2\left(\frac{L}{b}\right)^2}\left(\frac{h}{b}\right)^2\sqrt{\left(\frac{I_{y'}}{2\,I_{x'}}\right)^2 + \frac{K\,I_{y'}}{2\,(1+\nu)\,I^2_{x'}}\left(\frac{L}{\pi\,h}\right)^2} \quad \text{(41)}$$

Eq. 41 was used for plotting the $\left(s_c - \frac{L}{b}\right)$-curves in Fig. 2. From these four sets of curves the following conclusions may be drawn:

Conclusion (*A*).—The general character of the $\bar{s}$-curves is the same for all beams. They start with $\bar{s} = \frac{s_y}{1+k}$ for $\frac{L}{b} = 0$ and approach the s_c-curves asymptotically at large values of $\frac{L}{b}$.

Conclusion (*B*).—For any given values of k and $\frac{L}{b}$ the corresponding value of $\bar{s}$ depends to a considerable degree upon the dimensions of the section. Of the four beams investigated beam B is the weakest laterally, showing the smallest $\bar{s}$ for a given k and $\frac{L}{b}$. It is followed in the order of increasing lateral strength by beams *A*, *D*, and *C*:

Beam	Values of $\bar{s}$ for $k = 0.25$ and $\frac{L}{b} = 50$
B	13,300
A	14,400
D	17,700
C	19,600

Conclusion (*C*).—The $\bar{s}$-curves approach the s_c-curves faster for the laterally weaker beams (AB), so that for such beams s_c is a fair measure of strength for large values of the slenderness ratio $\frac{L}{b}$. However, for laterally stronger beams (CD) the $\bar{s}$-curves fall considerably below the s_c-curves even for large values of $\frac{L}{b}$. Therefore, for such beams, the critical loads computed in the usual way (5)(10) for ideal straightness and ideal accuracy of loading are hardly to be regarded as a reliable criterion for the strength of structural beams with their usual inevitable imperfections.

Conclusion (*D*).—The strength of beams, particularly those of small and medium slenderness, depends mainly on the degree of imperfection k. In this connection it is interesting to note that the inclinations of the planes of loading corresponding to $k = 0.1$ to 0.5 are very small indeed. From Eq. 17 it is seen that

$$k = \frac{M_y}{M_x}\frac{S_{x'}}{S_{y'}} \quad \text{(42)}$$

in which $S_{x'}$ and $S_{y'}$ are the section moduli about the x' and y' axes, respectively. Consequently, the inclination ψ of the loading plane is

$$\psi = \frac{M_y}{M_x} = k\,\frac{S_{y'}}{S_{x'}} \qquad (43)$$

Since, for rolled I-sections, in general $S_{y'} : S_{x'} = 1 : 10$, the degrees of imperfection $k = 0.10$, 0.25, and 0.50 correspond respectively to inclinations of the loading plane of $\psi = 1 : 100$, $1 : 40$, and $1 : 20$. (This compares with a tolerance of 1 : 32 for "out of square or parallel" for American standard beams (11).)

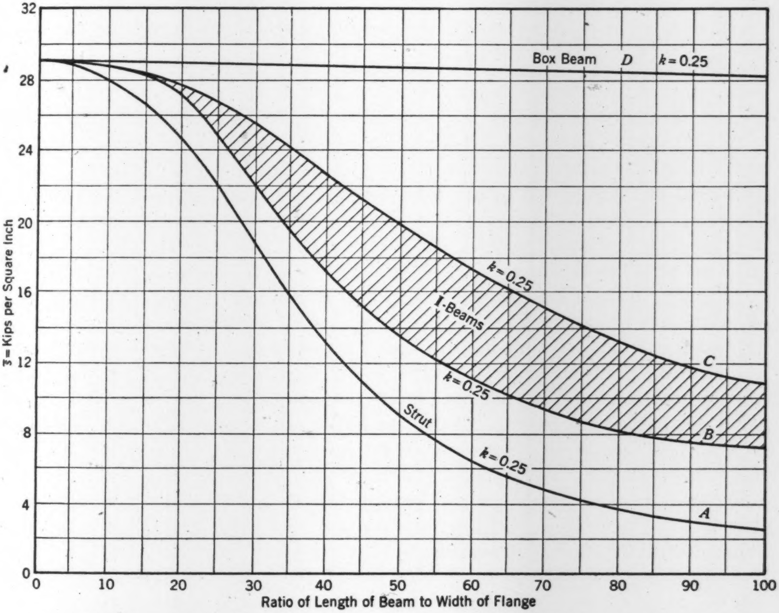


Fig. 4.—Ultimate Stress $\bar{s}$ for a Yield Point of 36,000 Lb per Sq In. and for $k = 0.25$
Curve A: Compression Flange Taken as Disconnected Compression Member Free to Buckle Laterally
Curve B: $\bar{s}$-Curve for Laterally Weak I-Beam B
Curve C: $\bar{s}$-Curve for Laterally Strong I-Beam C
Curve D: $\bar{s}$-Curve for Box-Beam (see Fig. 3 for dimensions of beams)

In Fig. 4, curves B and C for $k = 0.25$ have been drawn once more for the weakest and the strongest of the four beams. (The writer, emphatically, is not proposing to use $k = 0.25$ for design purposes. He selected this value for convenience exclusively, chiefly because design curves for columns are generally based on $\frac{e\,c}{r^2} = 0.25$. The proper degree of imperfection, k, to be used in design can be established only by extensive tests.) Additional computations showed that the curves for most of the standard I-beams and for most of those wide-flange beams which are generally used as beams rather than columns fall between these two extreme curves. In Fig. 4, therefore, the shaded strip represents the region that is of the most practical interest to the designer. (For establishing design curves it is desirable to make a more complete survey of the entire range of rolled sections than the writer was able to undertake. Also, in addition to investigating only a limited number of beams, the writer simplified the shape of the cross sections as shown in Fig. 3(*a*), and also used an approximate formula—$K = \frac{1}{3} \Sigma w t^3$—for determining K. Therefore, the shaded zone in Fig. 4 represents the range of rolled sections in an approximate way only.)

Curve A in Fig. 4 represents the secant curve $\left(\frac{e c}{r^2} = 0.25\right)$ for the compression flange as a strut free to buckle laterally. This curve is seen to fall below any of the beam curves. Since considering the compression flange as a free strut means neglecting the additional resistance to twist and to lateral deflection of the remainder of the beam it is but natural that the values of s so obtained should be much smaller than those computed for the entire beam. It is common practice with many designers to limit the stress in the compression flange according to the column formula. Fig. 4 demonstrates clearly that such a procedure imposes unnecessarily severe restrictions on the allowable compression stress in bending.

Finally, in the same Fig. 4, curve D is given for a box-beam, the dimensions of which are shown in Fig. 3. (The dimensions of this beam are such as to represent a small-scale model of a heavy box girder of the type used in crane structures.) This curve was computed by means of Eq. 22. It illustrates the far greater lateral strength of slender box-beams as compared with I-beams. This difference is caused chiefly by the large resistance to twist characteristic of such sections, or, in other words, by the large value of K as compared with $I_{x'}$. Some design specifications are so worded that the same limitations on allowable compression stress in bending apply both to box-beams and to I-beams. The curves in Fig. 4 show the much greater rigidity of box-beams which is wholly ignored in specifications of this kind. In fact, it appears from these curves that, if proper use is made of the large rigidity of box-beams, such sections are economically far more advantageous than I-sections for heavy structures of great span and considerable slenderness.

BEAMS SUBJECT TO VARIOUS TYPES OF TRANSVERSE LOADING

The foregoing conclusions were obtained by analyzing beams in pure bending; that is, subject to end moments only (see Fig. 1(*a*)). Structural beams, however, are acted upon by variously distributed transverse loads between supports rather than by end moments. It is to be asked, therefore, to what extent is an analysis of beams in pure bending applicable to transversely loaded structural members. An exact investigation of this question meets with practically insurmountable mathematical difficulties. It is easily possible, however, to explore the influence of the character of the load for the two extreme cases of very short beams on the one hand and very slender ones on the other. From such an investigation conclusions can be drawn for beams of medium slenderness.

In Eq. 3c, the moments M_x and M_y may result from any kind of transverse loading or pure bending. For given values of M_x and M_y, however, the magnitude of β is different for different types of loading. Therefore, the only term in Eq. 3c that depends on the type of loading is the one involving β. For very short beams, however, the influence of β is insignificant since, in the limit, $\beta = 0$ for $\frac{L}{b} = 0$. For this limiting case, therefore, Eq. 3c transforms into Eq. 1 which is independent of the type of loading. Consequently, for $\frac{L}{b} = 0$,

$$s = \frac{s_y}{1 + k} \qquad (44)$$

no matter how the beam is loaded. From Figs. 2 and 4 it is seen that all curves start at this value of s and all have horizontal tangents at that point. It can be stated, therefore, that the influence of the character of the load is nil for $\frac{L}{b} = 0$ and is negligibly small for beams of small slenderness ratio. If $\bar{M}_B$ represents the magnitude of M_x resulting in s_B for pure bending, and $\bar{M}_L$ the moment resulting in s_L for any particular type of transverse loading, then, for small values of $\frac{L}{b}$,

$$r = \frac{s_L}{s_B} = \frac{\bar{M}_L}{\bar{M}_B} = 1 \qquad (45a)$$

For slender beams, on the other hand, the secant curves of Fig. 2 approach asymptotically the curves for the critical buckling stress. Therefore, for such beams, the ultimate applied stresses s as obtained from the secant formula depend on the type of loading in the same way as do the critical buckling stresses, s_c. Since the buckling loads of beams subject to various types of loading have been investigated extensively (5)(10)(12), it is possible by means of available formulas to establish the ratios

$$r_c = \frac{s_{cL}}{s_{cB}} = \frac{M_{cL}}{M_{cB}} \qquad (45b)$$

in which M_{cB} is the critical moment for pure bending, M_{cL} that for any particular type of transverse loading, and s_{cB} and s_{cL} are the corresponding maximum fiber stresses. Then, because of the proximity of the s-curves and the s_c-curves for slender beams, $s_L \sim r_c\, s_B$. In this manner it is possible to investigate the influence of transverse loading for the two extreme cases of very short and of very slender beams.

To cover the most characteristic practical types of loading, the ratio r_c will be investigated for I-beams for a concentrated load at the center of the span, for uniformly distributed load, and for two equal loads applied at the quarter points.

The critical loads and moments of transversely loaded beams depend not only on the dimensions of the member and the type of loading, but also on the level, relative to the neutral axis, at which loads are applied (5)(10)(12). The ratios $\bar{r}_c$ for loads applied at the centroidal axis are independent of the configuration of the beam; for loads applied at other levels, however, $\bar{r}_c$ depends on the dimensions of the member. For this reason, loads applied at the centroid will be investigated first.

From Eq. 40, the critical moment for a symmetrical I-beam in pure bending is

$$M_{cB} = E\,\frac{\pi^2}{L^2}\sqrt{I^2_o\,h^2 + \frac{K}{1+\nu}\,I_o\,\frac{L^2}{\pi^2}} \quad \text{.............. (46)}$$

in which I_o is the moment of inertia of one flange about the axis of the web. For a concentrated load applied at the neutral axis (10*b*), the critical moment is

$$M_{cL} = \frac{P_c\,L}{4} = E\,\frac{3\,\pi^3}{L^2}\sqrt{\frac{1}{3\,(6+\pi^2)}}\sqrt{I^2_o\,h^2 + \frac{K}{1+\nu}\,I_o\,\frac{L^2}{h^2}} \quad \text{.... (47)}$$

Consequently, for a center load applied at the neutral axis

$$\bar{r}_c = \frac{M_{cL}}{M_{cB}} = \frac{3\,\pi}{\sqrt{3\,(6+\pi^2)}} = 1.36 \quad \text{.............. (48a)}$$

In the same manner it is found that (12*a*), with loads applied at the neutral axis, for uniformly distributed load,

$$\bar{r}_c = \frac{60\,\pi^2}{8\,\sqrt{30\,(\pi^4+45)}} = 1.13 \quad \text{................ (48b)}$$

and, for quarter-point loads,

$$\bar{r}_c = \frac{17.3\,\sqrt{5.63}}{4\,\pi^2} = 1.04 \quad \text{.................. (48c)}$$

For center load applied at the top flange (10*c*),

$$M_{cL} = \frac{E\,I_o}{L}\,\frac{12\,\pi^2}{6+\pi^2}$$

$$\left\{-\frac{h}{L} + \sqrt{\frac{h^2}{L^2}\left[1 + \frac{\pi^2\,(6+\pi^2)}{48}\right] + \frac{K}{(1+\nu)\,I_o}\,\frac{6+\pi^2}{48}}\right\} \quad \text{.... (49a)}$$

From this equation it is seen that M_{cL} depends in this case on $\frac{h}{L}$ and $\frac{K}{I_o}$. To obtain an estimate of the average magnitude of $\bar{r}_c$ for rolled I-beams, the mean value of $\frac{K}{I_o}$ for the four beams A to D investigated previously will be used; that is $\frac{K}{I_o} = 0.20$. For reasons stated previously, $\bar{r}_c$ is of interest only in the region where the *s*-curves are close to the s_c-curves. From Fig. 2, a reasonable value for this purpose is $\frac{L}{b} = 50$. Since, on the average, for rolled I-beams $\frac{h}{b} = 2.5$, the corresponding value for $\frac{h}{L} = \frac{1}{20}$. For convenience of computation Eq. 46 is rewritten in the form

$$M_{cB} = \frac{E\,\pi^2\,I_o}{L}\sqrt{\frac{h^2}{L^2} + \frac{K}{(1+\nu)\,\pi^2\,I_o}} \qquad (49b)$$

Substitution of $\frac{K}{I_o} = 0.20$ and $\frac{h}{L} = \frac{1}{20}$ in Eqs. 49 gives, as an average value for rolled I-beams, for center load at the top flange, $\bar{r}_c = 1.10$. In a similar manner one obtains for center load at the bottom flange $\bar{r}_c = 1.66$.

By means of the methods just used for center load (12*a*), $\bar{r}_c$ for uniform load and for quarter-point load is easily established.

The values of $\bar{r}_c$ for the three types and the three levels of loading are given in Table 2.

TABLE 2.—VALUES OF $\bar{r}_c$ (EQ. 45*b*)

Load applied at:	Type of Loading		
	Uniform	Center	Quarter point
Top flange	0.96	1.10	0.90
Centroid	1.13	1.36	1.04
Bottom flange	1.34	1.66	1.21

For the slenderness ratio $\frac{L}{b} = 50$ for which Table 2 is computed, the stress $\bar{s}_L$ can now be determined from $\bar{s}$ by means of the expression $\bar{s}_L \sim \bar{r}_c\,\bar{s}_B$.

It is seen from Table 2 that if loads are applied at the top flange the value of $\bar{r}_c$ deviates from 1 by not more than 10%. On the other hand, for short beams $\bar{r} = 1$ (see Eq. 45*a*). For reasons of continuity it is reasonably safe to state, therefore, that $\frac{\bar{s}_L}{\bar{s}_B}$ is very close to 1 for beams of any slenderness and for any type of loading applied at the top flange. (The value $\frac{L}{b} = 50$ for which Table 2 was computed is arbitrary to some extent. However, to compute $\bar{r}_c$ for smaller values of $\frac{L}{b}$ seems inadvisable because of the increasingly large deviation of the $\bar{s}$-curves from the s_c-curves. If $\frac{L}{b} > 50$ had been chosen, the values for "load at centroid" would have stayed the same and the difference between them and those for "load at the top or bottom flange" would have been smaller. Therefore, for $\frac{L}{b} > 50$ the ratios r_c for loads applied at the top flange would still be close to 1 for beams within practically possible ratios of slenderness $\frac{L}{b}$.) Since $\frac{\bar{s}_L}{\bar{s}_B}$ is very close to 1, the influence of the character of the loading on the magnitude of s is seen to be practically negligible if loads are applied at the top flange. The conclusion to be drawn from this discussion is that it appears reasonable to use the s-curves for pure bending for all types of loading rather than to complicate design procedures by taking account of the secondary influence of the character of the load.

In the rather rare cases of loads being applied at the bottom flange such a procedure would be on the conservative side. This is illustrated clearly by Table 2 which indicates the greater stability of beams loaded at the bottom flange as compared with those loaded at the top flange.

THE TORSIONAL CONSTANT K

From the preceding discussion the strength of slender beams is seen to depend on three properties of the cross section—the two principal moments of inertia $I_{x'}$ and $I_{y'}$ and the torsional constant K. Although the structural designer is fully familiar with moments of inertia, some remarks may be in order on the magnitude of K.

For determining the torsional constants of the four beams A to D investigated, the writer used the approximate formula

$$K = \tfrac{1}{3} \Sigma\, w\, t^3 \qquad (50)$$

in which w and t are, respectively, the width and the thickness of the three component rectangles of the sections. More detailed and accurate formulas for I-beams, taking account of the radii of fillets, the slope of the flanges, etc., as well as formulas for other types of cross sections have been developed and compiled by various authors (7)(13). These formulas hold only for monolithic members (rolled sections and the like).

The torsional constants K of built-up (riveted or welded) girders are smaller than those computed for the corresponding monolithic sections. This difference is due to relative slipping of the component parts of fabricated members. Since the strength of slender beams depends directly on the torsional rigidity, it is important to make proper allowance for the smaller value of K for built-up girders as compared with monolithic beams.

Elaborate experimental investigations of the magnitude of K for built-up members were conducted by I. Madsen (14) in 1941. Four I-girders were tested, two of them riveted and two welded, and four box-girders, of which three were riveted and one welded. The girders were of the type commonly used in crane construction. The results of these tests show that for riveted girders, both of box-section and I-section, the effective K amounts to from 30% to 41% of the torsional constant computed for the corresponding monolithic section. It appears, therefore, that for design purposes a value of K equal to one third of that of the monolithic section should be used for riveted girders. The welded I-beams gave effective K-values of 67% and 69% of the value computed for the solid section, whereas the percentage for the one welded box-beam tested by Mr. Madsen was 94%. For welded sections, consequently, a value of K equal to two thirds of that of the monolithic section appears to be safe for design computations.

The amount of experimental evidence on the torsional behavior of built-up members cannot yet be regarded as sufficient. A greater number of tests is desirable on solid web beams in order to provide collateral evidence to Mr. Madsen's results. In addition, to the writer's knowledge, the torsional properties of open web trusses have not yet been investigated experimentally. In view of the general tendency toward lighter and more slender steel and metal structures, the question of the torsional behavior of structural members is becoming increasingly important. Here a wide field for useful experimental work is open to the investigator.

THE INFLUENCE OF LATERAL RESTRAINTS

The findings of the preceding parts of this paper apply to beams with freely supported ends; that is, to beams the ends of which are free to rotate about the x-axis and y-axis. However, beams are generally connected to other structural members in a way that provides some measure of elastic restraint at the supports. Also, long beams are frequently braced laterally at some intermediate points between supports which, with regard to lateral deflection, make them act as beams continuous over several supports, whereas, with respect to vertical deflections, they act as simply supported beams. Such measures increase the lateral stability of beams just as end restraints or intermediate bracing raise the ultimate load of a column above that given by the Eüler formula for hinged ends. It is the purpose of this last part of the paper to indicate the method of making allowance for the influence of such lateral restraints.

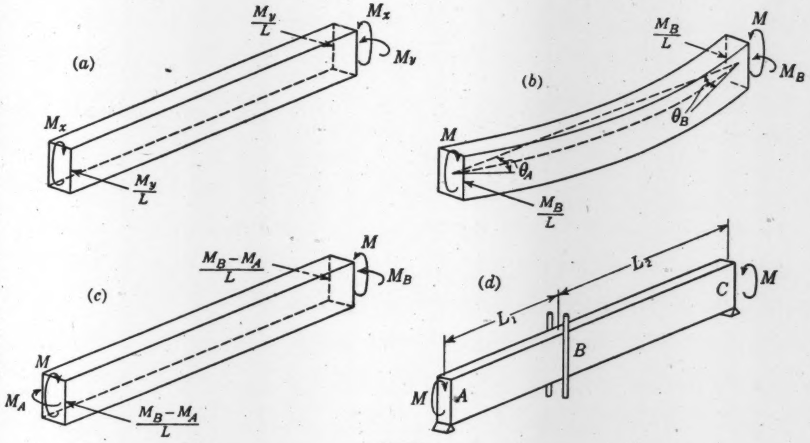

FIG. 5

This problem can be solved by first analyzing the case of a beam acted upon by end moments as shown in Fig. 5(a). With the same nomenclature as used heretofore, the differential equations of equilibrium, in this case, become

$$M_{y'} = \beta\, M_x + M_y \frac{z}{L} = E\, I_{y'} \frac{d^2u}{dz^2} \qquad (51a)$$

$$M_{x'} = -\, M_x + \beta\, M_y \frac{z}{L} = -\, E\, I_{x'} \frac{d^2v}{dz^2} \qquad (51b)$$

$$M_{z'} = -\frac{du}{dz} M_x + \frac{dv}{dz} M_y \frac{z}{L} = G\, K \frac{d\beta}{dz} \qquad (51c)$$

Elimination of u and v results in:

$$\frac{d^3\beta}{dz^3} + \frac{d\beta}{dz}\frac{1}{R_{z'}}\left(M^2{}_x + M^2{}_y \frac{z^2}{L^2}\frac{I_{y'}}{I_{x'}}\right) + \beta \frac{3\, M^2{}_y}{R_{y'}}\frac{z}{L^2}\frac{I_{y'}}{I_{x'}} = \frac{M_x\, M_y}{L\, R_{y'}}\left(\frac{2\, I_{y'}}{I_{x'}} - 1\right) \qquad (52)$$

Eq. 52 is not capable of solution in terms of simple functions. However, for the purpose of considering the stability of deep beams it is again permissible to neglect terms of order $\frac{I_{y'}}{I_{x'}}$ as compared with 1. For the same reason as in the preceding discussion (see comment on Eqs. 10 and 11), this is equivalent to neglecting the second term in Eq. 51*c*, which then becomes

$$-\frac{du}{dz} M_x = G\, K \frac{d\beta}{dz} \qquad (53)$$

Eliminating u from Eqs. 51*a* and 51*c*:

$$\frac{d^2\beta}{dz^2} + \alpha^2{}_1\, \beta = \gamma_1 \frac{z}{L} \qquad (54)$$

in which α_1 and γ_1 are given by Eqs. 11. (If Eq. 54 is differentiated with respect to z—

$$\frac{d^3\beta}{dz^3} + \frac{d\beta}{dz}\frac{M^2{}_x}{R_{y'}} = -\frac{M_x\, M_y}{L\, R_{y'}} \qquad (55)$$

A comparison of Eq. 55 with Eq. 52 shows that actually only terms of order $\frac{I_{y'}}{I_{x'}}$ have been neglected.)

If the beam is freely supported, the end conditions are

$$(\beta)_{z=0}\, (\beta)_{z=L} = 0 \qquad (56a)$$

and the solution of Eq. 54, satisfying Eqs. 51*a*, 53, and 56*a*, is

$$\beta = \frac{M_y}{M_x}\left(\frac{\sin \alpha_1 z}{\sin \alpha_1 L} - \frac{z}{L}\right) \qquad (56b)$$

For stability calculations it is convenient to use $\frac{du}{dz}$, the horizontal projection of the slope of the elastic curve. From Eqs. 53 and 56*b* this slope is found to be

$$\frac{du}{dz} = -\frac{G\,K}{L}\frac{M_y}{M^2_x}\left(\frac{\alpha_1\,L\cos\alpha_1\,z}{\sin\alpha_1\,L} - 1\right) \qquad (57a)$$

In particular, at the ends

$$\left(\frac{du}{dz}\right)_{z=0} = -\frac{G\,K}{L}\frac{M_y}{M^2_x}\left(\frac{\alpha_1\,L}{\sin\alpha_1\,L} - 1\right) \qquad (57b)$$

and

$$\left(\frac{du}{dz}\right)_{z=L} = -\frac{G\,K}{L}\frac{M_y}{M^2_x}(\alpha_1\,L\cot\alpha_1\,L - 1) \qquad (57c)$$

As an example, consider the case of a beam in pure bending built in laterally at $z = L$ (rotation about an axis parallel to y prevented at $z = L$) and freely supported at $z = 0$. In this case

$$\left(\frac{du}{dz}\right)_{z=L} = 0; \qquad \text{and} \qquad \alpha_1\,L\cot\alpha_1\,L = 1 \qquad (57d)$$

This transcendental equation is satisfied by $\alpha_1\,L = 4.49 \cdots$; and consequently, from Eq. 11*a*, the critical moment becomes

$$M_{xc} = \frac{4.49}{L}\sqrt{R_{y'}} \qquad (58)$$

It is worth noticing (5*b*) that the problem of a strut in compression fixed at one end and hinged at the other leads to the same transcendental expression as Eq. 57*d*.

Eqs. 57*b* and 57*c* make it possible to discuss the stability of elastically restrained beams in complete analogy with Professor Timoshenko's treatment of elastically restrained compression members (5).

If θ_A and θ_B represent the horizontal angles of rotation of the elastic line at the supports, positive as shown in Fig. 5(*b*), by suitable transformation Eqs. 57*b* and 57*c* may be rewritten as follows: Comparing Eq. 57*b*—

$$\theta_A = \frac{M_B\,L}{6\,E\,I_{y'}}\frac{3}{\frac{1}{2}\,\alpha_1\,L}\left(\frac{1}{\sin\alpha_1\,L} - \frac{1}{\alpha_1\,L}\right) \qquad (59a)$$

and, comparing Eq. 57*c*—

$$\theta_B = \frac{M_B\,L}{3\,E\,I_{y'}}\frac{3}{\alpha_1\,L}\left(\frac{1}{\alpha_1\,L} - \cot\alpha_1\,L\right) \qquad (59b)$$

This particular form is convenient because, from the ordinary beam theory, $\frac{M_B\,L}{6\,E\,I_{y'}}$ and $\frac{M_B\,L}{3\,E\,I_{y'}}$ are the end rotations of a beam subject to M_B only ($M_x = 0$). The terms in Eqs. 59*a* and 59*b* containing α_1, therefore, have the significance of magnification factors which represent the influence of M_x on the magnitude of the horizontal end rotation θ.

Professor Timoshenko has tabulated (5*e*) values of the functions:

$$\phi(a) = \frac{3}{a}\left(\frac{1}{\sin 2\,a} - \frac{1}{2\,a}\right) \qquad (60a)$$

and

$$\psi(a) = \frac{3}{2\,a}\left(\frac{1}{2\,a} - \cot 2\,a\right) \ldots\ldots\ldots\ldots\ldots\ldots (60b)$$

in which $2\,a = \alpha_1\,L$. Consequently

$$\theta_A = \frac{M_B\,L}{6\,E\,I_{y'}}\,\phi(a) \ldots\ldots\ldots\ldots\ldots\ldots (61a)$$

and

$$\theta_B = \frac{M_B\,L}{3\,E\,I_{y'}}\,\psi(a) \ldots\ldots\ldots\ldots\ldots\ldots (61b)$$

For a beam acted upon by moments at both ends as shown in Fig. 5(*c*), by superposition the angles of rotation are, consequently:

$$\theta_A = \frac{M_A\,L}{3\,E\,I_{y'}}\,\psi(a) + \frac{M_B\,L}{6\,E\,I_{y'}}\,\phi(a) \ldots\ldots\ldots\ldots (62a)$$

and

$$\theta_B = \frac{M_B\,L}{3\,E\,I_{y'}}\,\psi(a) + \frac{M_A\,L}{6\,E\,I_{y'}}\,\phi(a) \ldots\ldots\ldots\ldots (62b)$$

with

$$2\,a = \alpha_1\,L = \frac{M_x\,L}{\sqrt{E\,I_{y'}\,G\,K}} \ldots\ldots\ldots\ldots\ldots\ldots (63)$$

These expressions are exactly the same as the corresponding equations for compression members (5*c*) except for the different significance of *a*. In beams horizontally restrained at the ends, M_A and M_B represent the restraining moments. Consequently, by means of the functions $\phi(a)$ and $\psi(a)$ it is possible to determine the critical moments of elastically restrained beams by exactly the same methods used to calculate the critical thrust for elastically restrained compression members.

Example (*a*).—Suppose a beam in pure bending is braced horizontally at point B as schematically indicated by the guides in Fig. 5(*d*). There are no horizontal restraining moments at the ends, $M_A = M_C = 0$; and, for reasons of equilibrium, $M_{1B} = -\,M_{2B}$. Consequently:

$$\theta_{1B} = \frac{M_B\,L_1}{3\,E\,I_{1y'}}\,\psi(a) \ldots\ldots\ldots\ldots\ldots\ldots (64a)$$

and

$$\theta_{2B} = -\,\frac{M_B\,L_2}{3\,E\,I_{2y'}}\,\psi(a_2) \ldots\ldots\ldots\ldots\ldots\ldots (64b)$$

The continuity of the beam requires that $\theta_{1B} = \theta_{2B}$, which results in

$$\psi(a_1) + \frac{L_2\,I_{1y'}}{L_1\,I_{2y'}}\,\psi(a_2) = 0 \ldots\ldots\ldots\ldots\ldots\ldots (65)$$

If, for example, the beam is of constant cross section and $L_2 = 2\,L_1$, it follows that

$$\frac{\psi(a_1)}{\psi(2\,a_1)} = -\,2 \ldots\ldots\ldots\ldots\ldots\ldots (66)$$

From Professor Timoshenko's tables (5*e*) it is then found that $2a_1 = \alpha_1 L = 1.93$. Consequently, from $\alpha_1 = \frac{M_x}{\sqrt{E I_{y'} G K}}$:

$$M_c = \frac{1.93\sqrt{E I_{y'} G K}}{L_1} = \frac{3.86\sqrt{E I_{y'} G K}}{L_2} \quad \text{(67)}$$

The corresponding problem for a braced strut in compression is developed by Professor Timoshenko (5*d*), and the critical load for this case is

$$P_c = \frac{1.93^2 E I}{L^2_1} = \frac{3.86^2 E I}{L^2_2} \quad \text{(68)}$$

Example (*b*).—As a second example consider the beam built in laterally at both ends. In this case $M_A = M_B$ and $\theta_A = \theta_B = 0$. From Eqs. 62, $\frac{\psi(a)}{3} + \frac{\psi(a)}{6} = 0$, and $\phi(a) = -2\psi(a)$; and from Professor Timoshenko's tables (5*e*) $2a = \alpha_1 L = 2\pi$. Consequently,

$$M_c = \frac{2\pi\sqrt{E I_{y'} G K}}{L} \quad \text{(69)}$$

Eq. 69 can also be obtained directly from Eqs. 10 and 12 by making $\frac{du}{dz} = 0$ at the ends. In general, then, the critical moment for a beam in pure bending can be expressed in the form

$$M_c = \frac{\pi\sqrt{E I_{y'} G K}}{L'} \quad \text{(70a)}$$

just as the critical thrust for compression members is given by

$$P_c = \frac{\pi^2 E I}{(L')^2} \quad \text{(70b)}$$

In both cases L' is the "equivalent span" and is equal to the distance between the inflection points of the elastic curve. From the three examples computed herein (Eqs. 58, 67, and 69) it is apparent that the ratio $\frac{L}{L'}$ of the actual to the equivalent span for lateral buckling of beams is the same as the ratio $\frac{L}{L'}$ for struts in compression, with corresponding conditions of loading and restraint.

Consequently, in order to take account of any degree of lateral restraint in the design of slender beams one has only to reduce the actual span by an appropriate amount. The equivalent span L' so obtained is then used in the secant formulas or the corresponding curves instead of the actual span L.

The degree of end restraint provided by the usual types of riveted or welded end connections can hardly be determined analytically. For this reason, and also to establish the proper degree of imperfection k to be used in design, it is desirable to make systematic tests on beams under conditions simulating those in actual structures.

SUMMARY

In this paper the writer endeavors to establish a rational basis for the design of slender beams. Just as in the case of column analysis, such design should be based on the occurrence of inevitable imperfections of shape and loading. The paper contains:

(*a*) The derivation of a secant formula for rectangular and box-beams and similar shapes;

(*b*) The derivation of a secant formula for I-beams;

(*c*) Illustrative beam curves which show the influence of variations of shape and degree of imperfection on the ultimate strength of slender beams (curves of this type should serve as design criteria, rather than the buckling load of the compression flange regarded as a free strut, as is frequently done);

(*d*) A discussion of the influence of the character of the load on the ultimate strength;

(*e*) A discussion of the magnitude of the torsional constant K and particularly its value for fabricated (riveted or welded) sections; and

(*f*) A method of accounting for the influence on the ultimate strength of additional restraints such as intermediate bracing, or complete or partial end restraint.

The writer does not propose definite design curves or formulas. To establish design specifications extensive experimental work appears to be necessary to determine the degree of imperfection and the amount of end restraint under service conditions.

ACKNOWLEDGMENT

For the valuable assistance of Messrs. D. F. Gunder and Robert Lewis, Jun. Am. Soc. C. E., respectively Associate Professor and Assistant Professor of Civil Engineering at Colorado State College, Fort Collins, Colo., and at the time, respectively Resident Doctor and McMullen Research Scholar at Cornell University, Ithaca, N. Y., the writer expresses his sincere appreciation. As stated, Professor Gunder collaborated with the writer in deriving Eq. 26; and Professor Lewis undertook the numerical computations for the curves in Figs. 2 and 4.

APPENDIX II

NOTATION

The following letter symbols, adopted for use in the paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials,[3] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932. At the same time, an effort has been made to reconcile the notation of other authors in this field, particularly Professor Timoshenko.

A = cross-section area;
A', B', C', D' are non-dimensional characteristics of the cross section (see Eqs. 19, 34, 36);
$a = \dfrac{\alpha_1 L}{2}$ (see Eq. 63) for use in the Timoshenko tables (5*e*);
B' = (see A');
b = width of beam;
C = a constant (10) $= \dfrac{K}{2\,(1 + \nu)}$; C_1 and C_2 are integration constants determined from the conditions at the ends of a beam;
C' = (see A');
c = distance from the neutral axis to the extreme fiber; $c_{x'}$ and $c_{y'}$ are the distances c measured perpendicular to the x' and y' axes, Fig. 1;
D' = (see A');
E = Young's modulus of elasticity;
e = eccentricity of a load;
G = shearing modulus of elasticity;
h = height of a beam cross section;
I = rectangular moment of inertia: $I_{x'}$ and $I_{y'}$ are the moments of inertia about the axes x' and y', Fig. 1; and I_o is the moment of inertia of one flange about the axis of the web;
K = a torsional constant;
k = degree of imperfection of loading and shape of a beam, defined in Eq. 17;
L = span length;
L' = equivalent span, or the distance between the inflection points of the elastic curve;
M = bending moment:
    M_c = critical moment;
    M_m = maximum moment;
    M_x, M_y, M_z, $M_{x'}$, $M_{y'}$, and $M_{z'}$ = the components of M on the axis denoted;
    M_B = bending moment due to pure bending;
    M_L = bending moment due to any kind of loading except pure bending;
    $\bar{M}$ = the magnitude of M that causes an ultimate applied unit stress $\bar{s}$;
m_1 and m_2 = constants first used in Eq. 26, defined in Eqs. 27 and 29;
P = a concentrated load: P_c = a critical concentrated load;
p_1 and p_2 = constants first used in Eq. 26, defined in Eqs. 27*d*;
q = a constant first used in Eq. 26, defined in Eq. 28;
$R = E\,G\,K\,I$, an abbreviation first used in Eq. 5;

---

[3] ASA—Z10*a*—1932.

r = least radius of gyration;

$\bar{r}$ = a ratio of ultimate stresses or moments: $\bar{r}_c$ = a ratio of critical stresses or moments;

s = stress per unit area:

s_c = critical unit stress;

s_m = maximum unit stress;

s_y = unit stress at the yield point;

s_B = unit stress due to pure bending;

s_L = unit stress due to any kind of loading except pure bending;

$(s)_y = \dfrac{M_y c_{y'}}{I_{y'}}$ = the applied bending stress due to M_y, for use in Eq. 17;

$\bar{s}$ = direct stress for ideally straight beam;

t = thickness; thickness of flange: t_1 = thickness of web;

u u and v (see Fig. 1) are horizontal and vertical displacement ordinates of a section of a beam after rotation through an angle β;

v = (see u);

w = width of component rectangles of an I-section;

x x, y, and z are distances measured parallel to the respective axes; x', y', and z' are the corresponding distances referred to the rotated section. As subscripts they refer a given symbol to the rotated section;

y = (see x);

z = (see x);

α = a constant first used in Eq. 7, defined in Eq. 6*a*: α_1 = an approximate value for α (Eq. 11*a*);

β = angle of twist;

γ = a constant first used in Eq. 7, defined in Eq. 6*b*: γ_1 = an approximate value for γ (Eq. 11*b*);

θ = horizontal angle of rotation of the elastic line at the supports, θ_A and θ_B referring to supports A and B, respectively;

ν = Poisson's ratio;

ϕ = "function of:" as in $\phi(a)$;

ψ = inclination of the loading plane; also, where indicated in the text, ψ = "function of:" as in $\psi(a)$.

Subscripts and Other Modifiers.—Used as subscripts, c = critical, m = maximum; A and B denote the ends of beam AB (except where B is specially defined as meaning "due to bending"); and L denotes "due to any other kind of loading except pure bending." Subscripts x, y, z, x', y', and z' refer to the corresponding axes. Primed symbols in general refer to a non-dimensional characteristic (see A') but they are also used to denote an equivalent value, as in L'. Numerical subscripts 1 and 2 serve to distinguish between two individual quantities of the same general nature, such as C_1 and C_2, m_1 and m_2, etc. Barred symbols in general refer to critical or ultimate values, except that $\bar{s}$ denotes a value for an ideally straight beam.

DISCUSSION

T. McLean Jasper,[4] M. Am. Soc. C. E.—A mathematical attempt to solve a very important problem, and one which is recognized as a necessary addition to the problems dealing with buckling, is very welcome. As a supplement to the work by Professor Winter, the writer would cite the tests on light I-beams by Jasper O. Draffin, M. Am. Soc. C. E., and Milo S. Ketchum, Jr., Assoc. M. Am. Soc. C. E., in 1932 (15) and those by Harald M. Westergaard, M. Am. Soc. C. E., in 1922 (16). The purpose of presenting the first of these references is to suggest some test results to which the author may connect his theories, and the second reference to the generalized problem of buckling which the author has not mentioned should be a helpful extension to the Bibliography.

The writer is particularly intrigued by Fig. 2 and the application of mechanics to this problem. This paper offers a method of approach that can help the designer to simplify the application of the problem. The problem is not a simple one. The physical properties of the material used influence the heavier beams greatly whereas the *E I*-values of the shape and material undoubtedly influence the lighter sections.

The other references (17)(18)(19), with their respective discussions, present very similar cases and may be useful to students of this problem in supplying test data and analysis methods that may inspire further tests which apply more directly to safe designs for slender beams.

C. M. Goodrich,[5] M. Am. Soc. C. E.—In the usual case of the loading in Fig. 6, an eyebeam ideally straight would be prevented from twisting about its longitudinal axis. In one with a slight turn, twisting would be permitted only up to the point where there was flat contact between the two pieces.

In the case of columns, two eccentricities are considered, the first due to an eccentric end load, and the second due to the maximum deviation of the axis from a straight line between the ends. Only the latter needs to be considered in the case of beams.

Fig. 6

If the rule for reduction of stress in beams, either in the American Institute of Steel Construction (AISC) specifications or in those of the Canadian National Building Code, is multiplied by $\frac{10}{6}$, a result fairly close to $40{,}000 - \frac{100\,L}{i}$ is obtained (assuming $i = 0.2\,b$). The assumption that $i = 0.2\,b$ was not too violent when only American standard beams were rolled. For this assumption, there is now a variation of from $i = 0.15\,b$ to $i = 0.27\,b$ for rolled beams, with grotesquely varying results if the moment of inertia is accepted as a measure of stiffness; and, of course, built girders and box-beams are not included in the rule, which leaves these cases in the air.

---

[5] Cons. Engr., The Canadian Bridge Co., Ltd., Walkerville, Ont., Canada.

Brik (20) presents eight tests, including those for built and box girders; H. F. Moore (21) gives forty tests, reviews many more, and recommends the formula,

$$\breve{s} = 40{,}000 - 60\,\frac{m\,L}{i} \qquad \text{(71)}$$

in which $m = 1$ for a cantilever, $m = \frac{2}{3}$ for a uniformly loaded beam, etc. In any case of two supports, the constant m is the ratio of the area of the moment diagram to its enclosing rectangle. The range of variation in the tests is stated to be ± 2,500 lb per sq in. His testing arrangement gives the test beam every opportunity to twist if so inclined. Assuming $i = 0.2\,b$, for $\frac{L}{b} = 40$ which corresponds to $\frac{L}{i} = 200$, the minimum stress would be more than 29,000 lb per sq in. for uniformly loaded beams against about 17,000 in Fig. 4. At $\frac{L}{i} = 0$, Professor Moore gives 37,500 from tests, while Fig. 4 gives 29,000. The author cautions that (see heading, "Beam Curves") "The proper degree of imperfection, k, to be used in design can only be established only by extensive tests." It is of interest, however, to note what existing tests reveal, and apparently they show that the AISC and Canadian National Building Code formulas are undesirable, while the author's mathematics yield no rule for the designer.

The factor of stiffness is taken by S. Timoshenko (22) as $\frac{A^4}{40\,(I_{xx} + I_{yy})}$, and, in his example of a 24-in., 79.9-lb I-beam, it is 3.46. This is the Saint Venant rule, which, however, was intended for sections with a chunky solid center, and not for such shapes as I-beams. For the same section the Bethlehem handbook gives 5.01 as the factor of stiffness, and $\Sigma\,\frac{1}{3}\,w\,t^3$ equals about 4, if average thickness is used in the flanges. (August Föppl's tests (23) led him to the factor of stiffness of 1.29 for this type of section, and 1.29 × 4 = say 5.1.)

In designing, when unhampered by specifications, one may perhaps use Professor Moore's rule up to $\frac{L}{i} = 200$, and, for greater values, some such formula as

$$\breve{s} = \frac{1{,}280{,}000{,}000}{\left(\frac{l}{i}\right)^2} \qquad \text{(72)}$$

for uniformly distributed loads, remembering that about 2,500 lb per sq in. is to be subtracted on account of the variation in beams.

The result, of course, is merely a probable ultimate for a condition to which any actual case is likely to be an approximation.

J. P. WADLECK,[6] ESQ.—The author should be complimented for his ability to treat the entire scope of his subject with such admirable simplicity.

---

[6] Development Engr., Niagara Machine & Tool Works, Buffalo, N. Y

The significance of his paper lies in the fact that, in so far as the writer is aware, this is the first direct attempt to rationalize the problem of lateral stability of ideal beams; that is, to find a mathematical solution to the lateral stability and the corresponding critical stress of real beams with inherent imperfections, eccentricity of load and reactions, possible slight obliquity of beam axis, etc.

The author's paralleling of the knowledge and design practice of the engineering profession on lateral stability of beams, as it is at present, with the situation existing in column design before the introduction of the secant formula, if it were true, would indeed be very fortunate.

The author undoubtedly had in mind knowledge as represented by engineering scientists and students of advanced engineering literature. The average graduate engineer, however, who, long before the existence of any of the "real column" solutions, did have or should have had a clearer understanding of the determining factors, governing stability of struts through Euler's basic column theory, finds that the mechanism of lateral beam failure and its stability theory is still beyond his grasp.

The fact that, thus far, relatively few cases of major failures, which are traceable to lateral buckling of beams, are on record is mainly due to the fact that all rolled sections were safely covered by permissible load versus span tables originating from the AISC handbook (2). It seems that, no matter how indiscriminating these tables are relative to the degree of end restraint and to type and position of loading, they apparently cover all errors with a margin on the safe side.

In the design of long, built-up I-section girders, which otherwise were not intended to resist external lateral loads, to the extent of the writer's knowledge, the designer was and still is aided only by his sense of proportion and conservative, occasionally feeble, rules of thumb, available in various specifications. How such elementary considerations proved adequate to guard against lateral failures of these built-up girders—not covered by the AISC tables—the writer can explain only with the substantial combined lateral bendings and torsional strength of the sections.

As new trends are developed, both in materials and fabricating methods, most of which will result in greatly decreased torsional rigidity of sections (due to the increasing use of welding, to the adoption of high-tensile, low-alloy steels, to the various light-weight and thin-wall formed structures in general), the problem of lateral stability of beams will rise to first-degree importance.

To meet this situation without an extensive research and test program is unthinkable. The existing meager data such as those in the AISC and the other steel handbooks are unusable, due to their limited scope.

To attain the widest validity of test results, with the least effort, it is essential that, in any test program of the future, the work be guided and the results be checked against a rigorous and rational analytical expression. In the establishment of such an approach lies the value of the author's work.

Whether the exact analytical expressions are not too involved for routine design work is another matter. If so, for the purpose of specification writing and tables, they could easily be supplemented with various empirical formulas each within the scope of the respective specification, and the use of the original analytical formula, which is in conformity with the entire range of tests, could be restricted to the treatment of special cases.

Concerning the mathematical phase of the paper the writer calls attention to some interesting possibilities by transforming Eq. 20, 22, or 23. Substituting the value of A' from Eq. 19 into Eq. 22:

$$s = \frac{s_y}{1 + k \sec\left(\frac{I_{x'}}{h}\, s\, \frac{L}{\sqrt{D\,C}}\right)} \qquad \text{(73a)}$$

in which $D = E\,I_{y'}$ = the lateral flexural rigidity; and $C = K\,G$ = the torsional rigidity of the beam. Recalling that $\frac{1}{2} \times \frac{2\,I_{x'}}{h} \times s = \frac{1}{2} M$ and $\frac{L}{\sqrt{D\,C}} = \frac{\pi}{M_c}$, thus:

$$s = \frac{s_y}{1 + k \sec\left(\frac{\pi}{2} \times \frac{M}{M_c}\right)} \qquad \text{(73b)}$$

or multiplying both sides by $\frac{2\,I_{x'}}{h}$:

$$M = \frac{M_y}{1 + k \sec\left(\frac{\pi}{2} \times \frac{M}{M_c}\right)} \qquad \text{(74)}$$

Inasmuch as values of $\sec\left(\frac{\pi}{2} \times \frac{M}{M_c}\right)$ vary between 0 and ∞ (when $M = 0$ and $M = M_c$, respectively), it would be well worth while to explore the possibility of expressing $\sec\left(\frac{\pi}{2} \times \frac{M}{M_c}\right)$ by a closely conforming rational function, by which Eqs. 3 could be transformed into a quadratic equation.

An extremely close approximation to all values of $\sec \alpha$ between 0 and $\frac{\pi}{2}$ (which unfortunately, however, yields a cubic equation) is due to H. A. Webb:

$$\sec \alpha = \frac{1 + \frac{4\,\alpha^2}{\pi^2} \times 0.26}{1 - \frac{4\,\alpha^2}{\pi^2}} \qquad \text{(75)}$$

by which:

$$\sec\left(\frac{\pi}{2} \times \frac{M}{M_c}\right) = \frac{M^2_c + 0.26\,M^2}{M^2_c - M^2} \qquad \text{(76)}$$

If substituted into Eq. 74, Eq. 76 will lead to the expression:

$$(1 - 0.26\,k)\,M^3 - (1 + k)\,M\,M^2_c - M^2\,M_y + M^2_c\,M_y = 0 \qquad \text{(77)}$$

By letting $(1 - 0.26\,k) = \alpha$ and $(1 + k) = \beta$, and as, in general:

$$M = s\,\frac{2\,I_{x'}}{h} \qquad \text{(78)}$$

Eq. 77 can be written as:

$$\alpha \bar{s}^3 - \beta \bar{s} s^2_c - \bar{s}^2 s_y + s_y s^2_c = 0 \qquad (79)$$

which is solvable for $\bar{s}$ by either the exact or one of the approximate methods.

H. D. HUSSEY,[7] M. AM. SOC. C. E.—It is interesting to compare the beam formulas in current use with the secant formula, Eq. 37. Beam formulas from current specifications are as follows: American Railway Engineering Association and American Association of State Highway Officials specifications for bridges,

$$s_b = 18{,}000 - 5 \frac{L^2}{b^2} \qquad (80a)$$

and American Institute of Steel Construction specifications for buildings (maximum = 20,000),

$$s_b = \frac{22{,}500}{1 + \dfrac{L^2}{1{,}800\, b^2}} \qquad (80b)$$

in which s_b is the maximum allowable compressive unit stress in bending.

If the bridge formula, Eq. 80*a*, is multiplied by $\frac{28.8}{18}$, and the building formula, Eq. 80*b*, by $\frac{28.8}{20}$, ultimate stresses may be obtained which will be consistent with those presented by the author in Fig. 4. Fig. 7 shows the ultimate stresses thus derived from the bridge and building formulas when plotted in Fig. 4.

Thus the equation for curve E, Fig. 7, is:

$$\bar{s} = \frac{28.8}{18}\left(18{,}000 - 5 \frac{L^2}{b^2}\right) = 28{,}800 - 8 \frac{L^2}{b^2} \qquad (81a)$$

and, for curve F, Fig. 7 (maximum, 28,800):

$$\bar{s} = \frac{28.8}{20}\left[\frac{22{,}500}{1 + \dfrac{L^2}{1{,}800\, b^2}}\right] = \frac{32{,}400}{1 + \dfrac{L^2}{1{,}800\, b^2}} \qquad (81b)$$

For $L/b = 30$, Eqs. 81*a* and 81*b* give identical results.

Fig. 7 indicates that the present design formulas are conservative. The close correspondence between the curves representing the present design formulas and the author's results suggests that the tentative value of $k = 0.25$ may be a satisfactory assumption until the correct value can be established by tests.

The author has proved the great torsional strength of box-beams, theoretically, and has confirmed the results of tests reported by I. Madsen (14) in 1941. One of Mr. Madsen's conclusions was: "For welded (box) girders with L/b ratios up to 110, and riveted (box) girders with L/b ratios up to 80, it is not necessary to reduce the allowable compressive design stress." This statement seemed rather startling until Professor Winter gave it a theoretical background, calculated the ultimate stresses for a box-beam for varying values of L/b, and plotted them in Fig. 4. This beam which has a maximum strength of 28,800 lb per sq in. when $L/b = 0$, has a strength of more than 28,000 lb per sq in. when $L/b = 100$. Current specifications make

---

[7] Designing Engr., Am. Bridge Co., New York, N. Y.

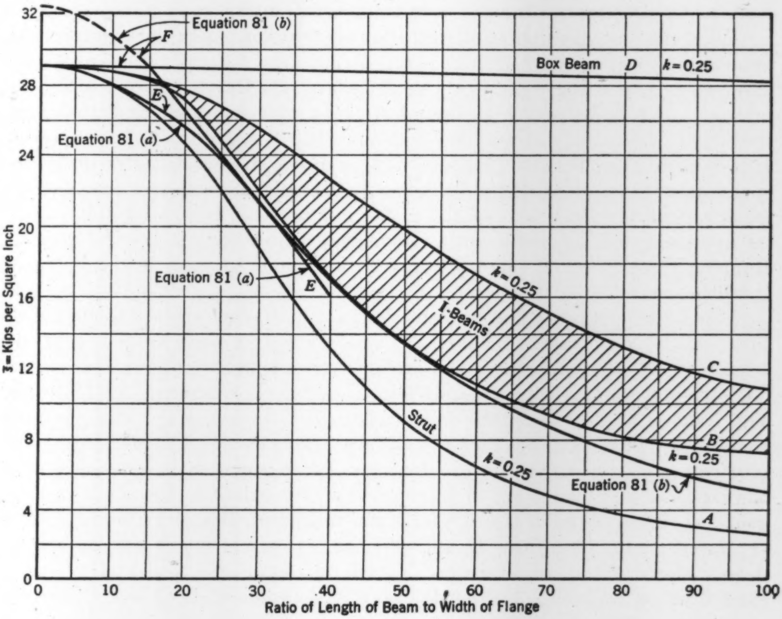

FIG. 7.—ULTIMATE STRESS $\bar{s}$ FOR A YIELD POINT OF 36,000 LB PER SQ IN. AND FOR $k = 0.25$ (COMPARE FIG. 4)

no distinction between the flanges of a box girder and an I-beam, as regards allowable flange stress. The same formula is used for both sections. Present evidence seems to justify a review of current practice in respect to allowable flange stresses in box girders.

The author is to be commended for having presented a rational solution of the strength of beams. He has demonstrated that this strength is represented by a secant formula and has thereby developed a basis for a working formula for beams. Since the secant formula cannot be solved readily, it would be necessary to use an approximation, as has been done for column formulas. Fig. 7 shows that Eqs. 81 give a good approximation of a secant curve for the ultimate stress $\bar{s}$ at any value of L/b.

Results presented in Fig. 7 indicate that (a) it is safe to use beams having an L/b ratio greater than 40, which is the currently specified limit; and (b) a formula of the Rankin-Gordon type would define a satisfactory design stress for such slender beams.

George Winter,[8] Esq.—The agreement among the discussers on the insufficiency, in some respects, of present design specifications for slender beams is gratifying to the writer. Messrs. Jasper, Wadleck, and Hussey also concur in recognizing the usefulness of this analytical treatment for establishing more rational design procedures than those used currently.

From the designer's point of view the practical conclusions drawn from the paper by Mr. Hussey, particularly Fig. 7, are most interesting. These conclusions, in which the writer fully concurs, are: (1) Current specifications do not account for the very high lateral strength of box-beams, and, therefore, lead to uneconomical design of such sections; (2) it is safe to use I-beams with an L/b-ratio larger than 40, provided that working stresses are adjusted correspondingly; (3) present design formulas for I-beams are conservative; and (4) for practical use the values of the rather cumbersome secant formula should be approximated by some more convenient expression of the Johnson or Rankine type, in much the same way as it is done in some current column specifications.

Fig. 7 demonstrates that present design stipulations are about correct or just slightly conservative for laterally weak members, such as 18-in., 54.7-lb I-beams. These specifications are extremely conservative, however, for laterally strong sections, such as 15-in., 75-lb I-beams. For example, for $L/b = 40$, Fig. 7 shows that for the latter beam a design stress is justified which is more than 30% higher than that for the former. This demonstrates the practical importance of one of the principal findings of this investigation—namely, that the ratio L/b is not sufficient to determine the strength of such beams. On the contrary, in addition to the L/b-ratio the characteristics of the cross section expressed by the quantities B' and C' (Eqs. 34) are of major importance for determining safe design stresses. Therefore, design specifications probably should not be limited to one single curve for I-beams of any shape, but a set of curves or formulas should be established to take account not only of the L/b-ratio but also of the characteristics of the cross section. This becomes even more important if the stipulations are also to apply correctly to built-up girders on the one hand and to junior I-beams on the other as observed by Mr. Wadleck. If members of this type are considered, the variations in strength for a given L/b-ratio will be found to be still larger than those for the standard I-beams in Figs. 4 and 7. These practical design formulas could well be of the Rankine type, as proposed by Mr. Hussey. A still better approximation to the secant curve can be obtained by taking a formula of the Johnson parabolic type for the lower range of L/b combined with one of the Rankine type for the higher range.

Mr. Goodrich's contention that "the author's mathematics yield no rule for the designer" is best answered by Mr. Hussey's very practical conclusions. The writer never intended to propose definite design specifications in his paper since the establishment of such codes is the task of the appropriate engineering organizations rather than of any single individual. When Eüler and others developed a rational theory of column behavior they did not, at the same time, attempt to prescribe definite design requirements; yet the total knowledge of the design of compression members would be poor indeed were it not for the fundamental investigations of these men.

---

[8] Asst. Prof., Civ. Eng., Cornell Univ., Ithaca, N. Y.

Mr. Goodrich cites Professor Moore's tests in 1913 and attempts to compare the results with Fig. 4 of the paper. Such a comparison is not quite appropriate for the following reasons:

(*a*) Fig. 4 is drawn for one definite yield point only, 36,000 lb per sq in. The writer could not find any reference by Professor Moore (21) to the yield points of this particular series of tests, but some other yield points reported in the course of the same investigation were as high as 40,000 lb per sq in. and more. Thus, the curves in the writer's paper, drawn for a yield-point stress of 36,000 lb per sq in., cannot coincide with Professor Moore's value of $s = 37{,}500$ to 42,500 lb per sq in. for $L/i = 0$. A further reason for this discrepancy is the well-known fact that short steel beams, with L/i close to zero, fail at loads higher than those which cause yielding in the outermost fiber (8). Since, however, incipient yielding is generally regarded as the limit of structural usefulness, this state rather than that of complete failure is analyzed by the secant formula. The difference between this limiting load and that causing complete failure decreases rapidly with increasing slenderness.

(*b*) Fig. 4 is drawn for an entirely arbitrary degree of imperfection $k = 0.25$. A comparison of Professor Moore's results with those for $k = 0.10$ would have yielded entirely different results. Probably, for the accuracy of a careful experimental investigation $k = 0.25$ is much too high.

(*c*) From a study of Professor Moore's testing arrangement complete freedom of twist and of lateral deflection does not seem to have been achieved. A rather minute restraint of lateral freedom at or near the mid-length of a column will increase the buckling strength considerably. The same is true for buckling of beams. Professor Moore's values, therefore, are likely to be rather high as compared with those that would be obtained in tests in which complete freedom of movement was provided. Such freedom in beam tests in standard testing machines is extremely difficult to achieve. To the writer's knowledge, the only satisfactory, although cumbersome, way of doing so is to suspend actual dead loads from the test beams rather than to apply the loads by means of a testing machine.

In connection with Professor Moore's tests it is interesting to cite corresponding tests on junior I-beams by Messrs. Ketchum and Draffin (15), quoted by Mr. Jasper. The formula given by these investigators,

$$s = 24{,}000 - 40\left(\frac{m\,L}{i}\right) \ldots\ldots\ldots\ldots\ldots\ldots (82)$$

gives values which are very considerably below those of Professor Moore's original formula, Eq. 71, despite the practical identity of testing arrangements. This divergence once again emphasizes the fact that neither the flange width b nor the radius of gyration i is sufficient to describe the lateral strength of beams. Empirical column formulas expressed in terms of L/i give reasonable results for the sole reason that L/i is the only shape factor on which the strength of columns depends. This is shown by all rigorous analytical investigations of column behavior. Conversely, all rigorous analytical investigations of buckling of beams (1)(5)(6)(10)(12), including the present one, show most decidedly that neither L/b nor L/i is sufficient to determine the strength of slender beams. Thus, none of the approaches proposed by Mr. Goodrich, based on L/i, will give satisfactorily accurate results. This has been recognized, for instance, in recommended design procedures for aluminum alloy products (24), in which the allowable design stress is determined by use of an "equivalent radius of gyration" whose value depends on precisely the same quantities as the writer's B' and C' and is in no way identical with Mr. Goodrich's ordinary radius of gyration i.

Mr. Goodrich's discussion of the value of the torsional constant K is somewhat extraneous to the subject of this paper. The writer gave an approximate formula, Eq. 50, and references to the most recent and complete information in this connection. Since the validity of this information is generally recognized, there seemed to be no need for a detailed discussion of this constant except as far as its value for built-up sections is concerned.

Mr. Wadleck's mathematical extension of the paper represents an interesting generalization of the writer's results. Eq. 73*b*, expressing s in terms of the ratio of the applied to the critical moment, M/M_c, agrees with general concepts on stability, in particular with the Southwell method (5*f*) of determining deflections of imperfect compression members.

Like Mr. Wadleck, the writer did attempt to express the secant formula in terms of a simpler, rational function, but met with the same difficulties as did Mr. Wadleck. However, the practical inconvenience of solving a secant formula can be overcome by approximating it with a combination of a Johnson and a Rankine type formula, as noted herein. A set of suitably chosen curves of this nature would eliminate any necessity for the designer to solve the secant formula directly. Graphs consisting of a large number of curves are widely used in reinforced concrete design where rather complicated equations are involved, like those governing the design of eccentrically loaded columns. The writer cannot see any objection to the introduction of graphs of this kind in steel design if by so doing design procedures are improved and economy is achieved.

RIVETED AND PIN-CONNECTED JOINTS OF STEEL AND ALUMINUM ALLOYS

BY LEON S. MOISSEIFF,[1] M. AM. SOC. C. E., AND E. C. HARTMANN,[2] AND R. L. MOORE,[3] ASSOC. MEMBERS, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JONATHAN JONES, AND LEON S. MOISSEIFF E. C. HARTMANN, AND R. L. MOORE.

SYNOPSIS

Development of low alloy steels and high-strength aluminum alloys, and their utilization in structures, have called the attention of engineers to the somewhat lower ductilities of these materials, as compared to carbon steel, and also to their generally higher ratios of yield strength to ultimate strength. Apprehension has been felt that these differences in physical properties would affect, unfavorably, the distribution of stress in members built of these materials, especially at connections. This belief is reflected by the fact that, in some instances, organizations responsible for design specifications, both in the United States and abroad, have set an upper limit for the ratio of yield strength to ultimate strength.

In recent years substantial advances have been made in the metallurgy of metals and in the production of numerous metallic alloys of various physical qualities. The utilizations of the metals of higher qualities have led engineers to scrutinize, more critically, the meaning and value of the information obtained from generally accepted standard tests. Along with this advance came a more thorough inquiry into the significance of the terms commonly used in characterizing and classifying metals. The old established values came to be questioned: Is there a true elastic limit? What is the true meaning of yield strength? What is ductility, and does elongation determine its value? How much ductility is needed for a given purpose, and what is its value?

In view of the practical importance of the problem and the need for experimental data concerning the behavior of these newer structural materials, it

FIG. 2.—PIN-CONNECTED JOINTS

was thought best to undertake a program of tests of riveted and pin-connected joints. Five metals—two steels and three aluminum alloys—having a fairly wide range of ductilities and ratios of yield strength to ultimate strength were included. All the joints tested behaved in a manner consistent with the basic assumptions of design and with the properties of the materials. Furthermore, the tests showed that the plastic yielding necessary to effect a uniform distribution of load among the rivets must be relatively small, and that differences in ratios of yield strength to ultimate strength, elongation values, and moduli of elasticity were not significant factors as far as static ultimate strengths were concerned.

INTRODUCTION

It is a fact well known to engineers and demonstrated by numerous investigators[4] that within the elastic range the load on a multiple-riveted joint is not uniformly distributed between the rivets. The basis for the usual assumption of equal shear per rivet in design is that, in ductile materials, the yielding which occurs at the points of highest stress effects a redistribution of load which becomes essentially uniform. Numerous tests on riveted joints have demonstrated the validity of this assumption as far as ultimate static strengths are concerned.[5,6]

The increasing use of alloy steels and high-strength aluminum alloys in the structural field has raised a question regarding the possible effect of the reduced ductility of these materials upon the load distribution and the strength of multiple-riveted joints. Ductility is an essential requirement of a structural material, but the limits within which it may be varied without appreciably influencing the behavior of large riveted joints are not known. In the case of the aluminum alloys, the belief has been expressed by some that the effect of reduced ductility may be offset somewhat by the low modulus of elasticity.

The tests described in this paper were undertaken in 1939, in an effort to obtain information regarding load distribution and the strength and general behavior of multiple-riveted joints involving various combinations of steel and aluminum alloys. An attempt was made to keep the specimen proportions within the limits of good design practice, and at the same time to provide a fairly wide range of strength, stiffness, and ductility. In addition to the multiple-riveted joints, a series of pin-connected joints of the same materials was also included. The scope of the program limited the tests to three rows of rivets on each side of the joint.

DESCRIPTION OF JOINTS

Five different types of joints were fabricated from each of the combinations of material investigated. Fig. 1(*a*) shows the dimensions of the wide double-

[a] 27S-T, 17S-T, and 53S-T are aluminum alloy and temper designations.

[b] Areas indicated are based on the nominal hole diameters shown in Figs. 1 and 2.

[c] Specimens of each alloy in this group were also fabricated with two, ⅞-in. rivets.

[d] The diameter of the 53S-W pins in Table 1(*e*) is 1 1/16 in.

strap butt joints having twenty-four $\frac{7}{8}$-in. rivets designed to fail in shear. The longitudinal spacing of the rivets was governed largely by the space required for the operation of a 2-in. Berry strain gage between rivet rows, although it is also consistent with design practice for the size of rivets and thicknesses of plate involved. Fig. 1(*b*) shows the dimensions of the narrow double-strap butt joints, also having twenty-four $\frac{7}{8}$-in. rivets, but designed to fail by tension in the plates. These joints were similar to the wide joints shown in Fig. 1(*a*) except for the over-all width and transverse spacing of rivets.

Small auxiliary double-strap butt joints, 5 in. wide and having two or four $\frac{7}{8}$-in. rivets, were designed to serve as control specimens for determining the shear strength of the driven rivets. The plate thicknesses were the same as shown in Fig. 1(*a*). Three of these specimens were provided for each combination of material, two being fabricated with four rivets (two in each half), whereas the third contained only two rivets.

Fig. 2(*a*) shows the dimensions of the joints having a single 2-in. pin, designed to fail by bearing in the outside cover plates. Fig. 2(*b*) shows the dimensions of the joints having four 1-in. pins designed to fail in shear. In one instance, it was necessary to make two sets of pins in order to obtain the close fit desired, and pins of $1\frac{1}{16}$-in. diameter were finally used.

The rivets used in the joints shown in Fig. 1 were not conventional ones, but consisted of $2\frac{1}{2}$-in. lengths of $\frac{7}{8}$-in. rod which were pressed into $\frac{7}{8}$-in. drilled and reamed holes and then upset cold in an 80-ton yoke-type riveter to approximately $\frac{15}{16}$ in. at the ends. This type of rivet was used to permit an inspection of the plate material adjacent to the rivets during the test, to provide additional clearance for taking strain readings between rivets, and to minimize the uncertain effect of friction.

FIG. 3.—STANDARD ROUND TENSION TEST SPECIMEN WITH 2-IN. GAGE LENGTH

The pins used in the joints shown in Fig. 2 were turned oversize by approximately 0.0005 in. per in. diameter to provide a press fit in the joints. All holes in both riveted and pin-connected joints were drilled and reamed in assembly. Table 1 gives a summary of the dimensions of all the joints as well as the areas used in computing shear, bearing, and tensile stresses.

Materials.—The following combinations of material,[7] providing a fairly wide range of ductilities and ratios of yield strength to ultimate strength, were investigated in each of the foregoing types of joints:

1. Silicon steel plates with carbon steel rivets or pins;
2. Carbon steel plates with carbon steel rivets or pins;
3. Aluminum alloy 27S-T plates with carbon steel rivets or pins;
4. Aluminum alloy 17S-T plates with 17S-T rivets or pins; and
5. Aluminum alloy 53S-T plates with 53S-W rivets or pins.

[a] "Normal" denotes that the specimen was normal to the direction of rolling; and "parallel" denotes "parallel to the direction of rolling."

[b] For aluminum, the yield strength is measured by the stress corresponding to an offset of 0.2% from the initial modulus line; and, for steel, it is the stress corresponding to the drop-of-the-beam yield point.

thicknesses of the same materials, particularly in the case of yield strengths, and there is also some evidence of directional properties. Ratios of tensile yield strength to ultimate strength ranged from a minimum of 0.54 for the silicon steel to a maximum of 0.92 for the aluminum alloy 53S-T. Corresponding ratios for the carbon steel plates exceeded those for the silicon steel, the highest value in any case being 0.78, which is considerably above that generally assumed for such material.

The elongation values given in Table 2 range from a minimum of 11% for the aluminum alloy 27S-T to a maximum of 39% for the carbon steel. It should be emphasized that elongation values do not necessarily bear a definite relationship to ratios of tensile yield strength to ultimate strength; nor do they always give a complete picture of the ductility of a metal. For example, the elongations found for the aluminum alloy 53S-T plates exceeded those for the aluminum alloy 27S-T; yet the ratios of yield strength to ultimate strength for the 53S-T alloy were considerably higher. The elongations for the aluminum alloy 17S-T plates were slightly higher than for the aluminum alloy 53S-T plates and the yield-ultimate strength ratios were lower; yet in general 17S-T alloy is not as satisfactory for forming operations as 53S-T alloy. The explanation for this behavior is indicated, at least qualitatively, by the reduction in area values included in Table 2. The values for the 53S-T alloy plates were higher than those for either of the other aluminum alloys, being more nearly comparable with those for the silicon steel. The reductions in area for the carbon steel plates were the highest observed.

---

[8] "Tentative Methods of Tension Testing of Metallic Materials," Supplement to ASTM Standards, Pt. 1, 1940, E8-40T, Fig. 3, p. 454.

No attempt was made to determine moduli of elasticity, the nominal values of 29,500,000 and 10,300,000 lb per sq in. being assumed satisfactory for interpreting the measured strains in the steel and aluminum alloys, respectively. The corresponding values of Poisson's ratio were assumed to be ¼ and ⅓.

Testing Procedure

All tests, except those on the small auxiliary shear specimens, were made in the Templin precision metal-working machine having a 1,000,000-lb maximum capacity tensile range (named for R. L. Templin, M. Am. Soc. C. E.).[9] Load was applied to the large joints of the type shown in Fig. 1 through 6.5-in. pins fitted in special tension shackles. The smaller pin-connected joints shown in Fig. 2 were loaded through 5-in. pins equipped with bushings to fit in the same tension shackles. Figs. 4 and 5 are close-up views of different types of joints. The small auxiliary shear specimens were tested in a machine having a 300,000-lb maximum capacity range.

The test procedure followed on all the large joints included one or more types of slip determination, using a 10-in. Whittemore strain gage or dial indicators on 2-in. and 48-in. gage lengths; the measurement of strains by means of 2-in. Berry strain gages; and the determination of ultimate strengths. The slip readings obtained by means of the Whittemore strain gage involved establishing 10-in. gage lengths on the edges of the main plates of the joints with one gage hole at each rivet section where slip was to be determined. Single gage holes were then located on the adjacent cover plates at these same rivet sections so that readings could be taken on three lines at each section using a common gage hole at one end. The difference in readings obtained on the main and cover plates gave the slip directly, irrespective of the strain that may have occurred over the gage lengths. The angle between the gage lines was so slight that the error introduced by the difference in slopes was on the order of one part in a thousand. Check readings were held to within a tolerance of one division of the dial, which corresponded to a change in gage length of 0.0001 in. Fig. 1 shows the location of the 10-in. slip gage lines.

A dial indicator, graduated in thousandths of an inch and having a 1-in. travel, was used for the combined slip and strain determinations made on the 2-in. and 48-in. gage lengths. For the short gage length, two points were attached to the indicator—one a fixed point attached to the back of the dial and one a movable point attached to the stem so that it could be operated over a considerable range in the vicinity of 2 in. Readings estimated to the nearest 0.0001 in. were taken with this instrument across the gap between the main plates at the center of all the double-strap butt joints and also diagonally across the main and cover plates in the pin-connected joints at the sections through the pins. Figs. 1 and 2 show the location of these slip gage lines. For the 48-in. gage lengths (which, of course, were limited to the large joints), a dial indicator was attached to an adjustable measuring rod and readings were taken between small pins screwed into tapped holes in the edges of the main plates.

---

[9] *Civil Engineering*, May, 1940, p. 323.

Figs. 1 and 2 show the location of the 2-in. longitudinal and transverse gage lines on which strains were investigated by Berry strain gages. It was appreciated that a complete picture of the highly localized stress distribution in the vicinity of the rivets and pins could not be obtained from the layout of the gage lines shown; yet this procedure seemed satisfactory as far as indicating general characteristics of behavior for different materials was concerned. Check strain readings were held to within a tolerance of four-tenths of one division on the dial, which corresponds to a stress of approximately 1,200 lb per sq in. in steel and 400 lb per sq in. in aluminum.

The measurement of both longitudinal and transverse strains at a number of points was necessary to determine the state of stress existing and to indicate the manner in which the strains should be interpreted. The consistent tendency for the measured transverse strains to range from ¼ to ⅓ the longitudinal values, and to be of opposite sign, provided ample justification for the assumption of a unidirectional state of stress on the sections investigated. Accordingly in all tests, measured longitudinal stresses (in the direction of loading) were obtained by multiplying the unit longitudinal strains by the modulus of elasticity.

Because of the fact that the tests on a number of the joints extended over a period of several days and it was not always possible to maintain a uniform temperature, particular attention was paid to the matter of providing standard bars for all the slip and strain measuring instruments used. These reference bars, of both steel and aluminum, were kept in contact with, or near, the joints being tested at all times.

All of the joints were subjected to a number of increments of load leading to ultimate failure. The general procedure followed was to select increments of load small enough that from six to eight sets of slip determinations could be obtained below the design load. In most cases these same increments were used as long as any slip measurements were taken. Permanent sets or slips were measured for the design loads and for several increments exceeding this value.

Strain measurements were usually limited to from four to six increments of load within the elastic range of the plate material or within the limits of strain that could be covered by the gages. In most cases an effort was made to obtain a complete set of strains at loads equal to approximately 1, 1½, 2, and 2½ times the design load. Intermediate as well as higher loads were used in a

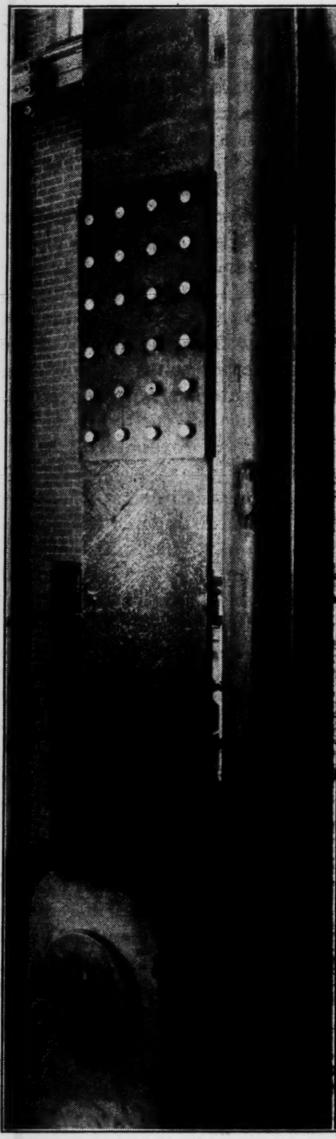

FIG. 4.—CARBON STEEL JOINTS, 12½ IN. WIDE

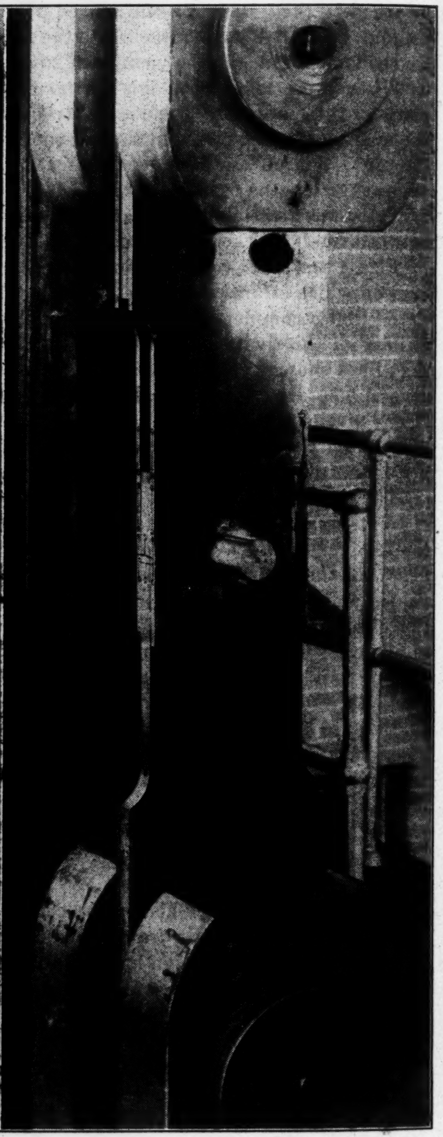

FIG. 5.—PIN-CONNECTED JOINT, 8 IN. WIDE; 2-IN. PIN

number of cases, however, particularly on the aluminum joints. All the joints of any one type were subjected to at least one common load so that a direct comparison of strains could be made. Design stresses used as a basis for selecting increments of test load are given in Table 3.

TABLE 3.—DESIGN STRESSES (KIPS[a] PER SQUARE INCH) USED AS A BASIS FOR SELECTING TEST LOAD INCREMENTS

[a] 1 kip = 1 "kilo-pound" = 1,000 lb. [b] The rivets and pins in this group were 53S-W.

RIVETED JOINTS DESIGNED TO FAIL IN SHEAR

Fig. 1(*a*) shows the dimensions of the large joints included in this series of tests. There are four points of interest to be considered: The distribution of load between the rivet rows; the load at which the first appreciable yielding or permanent slip between plates was observed; the distribution of measured strain in the plates; and the ultimate shear strength of the joints.

Table 4 presents data for plotting the load-slip relations for different rivet sections in the small auxiliary control specimens, having two and four rivets, and in the joints, 20¼ in. wide, having twenty-four rivets. By reducing all loads to an average value per rivet, it was possible to plot these relations for all joints of the same material in one figure, thereby facilitating direct comparisons (see Fig. 6). In the case of the auxiliary specimens having only two rivets, of course, there was no question as to the distribution of load. In the auxiliary specimens having four rivets the load should have been equally distributed between the rivets from conditions of symmetry, and the load-slip relations shown for these specimens support this contention. In the large joints having twenty-four rivets, however, there is a consistent difference between the slip obtained at sections A and C, through the end rows of rivets, and that obtained at section B through the intermediate rows. If the load on each row of rivets was proportional to the observed slip between the plates, then rows A and C were more effective than row B, which is in accordance with the theory for the behavior of such joints.[4] The fact that slip was observed in all joints beginning with the application of the first load indicates that there was no appreciable friction between the plates, which result is contrary to that reported by recent investigators using riveted joints of a more conventional type.[6,10] The relations between load and slip were not linear, even in the early stages of the tests, which is also contrary to the behavior usually assumed for riveted joints within the elastic range. There was no evidence of any slip necessary to bring the rivets into bearing, probably because the rivets in these joints were driven cold, in holes which had been drilled and reamed in assembly.

Table 5 gives a summary of the measured slips obtained on the auxiliary shear specimens with corresponding ratios of load to slip, or so-called "*K*-values." Since linear load-slip relations were not obtained for any of the joints, *K*-values have been given for the shear design loads only. Values of

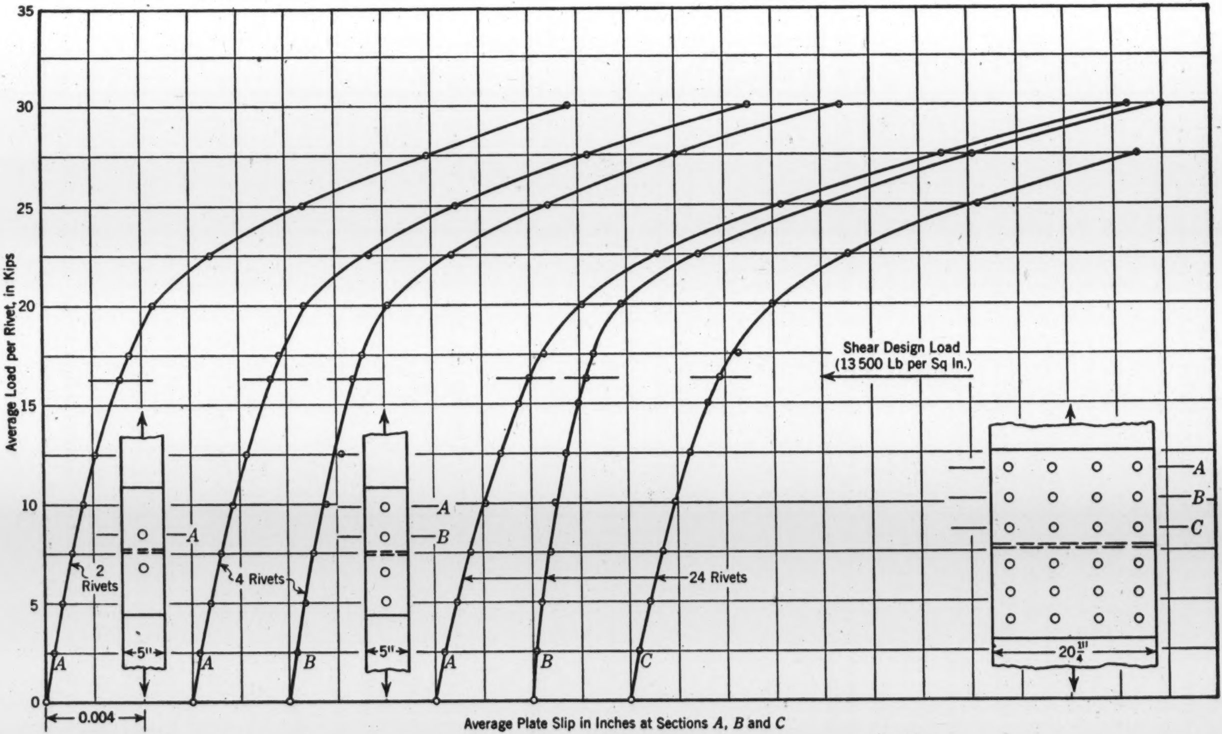

FIG. 6.—LOAD-SLIP CURVES FOR JOINTS OF 27S-T PLATES AND CARBON STEEL RIVETS

the latter are indicated on the curves in Fig. 6 and by the data in Table 5. There are several points of interest to be noted from the data given in Table 5. The measured slips for section A of the joints having only two rivets were practically the same as those measured on sections A and B of the joints having four rivets; the *K*-values for the joints having aluminum plates and rivets were about one third of those obtained for the all-steel specimens, which corresponds approximately to the ratio of the moduli of elasticity for these two materials; and the *K*-values for the joints having aluminum alloy 27S-T plates and steel rivets were about 43% of those obtained for the all-steel specimens, indicating that deformation in the aluminum plates rather than detrusion of the rivets was largely responsible for the magnitude of the slips observed.

[a] Determined from load-slip curves shown in Fig. 6 and Table 4. [b] Ratio of design load per rivet to average slip.

The distribution of load between sections A, B, and C of the large joints may be determined from the ratio of the measured slips on these sections without regard to the results obtained on the auxiliary specimens where the load distribution was known. Table 6 gives a summary of the measured slips on sections A, B, and C for the shear design loads and gives the corresponding percentages of load carried by each rivet row. These results are consistent

[a] Determined from load-slip curves shown in Fig. 6 and Table 4. [b] Determined from relative magnitudes of measured slips on sections *A*, *B*, and *C*. [c] Based on *K*-values given in Table 5.

in indicating that the two end rows in each half of the joints carry more load than the intermediate rows. There are differences between the percentage values for sections A and C, however, which cannot be explained, other than by stating that they probably resulted from minor inequalities in fabrication. In four out of five cases the rivets on section A apparently carried from 3% to 10% more of the total load than the rivets on section C which theoretically should have been equally effective. Table 6 also gives, for comparative purposes, the theoretical distribution of load for the large joints based upon the *K*-values obtained from the auxiliary shear specimens. The agreement between these theoretical values and those determined from the slip measurements is not particularly good, although in both cases the relative ineffectiveness of rivet row B, with respect to rows A and C, is clearly indicated. On the basis of the slip measurements it appears that the differences between the ordinary assumption of uniform load distribution and that actually obtained may be greater than indicated by theoretical considerations. This observation was also made by Raymond E. Davis and Glenn B. Woodruff, Members, Am. Soc. C. E., and Harmer E. Davis, Assoc. M. Am. Soc. C. E., who reported that inequalities arising from fabrication may cause an erratic and irregular load partition in large riveted joints which is great in comparison with the differences in load partition called for by the elastic theory.[6]

Table 7 gives a summary of loads for sections A, B, and C of the wide joints computed from the measured slips for the design loads and the *K*-values obtained from the small auxiliary specimens. The fact that the differences between the total loads obtained for the wide joints in this manner and those actually applied ranged from only 6% to 11% for all joints indicates a satisfactory correlation between the results of these related tests.

[a] Based on *K*-values for auxiliary shear specimens given in Table 5 and measured slips for sections A, B, and C of wide joints given in Table 6.

From the load-slips curves shown in Fig. 6 and from data in Table 4, it is not possible to select a well-defined point of first yielding although the "knees" in the curves for the steel joints are somewhat more pronounced than in those for the aluminum joints, as would be expected from the fundamental difference in the stress-strain characteristics of these materials. One observation which may be made from these data, however, is that the slip showed a marked increase at loads only slightly greater than the shear design values for the rivets. Slip measurements on 2-in. gage lengths across the gap between the main plates indicated the same load-slip characteristics as far as first yielding was concerned. Fig. 7 shows a typical set of load-slip curves of this type, as well as permanent slip data for the aluminum alloy 27S-T joints with carbon steel rivets. In every case, permanent slips corresponding to the design loads were on the order of only a few ten thousandths of an inch.

To determine the load-strain curves for the wide joints of this series, strains, combined with slip, were measured over 48-in. gage lengths. Except for the fact that these curves indicated a more definite elastic range or linear relationship between load and strain, their shape was similar to those in Fig. 7. Within the elastic range the total measured elongations varied from about 6% to 10% less than those computed for the same lengths of unspliced main plate, assuming moduli of elasticity of 29,500,000 and 10,300,000 lb per sq in. for steel and aluminum, respectively. This result is indicative of the tightness of the joints, where the effect of slip was more than offset by the effect of the extra plate thickness at the joint splices.

Fig. 8 shows the measured distribution of longitudinal stress in the wide joints for two increments of load, one within the range before any appreciable permanent slip had occurred and the other well above the range of first yielding. The values given are the measured unit strains multiplied by the moduli of elasticity—for steel, 29,500 kips per sq in., and for aluminum, 10,300 kips per sq in. An examination of the data indicates that essentially the same behavior was obtained for all the different combinations of materials investigated. On section A in the main plates a reasonably uniform distribution of stress was observed, as would be expected, and the averages of the measured values for all gage lines checked the average computed stresses within a few per cent. On sections B and C, between rivet rows on the cover plates, a fairly uniform distribution of stress was observed for the smaller load, but wide variations were found for the higher loads. In fact, compressive rather than tensile strains were measured in some cases on the longitudinal gage lines in line with the rivets.

Fig. 8 also shows the percentages of total applied load accounted for by the average measured cover-plate stresses on sections B and C. As will be noted from a comparison with the percentages given in Table 6, these values are not in very good agreement with the load distribution based on the slip measurements. The uncertainties apparent regarding the actual stress distribution produced in the cover plates suggest that the strain measurements as obtained were probably not very sensitive to the load distribution between rivet rows. There is no question, of course, as to the amount of load carried on section D at the middle of the joints. The distribution of stress measured at this section was quite varied, although the average values in most cases were within a few per cent of the averages computed.

It should be stated that the average measured stresses referred to herein, and throughout the remainder of this paper, are simply the arithmetic average of all the values found on the gage lines of any one section. No effort was

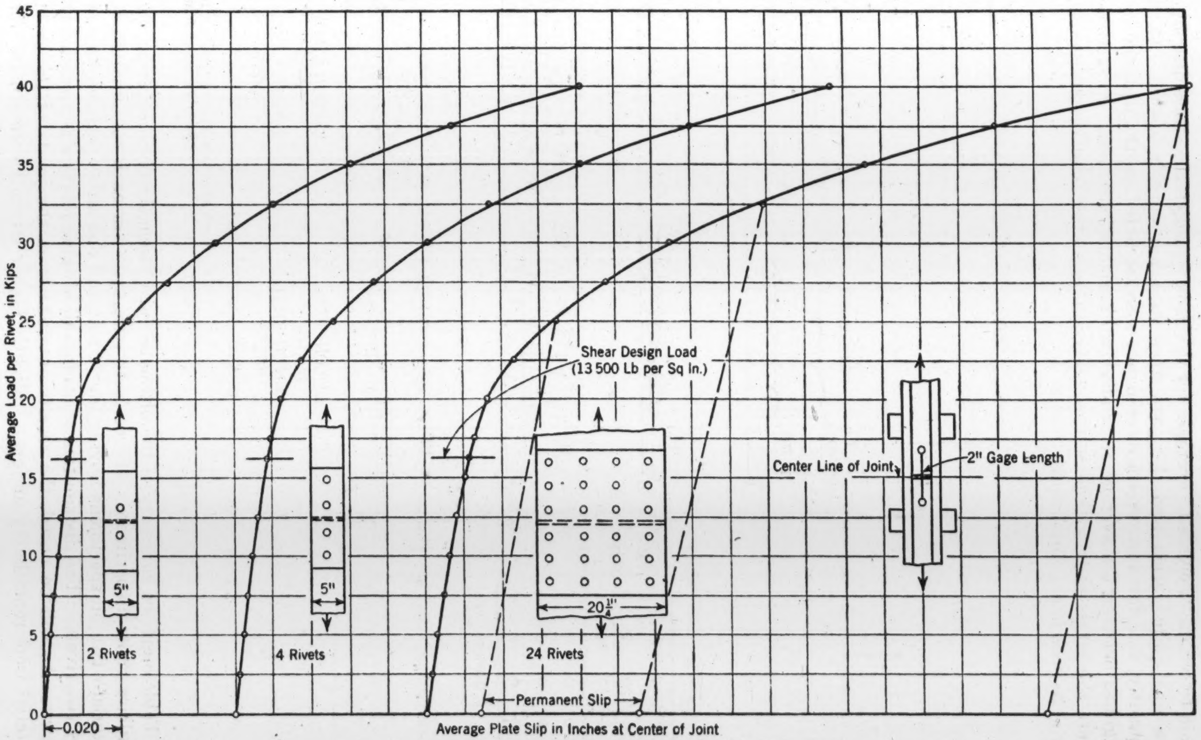

Fig. 7.—Slip Determined by a Dial Indicator on 2-In. Gage Lengths; Joints of 27S-T Plates and Carbon Steel Rivets, Designed to Fail in Shear

made to obtain "weighted" averages for the cases in which the stress distribution was quite varied and the gage lines were not equally spaced. Consequently, in a few instances a discrepancy may be noted on the distribution diagrams between the average and individual measured stresses. On sections where the stress distribution is reasonably uniform, the relative position of the gage lines is not important.

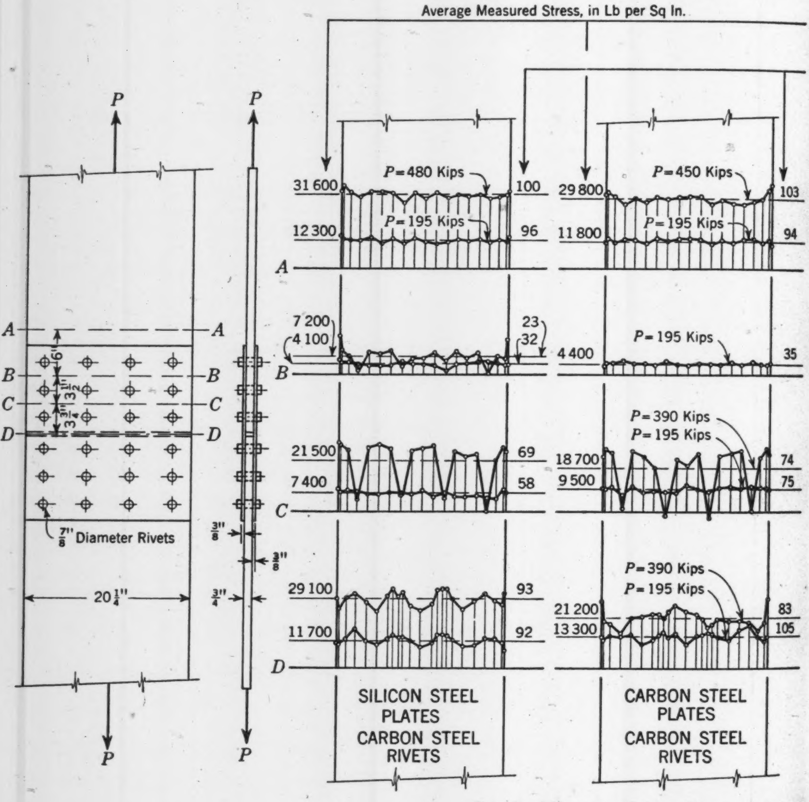

FIG. 8.—MEASURED STRESS DISTRIBUTION IN
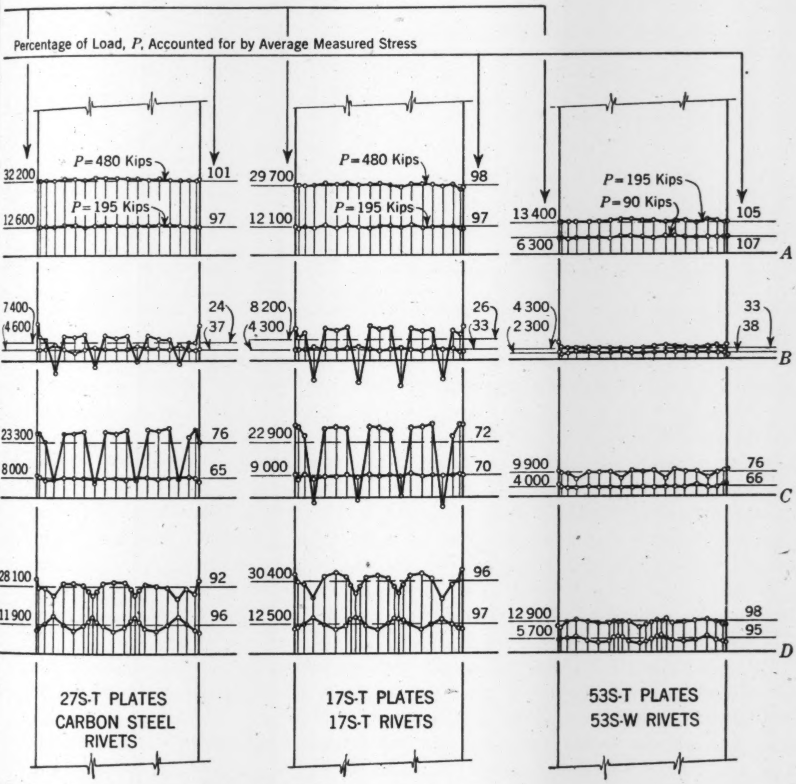
(Where Values of *P* Are Not

Table 8 gives a summary of the ultimate shear strengths obtained from the auxiliary control specimens. Three tests were made for each combination of material—two on specimens having four rivets and one on a specimen having only two rivets. The distribution of load in all of these joints was presumably known. As will be noted, the results obtained from the joints of the same material were remarkably uniform. Slightly higher strengths were found for the steel rivets in 27S-T plates than for the same kind of rivets in steel plates, although the difference was too small to appear significant. It is of interest to point out in connection with the shear strengths given for the steel rivets that tests on this material in an Amsler shear tool using a specimen ½ in. in diameter machined from the ⅞-in. rivet stock indicated an average strength of approximately 44,000 lb per sq in. From this result it appears that the full



Wide Joints Designed to Fail in Shear
Given, Refer to Curves Above)

shear strength of the material was not obtained in the type of rivet used in the joints. Considerable bending was observed in the rivets in all cases and this behavior was aggravated, of course, by the fact that the cover plates pulled away from the main plates as the ultimate strength was approached. The use of rivets with full-size heads would undoubtedly have resulted in higher shear strengths.

The maximum measured plate slips included in Table 8 give an idea of the deformations produced in the joints before failure occurred. There was no marked difference between the behavior of the steel and aluminum joints, considering the loads involved. These slip determinations seem reasonably consistent with those of Messrs. Davis, Woodruff, and Davis,[6] who reported that shear failures occurred in $\frac{7}{8}$-in. rivets at a detrusion of about 0.3 in.

[a] Readings were taken across the gap between the main

Table 9(*a*) gives a summary of the ultimate loads obtained on the wide joints with the corresponding average shear, tensile, and bearing stresses, maximum measured plate slips and predicted loads. Shear failures were obtained in all cases at loads averaging within about 2% of the predicted values, the latter based on the shear strengths obtained from the auxiliary control specimens. The obvious conclusion to be drawn from this result is that the nonuniform distribution of load observed within the elastic range was not a significant factor as far as ultimate strengths were concerned. Differences in ratios of yield strength to ultimate strength, in elongation values, or in moduli of elasticity, likewise appeared to have no bearing upon the results obtained. Factors of safety on the shear design loads against ultimate failure ranged from 3.0 for the steel rivets to 3.6 for the 17S-T rivets.

In connection with the uniformity of the shear strengths obtained in these tests in which one to twelve rivets were sheared simultaneously, a similar result has been found in tests of hull plate splices.[11] Joints containing both carbon steel and 53S-W rivets, in which nine to sixteen rivets were sheared simultaneously, gave average shearing strengths ranging from 92% to 100% of the strengths obtained for similar rivets tested in auxiliary control specimens. Considerable bending was observed in the rivets and this action naturally resulted in the cover plates pulling away from the main plates. The rivets themselves sheared on only one plane and were pulled through the main plates by the bending in the opposite cover plates. In the steel joints there was the customary scaling of the plates around the rivets, although it should be emphasized that this action was not observed until some time after it was evident from the slip measurements that yielding was taking place.

[11] "Static and Repeated Load Tests of Aluminum Alloy and Steel Riveted Hull Plate Splices," by R. L. Templin and E. C. Hartmann, *Technical Paper No. 5*, Aluminum Research Laboratories, 1941.

RIVETED JOINTS DESIGNED TO FAIL IN TENSION

Fig. 1(*b*) shows the dimensions of the joints included in this series of tests. The joints were similar to those designed for shear (Fig. 1(*a*)), except for the width of plates and the transverse spacing of rivets. The principal points of interest are, as before—the distribution of load between the multiple rows of rivets; the load at which first yielding or permanent slip occurred; the measured distribution of strain in the plates; and the ultimate strengths.

AUXILIARY CONTROL SPECIMENS

plates at the center of specimens, as indicated in Fig. 7.

Fig. 9 shows the load-slip curves for the three rivet sections investigated in each joint. The characteristics of these curves are similar to those in Fig. 6 and Table 4 for the wide joints designed for shear. The fact that the measured slip for the end rivet sections A and C was greater than that observed for the intermediate section B again emphasizes the difference in the effectiveness of these three rivet rows. As before, the load-slip relationships shown are not linear and there is no definite knee or break in the curves to indicate a point of sudden yielding or slip. It will be noted, however, that the increase in yielding in the steel joints is somewhat more pronounced than in those of aluminum. Although a definite yield point cannot be selected from these curves, the margin between the design loads, indicated on the figures, and the loads producing a considerable increase in slip appeared somewhat greater than was found for the joints designed for shear.

Table 10 gives a summary of the measured slips for sections A, B, and C, and the corresponding load distribution based on the relative magnitudes of the slip observed at the tensile design loads. The percentage of the total load carried by the rivets on each of the end sections A and C ranged from 37% to 42% of the total, and the loads on the intermediate section B ranged from 16% to 21% of the total. The differences between the supposedly like sections A and C are less than those found for the wide shear joints. The results are consistent also in indicating that the rivets in row B are less effective than in the wide shear joints.

Fig. 10 shows the load-slip curves for all joints obtained from measurements taken across the gap between the main plates at the center of the joints. The yielding of the joint composed of carbon steel plates is in marked contrast to that shown for the other materials. Fig. 11 shows the load-strain curves obtained from the measurements of combined strain and slip on the 48-in. gage lengths. Since these curves are more indicative of strain in the plates than slip between the plates, a fairly definite elastic range was observed. The total measured elongations within the elastic range were from 9% to 12% less than computed for the same lengths of unspliced main plate, assuming moduli of elasticity of 29,500 and 10,300 kips per sq in. for steel and aluminum, respectively.

[a] Based on the net areas given in Table 1. [b] The load corresponding to the plate slip given in Col. 7. [c] Readings for maximum measured plate slip were taken across the gap between the main plates, at the center of the joints, as indicated in Fig. 7. [d] Based on the average shear strengths obtained from the auxiliary specimens given in Table 8. [e] Based on the tensile strengths of parallel specimens given in Table 2 and shear strengths in Table 8. [f] ¾-in. plate. [g] ⅝-in plates. [h] Shear and bending of pin. [i] Readings for maximum measured plate slip were taken diagonally across the main plates and cover plates, at sections through the pins.

Fig. 12 shows the measured distribution of longitudinal stress in all the joints of this series for two increments of load and gives the percentages of total applied load accounted for by the average measured stress on each of the sections investigated. Similarly to Fig. 8, the values indicated are the average measured unit strains multiplied by the moduli of elasticity (29,500 and 10,300 kips per sq in., respectively). Values of load *P* for sections B, C, and D are the same as for section A. On section A in the main plates the distribution was reasonably uniform (as would be expected) and the average values of stress were within a few per cent of those computed. On sections B, C, and D, however, the distribution was quite varied. The percentages of load accounted for by the average measured stresses on sections B and C are not as consistent, nor can they be considered as reliable, as the distribution of load obtained from the slip measurements. On section D, the average measured stresses were, in most cases, in fair agreement with the corresponding computed values. Perhaps the most significant point to be emphasized is that the strain measurements indicated essentially the same characteristics of behavior for all combinations of materials.

[a] Based on net areas given in Table 1. [b] Determined from load-slip curves shown in Fig. 9. [c] Determined from relative magnitude of measured slips on sections A, B, and C.

Table 9(*b*) gives the ultimate strengths for all the joints of this series, with the corresponding shear, tensile, and bearing stresses, maximum measured slips, and predicted loads. Tensile fractures, either in the main plates or the cover plates, were obtained in all joints except the one composed of silicon steel plates and carbon steel rivets, where a shear failure was obtained. The latter result was expected, however, after the results of the auxiliary shear tests indicated rivet strengths somewhat less than those relied upon in the original design. The predicted shear load was within about 3% of that actually obtained. The predicted tensile loads, based on the properties of the plate material given in Table 2, were within 2% to 6% of the actual values.

Of the four cases of tensile fractures listed in Table 9(*b*), three show plate tensile strengths which were higher than the tensile strengths of the material determined on the control specimens. Recent tests by other investigators[9,10] show this same trend for both silicon steel and carbon steel riveted joints. In comparing the results of these tests with those reported by the other investigators, however, an important difference in the procedure for computing strengths should be noted. In the investigations by Wilbur M. Wilson, M. Am. Soc. C. E., and F. P. Thomas,[10] and by Messrs. Davis, Woodruff, and Davis,[6] the net section areas were based on hole diameters arbitrarily taken as $\frac{1}{8}$ in. greater than the nominal rivet diameters, a procedure commonly required by design specifications.[12,13] In these tests, however, the net section areas were based on the nominal rivet hole diameters, a procedure believed to be entirely justified for investigational purposes. Had the other procedure been used in these tests, the tensile strengths on the net sections would have been increased about 6% more than the values given in Table 9(*b*). Although it has not been possible to show a correlation between the tensile design loads and the loads producing the first appreciable permanent slip, the factors of safety against ultimate tensile failure ranged from 2.9 for the 27S-T joint to 3.9 for the 17S-T joint.

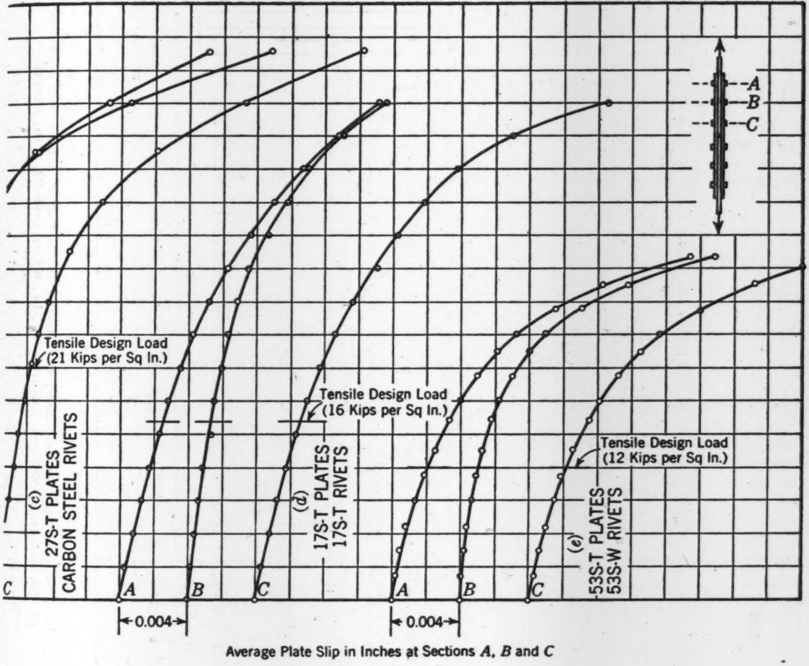
[13] "Specifications for Steel Railway Bridges," A.R.E.A. (1938), Article 409.

Fig. 13 shows typical examples of the tensile fractures obtained. In the case of the joint composed of carbon steel plates, the slip lines, elongation of the rivet holes, and lateral contraction of both main and cover plates at the most highly stressed rivet sections are clearly indicated. The first evidence of slip lines on the surface of the plates in this joint was obtained at a load of approximately 240 kips, or only a little more than one half the breaking load. The gap opening between the main plates at the center of the joint (originally closed) was 0.64 in., and this evidence of ductility is clearly indicated in the photograph.



TENSION (12½ IN. WIDE, WITH 24, ¾-IN. RIVETS; 10-IN. STRAIN GAGE)

Fig. 13(*b*) shows that failure in the 27S-T joint was accompanied by almost no elongation of the rivet holes, lateral contraction of the plates, or opening of the gap at the center of the joint. The opening between the main plates, determined after fracture, was only 0.08 in., as compared to the opening of 0.64 in. observed for the carbon steel joint. Despite this apparent lack of ductility it should be emphasized that the full strength of the 27S-T plate material was developed. Fig. 13(*c*), which shows the failure of the 17S-T joint, indicates a behavior more like that obtained for the carbon steel joint.

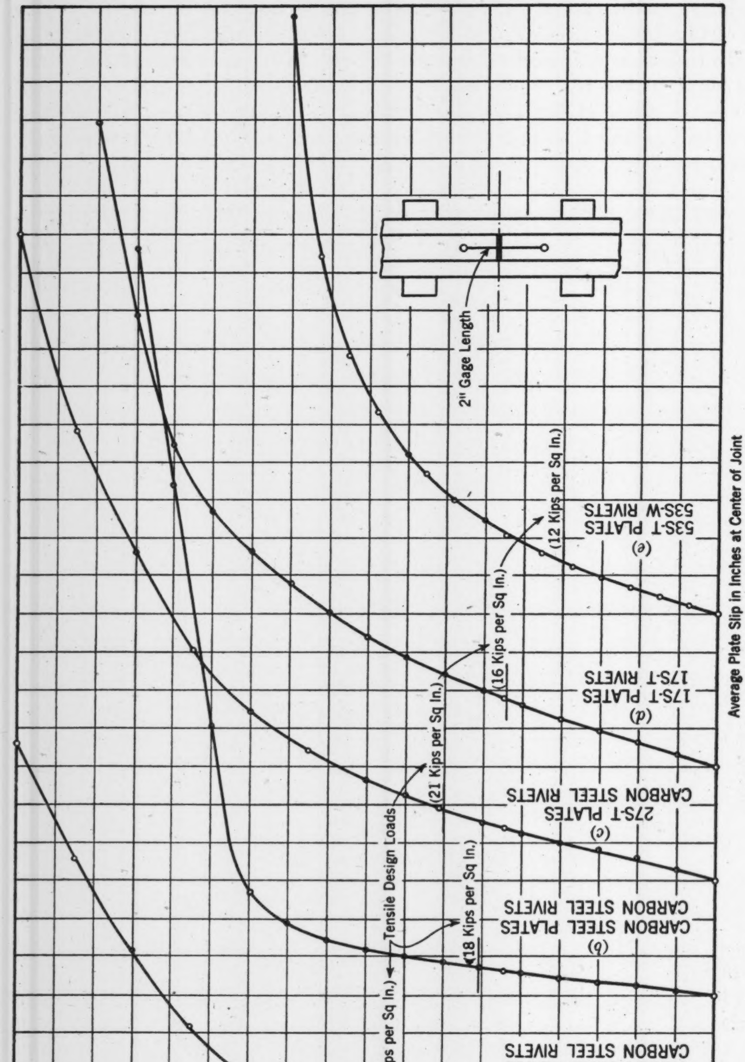


FIG. 10.—LOAD-SLIP CURVES FOR NARROW JOINTS DESIGNED TO FAIL IN TENSION; MEASUREMENTS TAKEN ACROSS THE GAP BETWEEN THE MAIN PLATES AT THE CENTER OF THE JOINTS; 2-IN. GAGE LENGTHS (12¼-IN. WIDE, WITH 24, ⅞-IN. RIVETS)

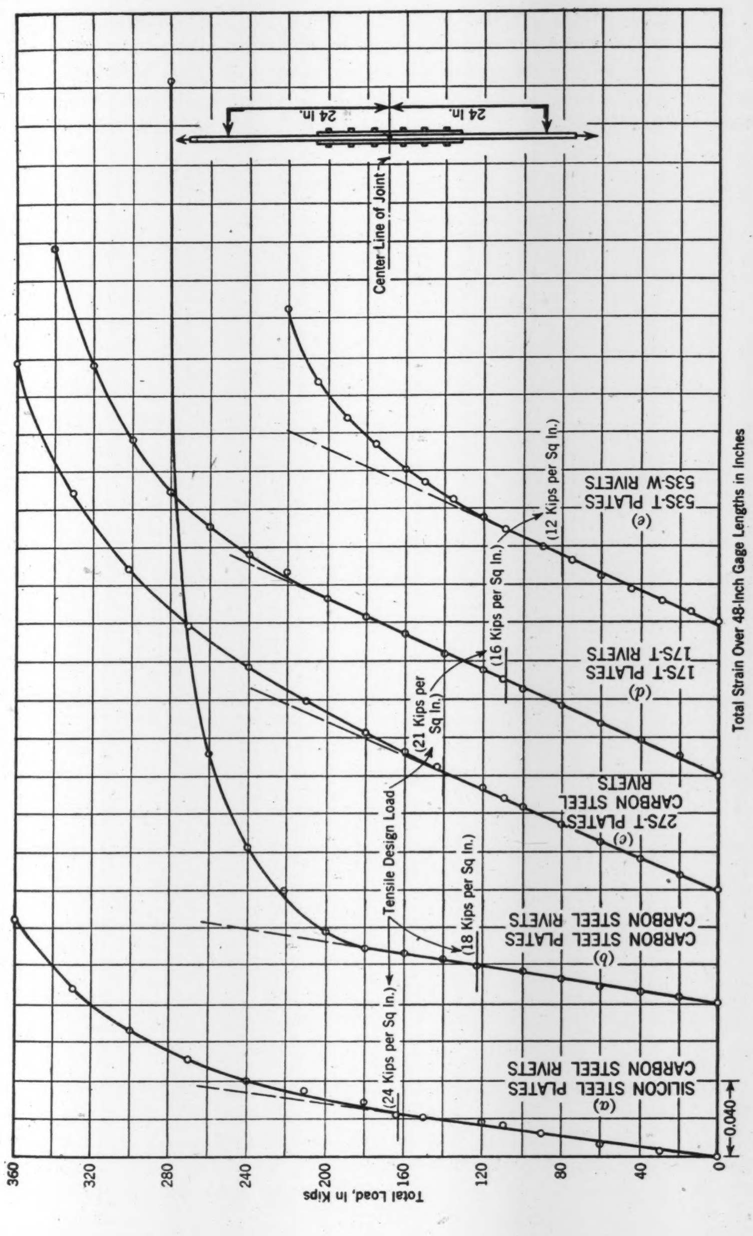

FIG. 11.—LOAD-STRAIN CURVES FOR NARROW JOINTS DESIGNED TO FAIL IN TENSION; STRAIN MEASURED BY DIAL INDICATOR ON 48-IN. GAGE LENGTHS (12½-IN. WIDE, WITH 24, ⅞-IN. RIVETS)

PIN-CONNECTED JOINTS DESIGNED TO FAIL IN BEARING

Fig. 2(*a*) gives the dimensions of the joints included in this series. All strain measurements were made with the nuts and washers removed from the pins, to permit access to the strain gage lines. At the conclusion of these measurements the nuts were replaced and the tests carried to failure.

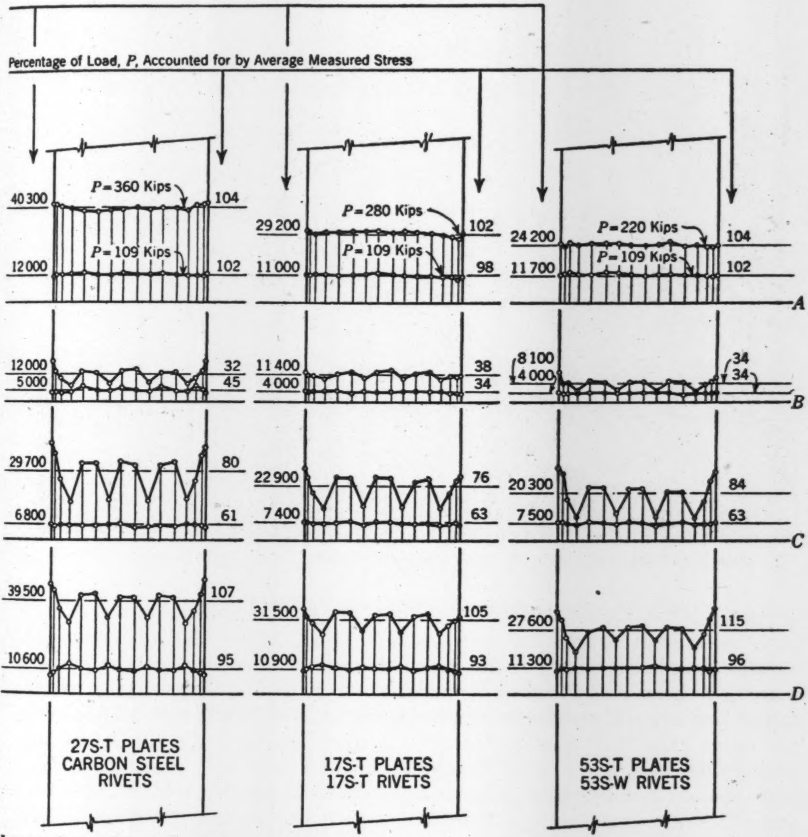
FIG. 12.—MEASURED STRESS DISTRIBUTION IN
(Where Values of *P* Are Not

As was the case in all the previous tests described, the relationships observed between load and slip were not linear and there was no definite point of first yielding. The margin between the loads corresponding to the bearing design stresses for the plate materials and the loads for which appreciable yielding was found appeared to be somewhat greater than that shown in Fig. 6

(or by the data in Table 4) for the wide joints designed for shear. Load-slip curves for the pin-connected joints have not been included herein because of their similarity to the numerous curves of this type already shown.

Fig. 14 shows the measured distribution of stress in these joints. Again (see Fig. 8), the values indicated are average measured unit strains multiplied by the moduli of elasticity of steel and aluminum (29,500 and 10,300 kips per sq in., respectively). As may be noted, essentially the same behavior was observed for all materials. On section A, which was considerably removed from the influence of the pin, a reasonably uniform distribution of stress was observed and the average measured values were within a few per cent of those



NARROW JOINTS DESIGNED TO FAIL IN TENSION
Given, Refer to Curves Above)

computed. On section B the effect of the pin was more pronounced although, in most cases, the averages of the measured stresses were within a few per cent of those computed. On section C, through the center of the pins, the range of stresses observed is clearly indicative of the high stress concentrations which must have been present at the boundaries of the pin openings. In view of the limited scope of the strain measurements and the fact that the strains on the inside gage lines exceeded the elastic limit for relatively low loads, no attempt has been made to make any comparisons between average measured stresses and the corresponding computed values. According to previous tests and photoelastic measurements[14] the stress concentration factor at the edge of a pin opening in plates of the proportions used should be approximately 4.7. Although it has not been possible to obtain a check on this concentration factor, it is of interest to point out that if such a stress concentration is assumed, the loads computed for first local yielding would correspond approximately to the design values for bearing. These computed loads were in every case below

[14] "Stress-Concentration Factors Around a Central Circular Hole in a Plate Loaded through Pin in the Hole," by M. M. Frocht and H. N. Hill, *Journal of Applied Mechanics, Transactions*, A.S.M.E., March, 1940, pp. A5–A9.

The strain measurements taken on section D, Table 11, represent the only attempt to measure bearing stresses directly. Even though it was obviously not possible to obtain maximum values from measurements over 2-in. gage lengths, centered 1½ in. from the edge of the pins, the stresses corresponding to the strains measured were in all cases greater than the maximum values found on section C for the same loads. Table 11 gives the longitudinal and transverse stresses for some of the same loads for which the stress distribution on section C was shown in Fig. 14. Values for the maximum loads have not been included because the corresponding strains were outside the range of the measuring instruments used. Since there was some tendency for bending in the ends of the cover plates, this action may have been partly responsible for the large strains observed.

[a] Based on longitudinal and transverse strains assuming elastic action.

Table 9(*c*) gives a summary of the ultimate loads developed by these single-pin joints, with the corresponding shear, tensile, and bearing stresses and the maximum measured slips. So-called bearing failures were obtained for all but the joint composed of silicon steel plates, in which case the pin was badly bent and finally sheared off at a stress considerably below the nominal shear value for steel.

Fig. 15 shows the different types of failures obtained. A typical bearing failure involved a combination of elongation of the hole, bending of the pin, and buckling of the free ends of the cover plates. The ultimate bearing stresses obtained from such a test are so dependent upon the relative proportions of the plates and pin and the amount of lateral restraint provided against the bulging of the plates that they can scarcely be considered as representing definite properties of the materials. It may be pointed out, however, that the ultimate bearing strengths obtained for the silicon and carbon steels were approximately 1.4 and 2.1 times the tensile strengths, whereas the corresponding ratios for the aluminum alloys ranged from about 1.6 to 1.8. The factors of safety on the bearing design stresses used ranged from a minimum of 3.3 for the 27S-T to 4.9 for the carbon steel.

PIN-CONNECTED JOINTS DESIGNED TO FAIL IN SHEAR

Fig. 2(*b*) shows the dimensions of this series of joints. The tensile and shear areas were nominally the same as in the single-pin joints designed to fail in bearing but the bearing areas were 100% greater. The first loadings were made with the nuts and washers removed, but these were replaced before completing the tests to failure.

FIG. 14.—MEASURED STRESS DISTRIBUTION
(Where Values of *P* Are Not

Since the load-slip curves for these joints exhibited the same general characteristics of behavior as were found for the other types of joints, none of them have been included here. The yielding in the joints with the steel pins was somewhat more pronounced than in the other cases, but the margin between the shear design loads and this yielding was about the same. The measured slips indicated an equal distribution of load between the two rows of pins. As was the case for all the different types of joints previously considered, essentially the same behavior was found for all combinations of material. On the sections outside the influence of the pins, the distribution of stress was reason-

ably uniform, particularly for the smaller loads, and the average measured stresses were in fair agreement with the corresponding computed values. On the sections midway between pins, the distribution of stress was extremely varied and the stress picture obtained was not complete enough to give a very satisfactory comparison of average measured and computed values.

Table 9(*d*) gives a summary of the ultimate loads with the corresponding shear, tensile, and bearing stresses and maximum measured slips. As may be noted from a comparison with the results given in Tables 8 and 9(*a*), the pins developed essentially the same shear strengths as the $\frac{7}{8}$-in. rivets used. The greatest difference was an increase in shear strength of about 8% found for the 17S-T pins. The pins were all slightly bent as well as sheared and the holes in the cover plates were somewhat elongated.

SUMMARY

1. The load-slip curves for all types of joints and for all the different combinations of materials were characterized by the following features:

(*a*) Slip occurred with the first application of load, which indicated no appreciable friction between the plates.

(*b*) The relation between load and slip was not linear, although the permanent slips measured for loads equivalent to the design values were on the order of only a few ten thousandths of an inch.

(*c*) There was no definite yield point on any of the curves, although the yielding of the steel joints was more pronounced than that of the aluminum joints.

2. The load-slip curves obtained for individual sections in all joints having two rows of rivets or pins indicated an equal distribution of load between rows, as would be expected.

3. In the auxiliary control specimens the ratios of load-to-slip corresponding to the shear design loads for the aluminum plates and rivets were approximately one third those obtained for the all-steel joints, which is consistent with the ratio of the moduli of elasticity of these materials. The load-slip ratio for the aluminum alloy, 27S-T, joint with steel rivets was 43% of that found for the all-steel joints, indicating the importance of plate action upon the amount of slip observed.

4. The load-slip curves obtained for the large joints having three rows of rivets in each half indicated that within the elastic range the end rows carried more load than the intermediate rows. From the relative magnitudes of the slips measured, it appears that the end rows each carried from 33% to 43% of the total load, whereas the intermediate rows carried from 16% to 26% of the total. These variations from a uniform distribution of load are greater than indicated by the elastic theory.

5. Measurements of combined slip and strain made on the large joints over 48-in. gage lengths indicated total elongations approximately 10% less than computed for the same lengths of unspliced main plate, assuming moduli of elasticity of 29,500 and 10,300 kips per sq in. for the steel and aluminum alloys, respectively.

6. The measured longitudinal strains agreed in general with the type of behavior expected on the sections investigated. The interpretation of these strains on the basis of a unidirectional state of stress gave average stresses which, in most cases, were in reasonably good agreement with the averages computed.

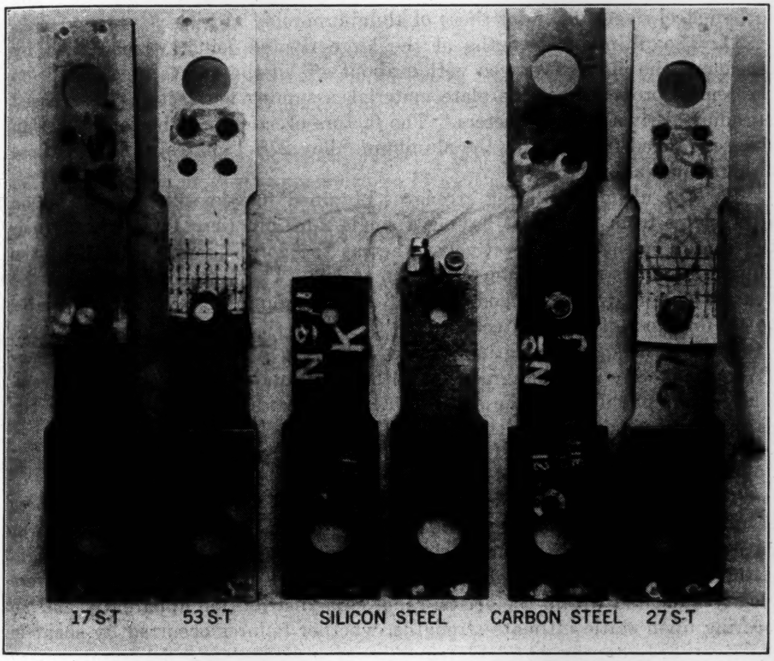

FIG. 15.—FAILURES IN NARROW JOINTS; 8 IN. WIDE, WITH A PIN 2 IN. IN DIAMETER

7. The maximum variations from a uniform distribution of measured stress in the riveted joints occurred in the cover plates on the gage lines in line with the rivets. For average tensile stresses well within the yield strength of the material, the individual stresses on these gage lines were in many cases found to be in compression.

8. The strains measured on the sections through the center of the 2-in. pins were clearly indicative of the stress concentrations which must have occurred at the edges of the pin holes, although no quantitative measure of the magnitude of these stress concentrations was obtained.

9. The loads at which the maximum stresses at the hole boundaries for the 2-in. pins were computed to be equal to the yield strength of the material, assuming a stress concentration factor of 4.7 as indicated by other tests, were below those at which first yielding was apparent from the load-slip curves.

10. The ultimate shear strengths obtained for the large joints having twenty-four rivets averaged within about 2% of the values predicted from the

tests on the auxiliary control specimens, having two and four rivets. From this result it appears that the inequality of the load distribution found within the elastic range had no bearing upon the ultimate shear strengths. Differences in elongations, moduli of elasticity, and ratios of yield to ultimate strength likewise appeared to have no bearing upon the strengths of the joints. The factors of safety on the shearing design stresses ranged from 3.0 for the carbon steel rivets to 3.6 for those of aluminum alloy 17S-T.

11. The ultimate strengths of the large riveted joints which failed by tension in the plates averaged within about 4% of the values predicted from the tensile properties of the plate material, assuming net section areas based on nominal rivet hole diameters. The factors of safety on the tensile design stresses ranged from 2.9 for the aluminum alloy 27S-T plates to 3.9 for those of aluminum alloy 17S-T.

12. The ultimate bearing strengths obtained for the silicon and carbon steel plates from the joints having a single 2-in. pin were 1.4 and 2.1 times the tensile strengths, respectively, whereas the corresponding ratios for the aluminum alloys ranged from about 1.6 to 1.8. The factors of safety on the bearing design stresses ranged from 3.3 for the aluminum alloy 27S-T plates to 4.9 for those of carbon steel.

13. The shearing strengths obtained from the joints having four 1-in. or $1\frac{1}{16}$-in. pins were in good agreement with those obtained from the $\frac{7}{8}$-in. rivets. The factors of safety on the shearing design stresses ranged from 2.9 for the carbon steel pins to 4.0 for those of 17S-T.

CONCLUSIONS

The most significant conclusion to be derived from the results of these tests is that the behavior of all the large riveted and pin-connected joints was entirely consistent with the basic assumptions generally made in design. Although inequalities in load distribution between multiple rivet rows were clearly indicated within the elastic range, this distribution apparently had no bearing upon static ultimate strengths, whether failures occurred by shear in the rivets or by tension in the plates. The amount of plastic yielding necessary to level off high stress concentrations and to effect a uniform distribution of load among the rivets must be relatively small. Essentially the same behavior was obtained for all the different combinations of the materials investigated. Elongations, moduli of elasticity, and ratios of yield to ultimate strengths were apparently not significant factors as far as the static strengths of these joints were concerned.

ACKNOWLEDGMENT

This paper was prepared under the auspices of the Committee of the Structural Division on Design in Lightweight Structural Alloys. The tests were made in 1939 at the Aluminum Research Laboratories, Aluminum Company of America, in New Kensington, Pa.

The tests described were made under the direction of Mr. Templin, chief engineer of tests, Aluminum Company of America. The writers wish to acknowledge the assistance of Mr. Templin and various members of his staff in planning and conducting these tests.

DISCUSSION

Jonathan Jones,[15] **M. Am. Soc. C. E.**—The only question the writer would ask with respect to the program as a whole is: If the objective was (as stated in the "Introduction") to investigate longitudinal distribution of rivet loads, would it not have been more convincing to arrange the twelve rivets on each side of a joint in two lines of six each or three lines of four each, instead of in four lines of three each, the plates to be correspondingly narrower and thicker? All further comment herein is directed solely to the tests of carbon steel plates.

The reported shearing strength of rivets (41,100 lb per sq in. in Table 8 and 40,600 in Table 9(*a*)) appears to be lower than may be expected in hot-riveted work. It should be noted that these rivets were not hot-driven, and their strength therefore was not enhanced by the usual driving "quench."[16] Neither was their strength enhanced by cold work, as in standard cold driving, since they had a press fit in the holes and the work of cold upsetting must have been substantially confined to the heads.

One of the most important findings to record from a test of a riveted joint is the ratio between the shear strength of the driven rivet and the tensile strength of the original rivet bar.[17,18] In the paper the latter value is not given, so it cannot be determined whether, as the writer has just intimated, this important ratio was low. If any of the original materials are still at hand it would be very interesting if the ratio in question could be recorded for (*a*) the rivets as driven and recorded in the paper, (*b*) rivets driven hot, and (*c*) rivets driven by the usual technique of cold driving in which the shank is $\frac{1}{16}$-in. slack in the hole before upsetting.

In sum, it is felt that the results reported in this paper should not influence the rivet shear allowance in specifications based on standard structural practices.

In the test designed to fail in bearing, the actual failure (see Fig. 15) was not a bearing failure, which implies collapse on the contact surface between pin and plate, but a bulging out behind the pin through a splitting or shearing action, accompanied by a transverse tension tending to rupture the free end of the plate. Evidently the greater the length of plate behind the pin, the more resistance there would be to this effect, and the higher the true bearing pressure could be raised. Had the length behind the pin in this test been about 4 in. instead of 3 in., it is probable, judging by other tests, that the load could have been increased and that there then would have been about an equal chance of failure of the type that did occur, and of failure in tension across the pinhole. A true bearing failure, meaning a crumpling of plate material at point of contact with the pin, is probably not attainable under ordinary relationships between thicknesses of plate and diameter of pin or rivet, although some thickening of the plate will be observed.

[16] "Static Tests of Riveted Joints," by Jonathan Jones, *Civil Engineering*, May, 1940 (see heading, "Strength of Rivets in Shear"), p. 286.

[17] *Ibid.*, p. 287.

[18] "Physical Properties of Driven and Undriven Rivets of High-Strength Structural Steels," Progress Report of the Committee of the Structural Division on Structural Alloys, *Proceedings*, Am. Soc. C. E., May, 1942, p. 769, Table 13, Col. 26.

In the tests reported[17] by the writer in 1940 the rivet bearing reached 165,000 lb per sq in. before joint yield was observed, and 204,000 lb per sq in. before failure occurred. The authors' test evidently did not exhaust the bearing capacity of the steel plate, despite the fact that the unit bearing stress at failure was 3.3 times the American Institute of Steel Construction (A.I.S.C.) allowance for enclosed rivet bearing and 4.1 times the A.I.S.C. allowance for nonenclosed rivet bearing or for bearing on pins.

In all pin-connected or riveted construction, due attention should be paid to the length of plate behind the pin or rivet. Tests have indicated that if a pin-connected flat plate of width *b* has a net width across the pin of 1.30 *b* and a net length behind the pin of 0.85 *b*, failure will occur in the bar and not in the head.

LEON S. MOISSEIFF,[19] M. AM. SOC. C. E., AND E. C. HARTMANN,[20] AND R. L. MOORE,[21] ASSOC. MEMBERS, AM. SOC. C. E.—If the sole object of this investigation had been to determine the load distribution on rivets, the arrangement of the twelve rivets in each half of the joints in three lines of four rivets or two lines of six rivets might have been a more desirable pattern, as Mr. Jones suggests. As the "Introduction" states, however, these tests were undertaken in an effort to obtain information on the strength and general behavior of large multiple-riveted joints involving different combinations of steel and aluminum alloys, as well as to obtain information on load distribution. The arrangement of the rivets in four lines of three each was chosen because it represented a more frequently used pattern of joint and appeared well suited for the over-all purposes of these tests. The results of tests of riveted joints involving combinations of steel and aluminum plates with five rivets in line on either side of the joints have been reported elsewhere.[22]

The average shear strengths of 40,600 lb per sq in. and 41,100 lb per sq in. obtained from the tests of carbon steel rivets in carbon steel plates (Tables 8 and 9(*a*)) were admittedly not as high as would be expected from conventional hot-driven rivets. These low-strength values, however, may be attributed principally to the type of rivet used rather than to deficiencies in the quality of the material. Shear strengths obtained from tests of ½-in. diameter specimens machined from the rivet bar, made in a double-shear tool, averaged slightly more than 44,000 lb per sq in. It should be emphasized that the rivets used in these joints were not conventional ones, but consisted of 2½-in. lengths of ⅞-in. rod which were pressed in the ⅞-in. drilled and reamed holes and then upset cold in a yoke type riveter to approximately 1⅛-in. diameter at the ends. This type of rivet was selected for test purposes to permit an inspection of the plate material adjacent to the rivets, to provide additional clearance for strain readings between rivets, and to minimize the uncertain effects of friction. The writers share Mr. Jones' opinion that the results of these shear tests should not be considered as having any effect upon rivet shear allowances in specifications for carbon steel.

[20] Research Engr., Aluminum Research Laboratories, Aluminum Co. of America, New Kensington, Pa.

[21] Research Structural Engr., Aluminum Research Laboratories, Aluminum Co. of America, New Kensington, Pa.

[22] Discussion by H. N. Hill and Marshall Holt of paper entitled "Work of Rivets in Riveted Joints," by A. Hrennikoff, *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 464.

Mr. Jones states that Fig. 15 does not show a bearing failure for the carbon steel pin-connected joint. The writers agree that a true bearing failure, which involves a crushing of the material at the contact surfaces between pin and plates, is probably not attainable in a ductile metal any more than is a definite value of the ultimate compressive strength of such a material. Fig. 15 merely illustrates the types of failure obtained in tests in which bearing stresses were of primary importance.

An increase in the marginal distance between the pin and the edge of the plate in the bearing tests would undoubtedly have increased the ultimate bearing strength of the carbon steel joint. The increase would not be as large, however, as would be obtained in specimens having a lower ratio of pin diameter to plate thickness (D/t). The failure to develop a bearing strength in the test of the carbon steel joint comparable to strengths developed in certain tests described by Mr. Jones,[16] probably may be attributed to differences between the D/t-ratios of the specimens used. Tests to determine allowable bearing values (unenclosed bearing) for aircraft structural design, for example, have shown that, for a D/t-ratio of 8, increases in edge distance beyond approximately 2 diameters, measured from the center of the hole, result in no appreciable increase in ultimate bearing strength. For D/t-ratios of 4 or less, however, bearing strengths increase with edge distance for values of the latter ranging from 2 to 4 diameters.

PENDLETON LEVEE FAILURE

By Kenneth E. Fields,[1] and William L. Wells,[2]
Assoc. Members, Am. Soc. C. E.

With Discussion by Messrs. Ralph B. Peck, K. Terzaghi, T. A. Middlebrooks, D. P. Krynine, and Kenneth E. Fields and William L. Wells.

Synopsis

In the fall of 1939 the Vicksburg Engineer District was forced to construct a setback levee along the south bank of the Arkansas River near Pendleton, Ark. At one point the proposed levee, known as the Pendleton New Levee, crosses Lake Lenox, a shallow body of water which was formerly the channel of the Arkansas River. Foundation investigations revealed that the levee would be underlain by extremely soft clay at the lake crossing. Calculations of sections required to insure stability showed that the most economical procedure would be to displace the clay. In view of this fact, construction of the levee presented an excellent opportunity for securing data concerning a foundation failure.

Investigations of the foundation were made to determine soil conditions and characteristics. Various devices were installed in the foundation to observe movements, and hydrostatic and earth pressures. By means of such observations, it was thought that valuable and much-needed data concerning the physics of the failure would be obtained. The data obtained are given herein along with several analyses of the failure employing these data.

Field and Laboratory Data

The results of the foundation explorations are shown in Fig. 1. As can be noted, foundation conditions were found to be as follows:

(*a*) A thin, noncontinuous surface stratum of clay (not shown);
(*b*) A stratum of fine sand, from 4 ft to 9 ft thick;
(*c*) A stratum of extremely soft clay, averaging about 12 ft thick; and
(*d*) A relatively thick stratum of fine to coarse sand, underlying (*c*).

The usual physical soil tests were performed on undisturbed samples of the soft clay. From consideration of the age of the deposit and the time-consolida-

tion characteristics of the material, it was found that the foundation material was fully consolidated under its present overburden pressure. From the results of conventional direct-shear tests of the consolidated quick type, a value of cohesion of 0.04 ton per sq ft was obtained, as well as an angle of internal friction of 19° (see Fig. 2). With these data, stability computations were made to determine the cross section that would produce failure for a height of approximately 30 ft.

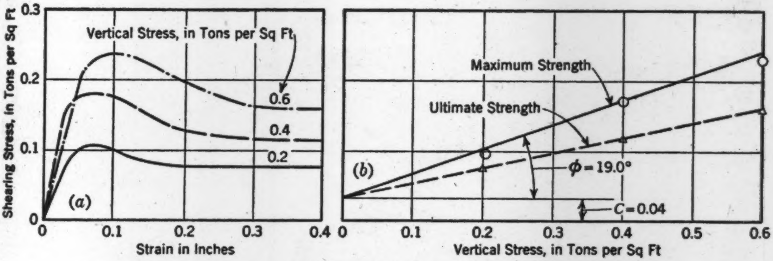

Fig. 2.—Shearing-Strength Curves; Sample from Clay Stratum

Provisions for Physical Measurements

Provisions for physical measurements consisted of settlement plates, earth and hydrostatic pressure cells, and cross-section surveys. Settlement plates were of the usual type (see Fig. 3(*a*)). Because of the short time available, the only earth pressure cells which could be obtained were six Wilson cells. These are similar to the Goldbeck cell in that internal air pressure is increased until a balance with the external pressure is reached. Further details of the installation are of no importance inasmuch as the cells failed to function.

As a means of observing pore-water pressures in the foundation during construction, piezometers were installed in the underlying clay stratum at one cross section. Details of the apparatus are shown in Fig. 3(*b*).

CONSTRUCTION AND FAILURE

Construction consisted first of the formation of the base of the embankment, the material for which was hauled in by tractors and wagons and spread by bulldozers. After the completion of the base, on January 15, 1939, a triangular section having a base width of about 320 ft and a total height of about 18 ft was then built. From this section a triangular section was built in 3-ft lifts as rapidly as possible.

FIG. 4.—GENERAL VIEW OF FAILURE

On the night of February 14, 1940, when the section had reached a height of about 32 ft, the foundation failed. This failure was confined to the land-side half of the embankment and extended longitudinally for about 500 ft. Fig. 4 shows a part of the embankment after failure. As can be noted from this photograph and from Fig. 5, the following phenomena were characteristic of the failure:

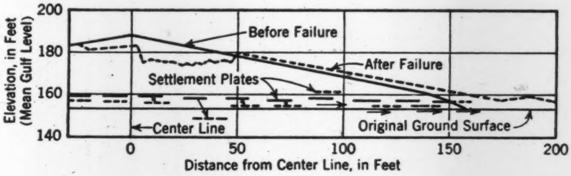

FIG. 5.—MOVEMENTS OF SETTLEMENT PLATES; LAND SIDE OF LEVEE

(*a*) A nearly vertical subsidence of 6 to 10 ft of that part of the embankment between the center line and points 50 to 70 ft land side of the center line (this subsidence left a trough-shaped depression in the embankment, in plan curving toward the land-side toe near the ends of the failure zone);

(*b*) A horizontal movement outward of the remainder of the land-side part of the embankment (approximately 10 ft); and

(*c*) An upheaval, 4 to 5 ft high, just beyond the land-side toe.

The most significant physical data obtained were those concerning pore pressures. Readings of the piezometer gages to the nearest 0.25 lb per sq in. were taken daily during the period of construction and to failure and beyond, except on days when the site was inaccessible due to rains. Fig. 6 shows plots of several typical sets of pore pressure data and corresponding loading diagrams. To be noted is the correlation between hydrostatic excess pressure and structure pressure near the center line and the building up of hydrostatic excess pressure to values greater than the pressure imposed by the structure near the toes (175 ft from the center line). Fig. 7 contains hydrostatic excess pressure data for all stations on the several dates indicated.

NOTATION

The letter symbols in this paper conform essentially with *Manual of Engineering Practice No. 22.*

ANALYSES OF FAILURE

In the study of the failure, plots, such as the one in Fig. 8, were made for each piezometer station. Thus, at Station 1844 + 50, 100 ft to the land side, the original effective vertical stress (the overburden load) was apparently decreased at piezometers 1 and 2. The word "apparently" is used purposely because the total stresses were estimated by use of the elastic theory and actual values may be different. If these effective stresses are used in the following well-known shearing strength formula:

$$s = c + (p - u) \tan \phi \qquad (1)$$

a loss of strength is indicated at all such locations where effective stresses decreased. Such decrease occurred at all stations near the toes of the structure and particularly near the bottom of the clay stratum. (In Eq. 1: s = unit shearing strength; c = cohesion per unit area; p = total normal stress on the plane of failure; u = unit hydrostatic or pore water pressure; and ϕ = true angle of internal friction of the soil.) Fig. 9 shows plots of shearing strength along the bottom of the clay stratum, estimated by use of Eq. 1. (The apparent increase in strength on the river side between February 5 and February 14 was caused by an unexplained decrease in the reading of piezometer 1, 100 ft to the river side at this station.)

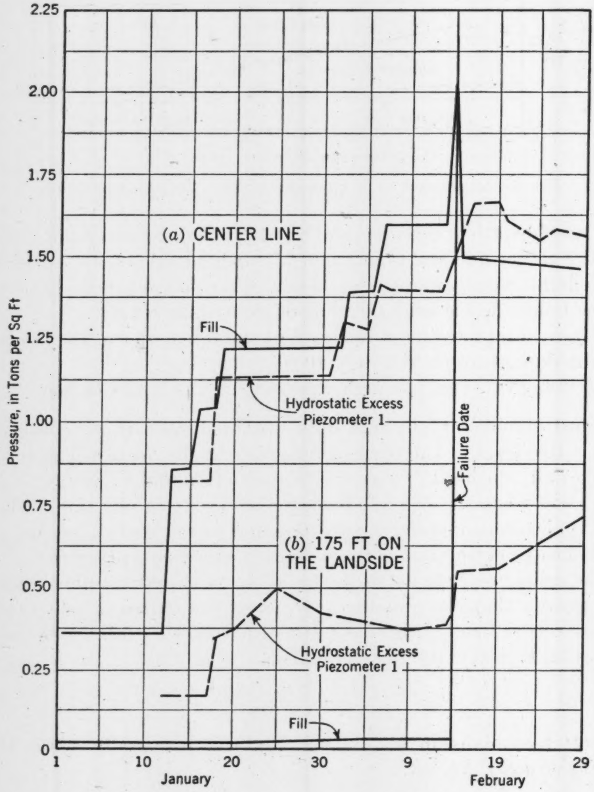

FIG. 6.—HYDROSTATIC EXCESS AND FILL PRESSURES, STATION 1844 + 50, DURING 1940

To extend the analysis of the failure still further in the foregoing manner, wherein shearing strength is expressed by Eq. 1, stability analyses by a modified circular arc method were made of the land side of the levee—the side that failed.

(See the Appendix for a description of the modified circular arc method.) These analyses at several cross sections in the failure zone gave factors of safety on the day of failure varying from 0.90 to 1.07. The factor of safety at one lift

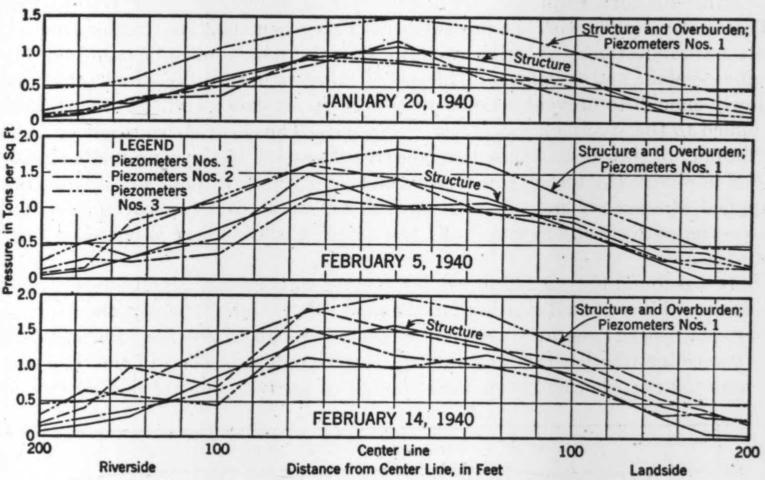

FIG. 7.—STRUCTURE AND EXCESS HYDROSTATIC PRESSURES, STATION 1844 + 50

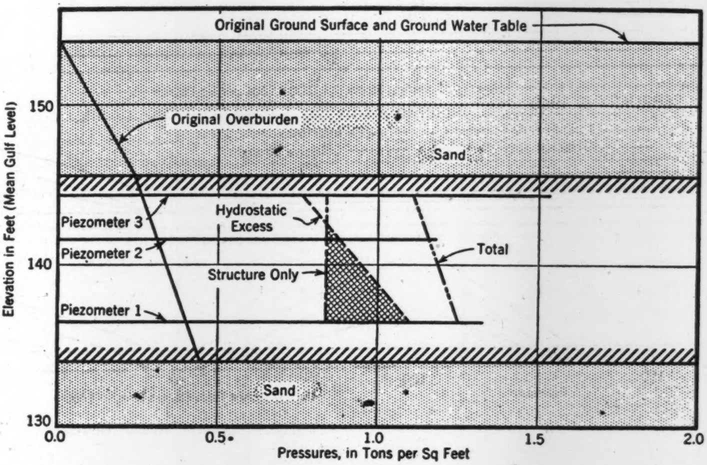

FIG. 8.—STRUCTURE AND HYDROSTATIC EXCESS PRESSURES, 100 FT ON THE LAND SIDE AT STATION 1844 + 50, FEBRUARY 14, 1940

before failure at Station 1843 + 50 was 1.31; just prior to failure, 0.90; and the day after failure, 0.98. Thus this method appears reliable when the failure surface and the hydrostatic excess pressures are employed in the stability analyses together with values of shearing strength, as expressed by Eq. 1 and values of c and ϕ, as determined by consolidated quick tests.

The peculiarity of the foregoing method of computation is that the values of shearing strength employed are based upon consolidated quick test results. This is at variance with the present belief that when effective stresses are used in the computation of shearing strength, slow test results must be used to determine c-values and ϕ-values. This belief is held because the slow test is run slowly enough to prevent a build-up of pore-water stress, and thus the stresses applied to the specimen are effective stresses. The shear curve resulting from a number of slow tests is based on effective stresses. In the consolidated quick test, however, the test is run rapidly and pore pressures built up. Thus, the applied stresses are not effective stresses but total stresses—part pore-water pressure, part effective stress—and the resulting shear curve is based on total stresses.

It was found that, if estimated in the same manner as the land side, the river side should have failed sooner than the land side. Unfortunately, the exploration and testing programs were not extensive enough to provide sufficient data to determine whether this was due to greater strength in parts of the river-side foundation; or whether the method of analysis used on the land side resulted in a factor of safety of approximately 1.0 only by accident—and that actually the method is not correct. This doubt, together with the fact that c-values and ϕ-values were determined from consolidated quick tests rather than slow tests, suggests caution in other cases; and also the great need for continued study of other failures and of the factors determining shearing strength.

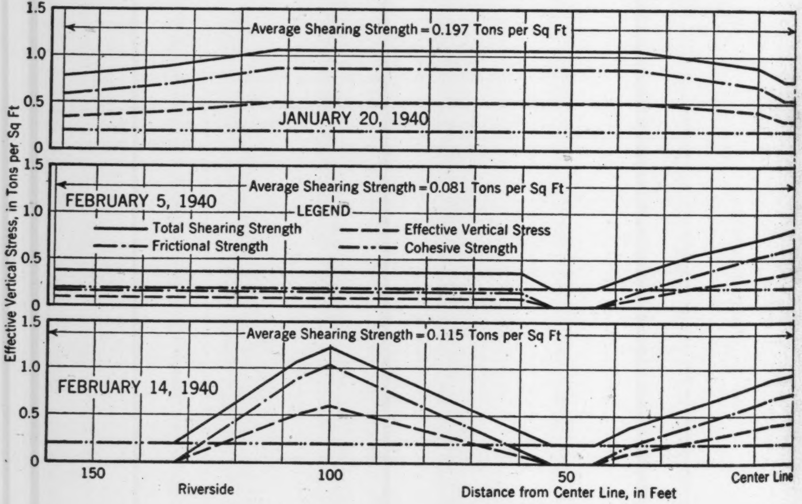

FIG. 9.—SHEARING STRENGTH ALONG THE BOTTOM

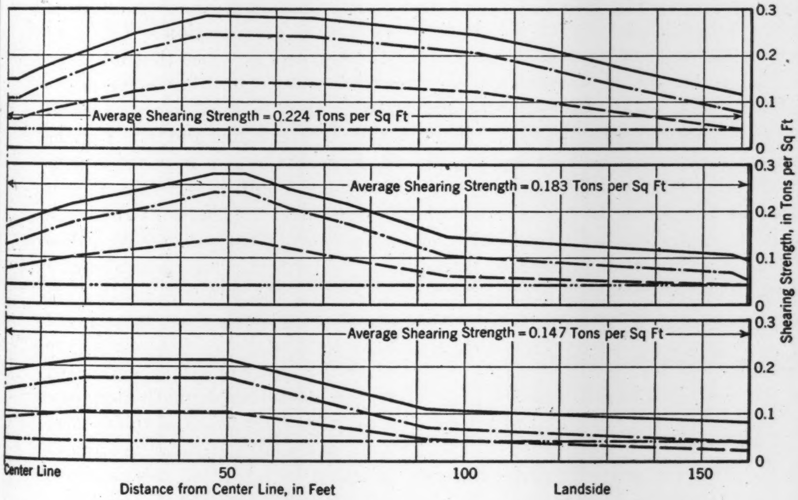
A more recent interpretation of the data obtained on the failure has been one in which the pore pressure data have been used to indicate the change in distribution of total stresses rather than as a means of estimating effective stresses.

The analysis is based on the premise that the excess pore pressures were built up primarily by the increased stress or deformation caused by the applied load. As the failure data approached, some of the excess pore pressures were no doubt caused by the remolding of the clay in areas where shearing stress exceeded strength. However, disregarding such a factor for the moment, it is of interest to consider the pore pressures only as an indication of the change in stress distribution which occurred; that is, from them to estimate total stresses on the day of failure. If this is done then (see Figs. 10 and 11) at Station 1844 + 50, on the 175-ft land side, where upheaval occurred, the total stresses on the cross-hatched, rectangular section (Fig. 11) of the clay stratum prior to construction were, for practical purposes: σ_y (average) = 0.38 ton per sq ft; and σ_x (average) = 0.34 ton per sq ft. (The assumption is made that $\sigma_x = 0.90\ \sigma_y$ for pressure at rest.) Values in Fig. 11 were computed from data in Fig. 10. From the pore pressure data the increase in pore pressure was 0.35 ton per sq ft (average). Considering this to mean an equal increase in σ_x, and that σ_y remained unchanged, since there is sand above and below the clay stratum, the total stresses on the section on the day of failure were: $\sigma_y = 0.41$ ton per sq ft (there was an increase of applied load of 0.03 ton per sq ft); and $\sigma_x = 0.37 + 0.35 = 0.72$ ton per sq ft. The maximum shearing stress, τ (max), for these principal stresses is then: $\tau\ (\text{max}) = \dfrac{\sigma_1 - \sigma_3}{2} = \dfrac{(0.37 + 0.35) - 0.41}{2} = 0.16$ ton per



OF THE CLAY STRATUM; STATION 1844 + 50

sq ft. This shearing stress at failure checks quite well with the shearing strength as indicated by the consolidated quick test data, since, for a normal pressure of $\sigma_y = 0.38$ (the original average overburden pressure for the section), the shearing strength is 0.17 ton per sq ft (see Fig. 2). Similar computations for the river side also indicate a fairly close agreement of stress and strength.

Another interesting interpretation of the failure is that it was caused by the building up of pore pressure in the clay stratum near the toes of the structure to values equal to or greater than the overburden pressure at that point. Thus the upper piezometer located 175 ft on land side of the center line (Fig. 10), where upheaval occurred, indicated a hydrostatic excess pressure of 0.36 ton per sq ft on the day of failure. Computed vertical pressure, due to the natural overburden and structure, at the same point and on the same date was 0.35 ton per sq ft. It is pertinent to note that similar comparisons for the river side show that the hydrostatic excess pressure exceeded the computed vertical stress prior to the date of actual failure.

The natural question is how to proceed in subsequent problems. In an effort to indicate how an engineer would proceed in other problems, a stability analysis by the modified circular arc method for the slope and height attained was made, using the values of strength corresponding to original overburden pressures and the consolidated quick test curve. Although this computation gave a factor of safety of 1.3, failure occurred for that cross section. This may be due to the fact that in such an analysis the engineer assumes that all along the failure arc the maximum shearing strength is mobilized. Since the materials vary in strength-deformation characteristics, the strain necessary to mobilize maximum strength will vary. Failure will be progressive and in the upper sections such as segments 1A and 2A, Fig. 14, Appendix, cracks may occur prior to complete failure. These decrease the shearing strength there. Hence it is normally impossible to mobilize maximum strength at all points at the same time. By referring to Fig. 12(*c*) (Appendix), which shows the forces on a slice of the embankment, it can be seen that, to maintain equilibrium, either shearing strength on the bottom of the slice or normal force on the side of the slice must be mobilized. For equilibrium a decrease or deficiency in one must be balanced by an increase or sufficiency in the other. At Pendleton the σ_x-forces at the toes were built up to their limiting values when the factor of safety, estimated on the original strength, equaled 1.3. Thus, the maximum strength along the failure arc was not mobilized at the time of failure. How much of this lack of maximum strength is due to insufficient strain, or to failure and remolding of the clay, cannot be determined from the available data. All that can be said is that such lack of maximum strength apparently did exist and that it is probably common in every failure.

The writers believe that this latter picture of the physics of the failure is the correct one. Thus, the visualization of the problem is one having two aspects. The first, in design, is the use of strengths from quick tests and a factor of safety which will insure that sufficient shearing strength is mobilized to prevent pressures at the toe sufficient to cause upheaval. The factor of safety to use would depend upon the materials involved, and their characteristics. The second, in control of construction, is the measurement of total pressures and pore pressures to prevent upheaval at the toes.

Of course, more definite recommendations for future cases are desirable; but the shearing strength of clays is a subject on which there is much more to learn. The trend of all thought has been toward the belief that effective stresses are a prime factor. To date, however, there have been few, if any, cases wherein the effect of effective stresses on shearing strength has been isolated. Measurements of both pore pressures and total pressures must be accomplished to do this. It is believed that the Pendleton experiences will assist, in some measure, the future studies of this most difficult question.

APPENDIX

Modified Circular Arc Method

The modified circular arc method differs from the normal method in regard to the resultant forces considered to be acting on the failure surfaces of the slices into which the sliding mass is divided. In the normal method, the forces acting on the sides of the slices are neglected since they are assumed to be equal and opposite. Actually, because of equilibrium requirements, such an assumption means that the slice is considered to exert a force on the failure surface which is the resultant of the weight of the material in the slice and a balancing force acting parallel to the failure surface (see Fig. 12). In the modified method the force is considered to be the resultant of the weight of the material in the slice and a balancing force acting horizontally. Fig. 12(a) shows that in the Pendleton failure the movement of the greater part of the sliding mass was horizontal.

[a] A signifies embankment material; B signifies foundation sand; and C signifies clay.

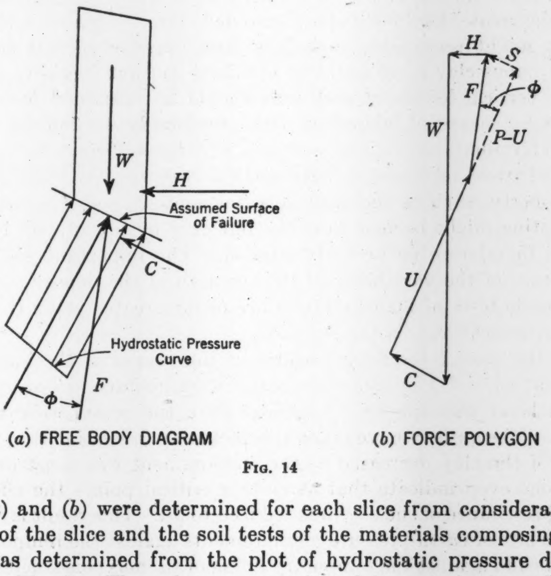
(*b*) The total cohesion, C, acting along the base of the slice, known in magnitude and direction;

(*c*) The total hydrostatic pressure, U, acting on the base of the slice (the direction of this force is normal to the assumed failure surface and its magnitude is determined from the hydrostatic pressure observations);

(*d*) The intergranular soil reaction, F, acting on the base of the slice (the direction of this force is at an obliquity of ϕ degrees with the normal to the assumed failure surface);

(*e*) The total normal stress, P; and

(*f*) The horizontal force, H, required either to maintain the slice in equilibrium or to overcome the resistance of the slice to movement (its direction is assumed to be horizontal, as movement of the greater portion of the sliding mass was horizontal).



(*a*) FREE BODY DIAGRAM (*b*) FORCE POLYGON

FIG. 14

Items (*a*) and (*b*) were determined for each slice from consideration of the dimensions of the slice and the soil tests of the materials composing the slice. Force (*c*) was determined from the plot of hydrostatic pressure distribution contained in Fig. 7. These forces were plotted in magnitude and direction, as shown in Fig. 14. The direction of the soil reaction $(p - u)$, was then plotted on the force diagrams, and the magnitude of the horizontal force to close each diagram was determined. Horizontal forces acting in the direction of motion were considered positive, whereas those acting to oppose motion were considered as negative.

The factor of safety is then defined as the ratio of the horizontal forces opposing motion to the unbalanced forces tending to cause motion. This is not comparable to the factor of safety as ordinarily defined (that is, the ratio of total resisting forces to total driving forces), but is a more sensitive index of stability as unbalanced forces only are considered.

DISCUSSION

Ralph B. Peck,[3] **Jun. Am. Soc. C. E.**—The results of a type of field test whose importance cannot be overestimated in the field of soil mechanics are presented in this paper. The ability to recognize the possibility for valuable observations in the circumstances surrounding the construction of the new levee, and to make the observations, is to be commended greatly.

A feature that would have greatly enhanced the value of the investigation is a more adequate foundation exploration. Inasmuch as the failure occurred along an essentially horizontal surface, the presence of a single lens or stratum of weak material, even if only a few inches thick, might have conditioned the entire failure. Such a foundation detail could easily have been responsible for the land-side failure of the structure when water-pressure measurements suggested the greater likelihood of a river-side failure. An adequate foundation exploration might reasonably include a large number of test borings from which continuous clay cores could be obtained without excessive disturbance. The entire vertical length of each core should be examined for the possible weak zones by means of laboratory tests, preferably unconfined compressive strength determinations on every sample. After sufficient tests had established a statistical relationship between the compressive strength and some simpler property, such as the natural water content, some reduction in compression testing might become possible, but only by a thorough investigation can such a foundation be properly studied. The important goal is the statistical picture of the variability of the strength of the deposit. In this connection, simple tests of many samples are of far greater value than the most elaborate investigation of a few samples.

One of the most interesting features of the results of the investigation is the fact that the total measured increase in hydrostatic pressure in the clay foundation layer was appreciably greater than the added weight of the embankment. The authors have taken this fact as an indication that the shearing resistance of the clay decreased as the embankment was constructed. Their computations even indicate that at certain critical points the effective angle of shearing resistance of the clay was reduced to 0°. This result is in agreement with the results of earth-pressure measurements against the temporary bracing of open cuts and against the temporary lining of tunnels constructed in Chicago (Ill.) clays for the subway. In these cases the field evidence for an inconsequential angle of shearing resistance is very strong. The shearing resistance in the field was in close agreement with the laboratory results on simple, unconfined compression tests. Furthermore, the mobilization of that part of the shearing resistance which was effective, and the simultaneous loss of frictional resistance, occurred at a relatively small strain. This amount of strain appeared to be so small in the case of the Chicago open cuts that it may be considered to be the minimum strain inevitably associated with the development of the shearing resistance. It is possible that the term

---

[3] Research Asst. Prof., Soil Mechanics, Univ. of Illinois, Urbana, Ill.

"remolding" is too extreme to describe this phenomenon. The best so-called "undisturbed" samples have probably experienced greater strains in the sampling process.

In spite of the aforementioned field evidence, it has not been possible in the laboratory to subject samples to shear tests which appear to be analogous to the conditions in the field and to duplicate the result of a small angle of shearing resistance. The consolidated, quick type of test produces an apparent angle of shearing resistance of approximately 17° for almost any clay. Whether the small disturbance caused by the sampling is sufficient to overshadow subsequent laboratory procedure is unknown. The fact remains that, so far, a discrepancy exists between the results of field and laboratory that constitutes an important gap in current knowledge. Only the unconfined compression test, free from lateral pressure or surcharge, seems to give values of shearing resistance in accord with the field measurements.

Measurements of earth pressures and of accompanying hydrostatic pressures in regions where large shearing stresses are anticipated may constitute an important source of future knowledge. The water-pressure measurements described in this paper appear to have been satisfactory. Other types of installations may be desirable for attacking the same problem under different circumstances. For measuring water pressures in Chicago clays, for example, the device shown in Fig. 15 was developed. It consists essentially of an ordinary Bourdon gage, a length of pipe, and a porous tip, all assembled and completely filled with water before installation. Because of the low permeability of clays, it is extremely important that no leakage should occur in the measuring system. The Chicago devices possess the advantage that the porous tip can be replaced in the laboratory by a pipe cap and the entire assembly subjected to a large hydrostatic pressure for a sufficient length of time to detect any leaks. The porous stone is then substituted for the pipe cap. The assembly does not require the drilling of a hole in advance. It is merely jacked into the clay. It may be used in any position as long as the pressure is positive at the elevation of the pressure gage, a restriction which also applies to the Pendleton devices. In the Chicago clays, which have a permeability of approximately $5 \times (10)^{-8}$ cm per sec, the time necessary to reach equilibrium was between 12 hr and 24 hr.

The Chicago devices have proved satisfactory in measuring hydrostatic pressures around the subway tunnels. An example of the results is shown in Fig. 16, where a decrease in water pressure around the tunnel tubes, due to their action as drains, was measured, in spite of the fact that the free water surface remained constant over the tunnels because of the presence of a pervious silt layer in which it lay. Similar installations could provide valuable information concerning the excess water pressure along the theoretical failure surfaces adjacent to open cuts. Although the water devices were not developed to a satisfactory point in time to perform such experiments on the initial system of Chicago subways, it is hoped that the success of the water-pressure measurements described in this paper, and those elsewhere, will encourage additional measurements to obtain evidence on this extremely important aspect of the shearing resistance of natural clay soil.

FIG. 16.—WATER-PRESSURE MEASUREMENTS; CHICAGO SUBWAY EXPERIMENTAL SECTION S-3

K. TERZAGHI,[4] M. AM. SOC. C. E.—The Pendleton Levee failed along a surface of sliding that was mostly within a fairly horizontal stratum of clay. During the fifteen years since 1928 several major failures of a similar nature have occurred. The failure of the Lafayette Dam in California in September, 1928,[5] was followed by the failure of the embankment for the water supply reservoir, Chingford II, north of London, in July, 1937,[6] the failure of the Marshall Creek Dam in Kansas in September of the same year,[7] and the failure of a flood-protection dike within the city limits of Hartford, Conn., in August, 1941.[8] The loss of capital due to these failures amounted to several million dollars and the frequency of the failures of fills above horizontal clay strata does not yet show any tendency to decrease. Therefore the subject of the paper by Messrs. Fields and Wells deserves the attention of every engineer who deals with the construction of earth dams or embankments.

---

[4] Winchester, Mass.

[5] "Reconstruction of Lafayette Dam Advised," *Engineering News-Record*, Vol. 102, 1929, pp. 190–192.

The paper is divided into three parts: (1) The results of the soil tests and field observations; (2) an analysis of the failure; and (3) the description of a graphical method for computing the stability of fills on horizontal clay strata.

The graphical stability computation consists essentially in replacing the true surface of sliding by one plane and one or two cylindrical surfaces. Such ideal surfaces are known as composite surfaces of sliding. The method seems to have originated before 1933 in the Preussische Versuchsaustalt für Wasserbau aud Schiffbau in Berlin, Germany, and it has been used repeatedly with minor modifications both in the analysis of failures and in the design of new dams. Thus, for instance, the failure of the Chingford embankment was analyzed by the writer in 1938 by means of this method. The method is accurate enough for any practical purpose, provided fairly accurate values have been chosen for the soil constants. Therefore, only the method for determining the soil constants is properly a topic for discussion.

The failure analysis in the paper under discussion is based on the tacit assumption that the clay stratum does not contain any layers of cohesionless material. The c-value of the material within the stratum is equal everywhere to 0.04 ton per sq ft, and the ϕ-value is equal to 19°. The value of ϕ has been determined by means of quick shear tests. On the basis of these data, the authors found that the factor of safety of the land side of the embankment was roughly equal to unity at the instant of failure. However, according to the results of a similar computation based on the same values, the factor of safety of the river side where no failure occurred was even less than unity. This fact suggests that the correct result which was obtained for the land side was merely due to chance. Further, it should be noted that the computation of the shearing resistance was made by means of a formula (Eq. 1) which contains the pore water pressure u. The value ϕ which appears in such an equation should be determined by means of slow, and not of quick, shear tests. The slow tests yield an angle of shearing resistance ϕ_1, a much higher value than the quick tests. The computation should have been made on the basis of the higher value, ϕ_1. Under this condition it would have led most likely to the conclusions that the factor of safety of the land side, on the day of the failure, was equal to about 1.4 and that of the river side was equal to about 1.2 (writer's guess). In other words, the computation would not account for the failure of the land side of the levee.

[6] "The Analysis of the Failure of an Earth Dam During Construction," by L. F. Cooling and H. Q. Golder, *Journal*, Institution of Civ. Engrs., No. 1, November, 1942, pp. 38–55.

[7] "Foundation of Earth Dam Fails," *Engineering News-Record*, Vol. 119, 1937, p. 532.

[8] "Foundation Failure Causes Slump in Big Dike at Hartford, Conn.," *ibid.*, Vol. 127, 1941, p. 142.

This conclusion leads to what appears to be a weak point of the present attitude of engineers toward stability computations in general. Since about 1928 the attention of research men has been concentrated almost exclusively on the mathematics of stability computations and on refining the technique of sampling and testing. The results of these efforts were very useful and illuminating. At the same time they created a rather indiscriminate confidence in laboratory test results. In some instances confidence is warranted, but, in many others, it can lead to erroneous conclusions, because the attention of the investigator is diverted from what is really essential. The failure of the Pendleton Levee demonstrates that the essentials in the stability conditions are by no means always within the reach of the laboratory eye and of the slide rule.

When examining Fig. 5 the reader will notice that a strip of the fill, about 50 ft wide, on the land side of the center line subsided. The remainder of the fill, beneath the lower part of the land-side slope, moved bodily forward, and the slope angle remained almost unchanged. It should be noted further that the settlement plate beneath the area of subsidence descended to a depth of more than 5 ft below the level of the adjoining settlement plates.

These observations suggest that the failure occurred as indicated in Fig. 17. The fill beneath line ab settled into a trough-like depression. The block of fill, sand, and clay beneath the slope section bc moved bodily on a plane ef through a distance of about 6 ft to the right. The horizontal pressure exerted by the moving mass bceg caused a horizontal shortening and an upward bulge of the block cdgf whose presence interfered with the movement. The absence of any appreciable deformation within the mass bceg indicates that the resistance against sliding on the base ef of this mass was practically equal to zero. If the weight of the overburden above a horizontal section through a mass of homogeneous clay is carried by the pore-water pressure, the shearing resistance along this section is equal to the cohesion of the clay. Therefore, the type of failure illustrated by Fig. 17 suggests that the surface of sliding ef was not within the clay but within a fairly continuous layer of sand or silt which separated the lower stationary part of the clay stratum from the upper, moving one. Since the piezometer readings showed that the pore-water pressure was equal to, or greater than, the overburden pressure over the entire area ef, the frictional resistance in the layer was equal to zero. The presence of fairly continuous layers of highly permeable material in the central part of the clay stratum is demonstrated by Fig. 10. In this figure the dashed lines marked February 5, 1940, and February 14, 1940, indicate a hydraulic gradient

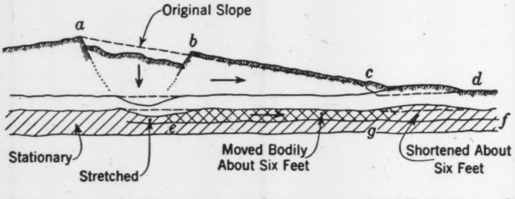

FIG. 17.—MASS MOVEMENTS AND DEFORMATIONS ASSOCIATED WITH FAILURE OF PENDLETON LEVEE

which was directed from the boundaries of the clay stratum toward the central part of the stratum. Hence, at the points where the piezometers were located, the excess water drained toward the central part of the stratum. No such flow possibly could have occurred unless the central part of the stratum contained some layers through which the water could escape in horizontal directions.

The only point that requires any further discussion is the origin of the excess hydrostatic pressure in the clay above and below section ef, Fig. 17. Under the heading, "Analyses of Failure," the authors state that "* * * some of the excess pore pressures were no doubt caused by the remolding of the clay in areas where shearing stress exceeded strength * * *." In this connection it should be noted that the deformation of the clay on both sides of section ef of the surface of sliding remained insignificant until the failure occurred. Hence, if any of the excess pore-water pressure were really due to remolding, these pressures must be considered not a cause but a consequence of the failure. Yet, no such hypothesis is required, because the excess pore-water pressures in the clay beyond the toes of the fill can be explained adequately by the sedimentary origin of the clay. The permeability of clays that were placed in horizontal layers is much greater in horizontal directions than in vertical ones. Therefore, the excess pore-water pressure produced by a local surcharge spreads from the area covered by the surcharge in both directions. The mechanics of this process are illustrated by Fig. 18, which shows a horizontal clay stratum between two sand strata. The surface of the upper sand stratum carries a fill with inclined sides. If the clay stratum is perfectly homogeneous, the excess water drains out of the clay in an almost vertical direction and the distribution of the excess pore-water pressure over a horizontal section through the clay is as shown in Fig. 18(*a*). The excess pore-water pressure, represented by the vertical distance between the water table and the dashed line, decreases from a maximum beneath the crest of the fill to almost zero beneath the toes. On the other hand, if the clay stratum contains fairly continuous layers of

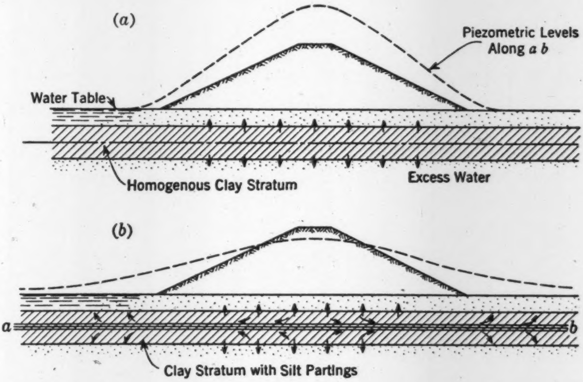

FIG. 18.—INFLUENCE OF SILT PARTINGS IN A CLAY STRATUM ON THE DISTRIBUTION OF EXCESS HYDROSTATIC PRESSURE AT THE MIDHEIGHT OF THE STRATUM

coarse silt, part of the excess water drains out of the clay into the silt, leaving the silt beyond the area which is occupied by the fill. The clay stratum beneath the Pendleton Levee contained such layers, because, according to Fig. 10, part of the excess water drained out of the clay toward a plane not far from midheight of the stratum. The distribution of the excess pore-water pressure over a horizontal section through the layer of silt is shown by the dashed line in Fig. 18(*b*). The presence of the layer reduces the excess pore-water pressure beneath the central part of the fill and increases it within the belts beneath the toes.

The preceding failure analysis leaves no doubt that the clay stratum contained fairly continuous silt or sand partings and that these partings played a decisive rôle in the mechanics of the failure. On account of the presence of these partings, the resistance against sliding was equal to zero over two broad areas in silt or sand partings in the clay, beneath the toes of the fill. The safety of the fill with respect to sliding depended primarily on the position of the inner boundaries of these areas with reference to the center line of the fill; yet the position of these boundaries depended on minor geological details that could not be ascertained by any practicable means of exploration or computation. Therefore, one cannot predict which side of the fill will fail first, unless the stability conditions on both sides of the center line are conspicuously different.

At the instant of failure the mass of soil above one of the two frictionless areas moved out bodily. The outward movement was resisted only by the passive earth pressure of the mass of soil above the frictionless area, beyond the toe of the fill. Within the clay stratum the passive resistance of the clay is equal, roughly, to the average unconfined compressive strength of the clay.

The inevitable uncertainties involved in estimating the distribution of the excess pore-water pressure on horizontal sections within sand or silt partings eliminate the usefulness of refined theoretical or experimental investigations in connection with the design of fills above horizontal clay strata of sedimentary origin. This is demonstrated by the disappointing results of the theoretical investigations contained in the paper. The most important requirement for adequate design is a thorough knowledge of the type and character of the stratification of the clay stratum, of the initial shearing resistance of the weakest layer, and of the average unconfined compressive strength of the entire layer at different points.

The safest way to secure information concerning the stratification is to inspect the sides of amply large test shafts closely. If the excavation of test shafts is impracticable, a careful study should be made of continuous cores of the stratum. To estimate the initial shearing resistance of the weakest layers of the clay and the average unconfined compressive strength, compressive-strength diagrams are needed which show the variation of the unconfined compressive strength in a vertical direction in different parts of the clay stratum. The samples can be obtained by means of 2-in. seamless tubes. One compressive-strength value should be secured for every 4-in. section of the cores. One compression test requires about 10 min. However, after an experienced experimenter has made some forty or fifty tests on very different samples from the same stratum, he is able to estimate the compressive strength of any sample from this stratum. Once he has acquired this capacity he needs to test only the softest and the stiffest samples. The strength of the intermediate ones can be estimated. The compressive-strength profiles should be supplemented by water-content diagrams, because these diagrams facilitate the identification of individual layers encountered in different drill holes. Consolidation tests and Atterberg limit tests should be made on representative samples, primarily for the purpose of securing general information concerning the clay. The test results can be used for computing the rate of consolidation, only if the ratio between the average coefficient of permeability of the clay in a horizontal and in a vertical direction is known.

In conclusion the writer wishes to emphasize once more the outstanding practical value of the observations made on the Pendleton Levee. The published data give a clear picture of the processes that precede the failure of a fill on a horizontal clay stratum, and they illustrate impressively the uncertainties involved in any attempt to predict the failure conditions. In connection with the design of foundations, a clear realization of the inevitable gaps in current knowledge is the beginning of wisdom, and these uncertainties can be realized only on the basis of comprehensive field observations such as those made by the authors. It is hoped that Messrs. Fields and Wells will supplement the information contained in their paper by further information concerning the structure and stratification of the clay stratum. It is also hoped that, some day, they will be able to supplement their record of the failure by several water-content profiles and compressive-strength profiles of the clay. The record is by far too valuable to remain incomplete.

In connection with the technique of the field observations, many readers, including the writer, would appreciate information concerning the technique of sealing the drill holes for the piezometric tubes. The paper does not mention the grain size of the commercial bentonite product used. If the product is very fine-grained, the seal may be imperfect, and, if it is very coarse-grained, the swelling pressure is likely to create a local disturbance of the hydrostatic pressure conditions in the clay. The data in the paper suggest that some of the measured pore-water pressures are too high, because, beyond the toes of the fill, the pore-water pressure cannot become greater than the total weight of the material above the seat of the pressure. As soon as the pore-water pressure in a sand or silt parting becomes equal to the weight of the overburden, the overburden is lifted gradually by the accumulating water; but the pore-water pressure remains constant.

T. A. MIDDLEBROOKS,[9] ASSOC. M. AM. SOC. C. E.—The levee failure in the Vicksburg Engineer District is an interesting experiment which the writer has followed from its inception. The authors are to be complimented on their paper. Installation of the hydrostatic pressure points was part of a general program to obtain information on the development and distribution of hydrostatic pressure in unconsolidated silt and clay strata when subjected to a superimposed load.

---

[9] Prin. Engr., Corps of Engrs., War Dept., Soil Mechanics Unit, Washington, D. C.

Evidence, accumulated over a period of years, has convinced the writer that excess hydrostatic pressure is a major factor in the design of embankment over unconsolidated foundations. During the Mississippi levee construction program after the 1927 flood, the writer had the opportunity of observing numerous foundation failures over soft clay foundation. After developing an empirical method of designing levees over such a foundation and using it satisfactorily for levees constructed at a normal rate, the writer was surprised to find that it was not satisfactory for a levee constructed at top speed. On a levee which had to be completed before a flood, the width of the berm, or total base width of the levee, had to be more than doubled to provide a stable section for such rapid construction.

Hydrostatic pressure observations are considered essential as a check on design and control during construction. The rate of consolidation, which is one of the most important variables in design, can be checked closely during construction and, if excessively high pressures are developed, the rate of construction can be decreased or the slopes flattened to insure a stable structure. Such observations are inexpensive insurance against possible trouble. In most cases, there is no need for elaborate installation. These observations can be made by a simple installation of small, open-end pipes set in the clay at the desired elevation.

As construction control measures and for research purposes, the War Department has made numerous installations for observing hydrostatic pressure under earth dams and levees in the past few years. Two recent installations under large earth dams—one in a silt stratum and one in a micaceous clay stratum—confirmed the conclusions indicated by laboratory tests that these strata would consolidate rapidly during construction. In both of these cases, the building up of excess hydrostatic pressure was small and decreased rapidly when construction of the embankment was delayed due to weather or other reasons.

The writer cannot agree with the authors' use of the "consolidated-quick" test for determining the strength of the clay where the excess hydrostatic pressure readings are available. In this type of test, there is a building up of hydrostatic pressure in the sample due to the rapid rate at which the sample is sheared. In using these test results, the effect of excess hydrostatic pressure is doubly accounted for: First, in the quick shear strength value; and, second, in the actual hydrostatic pressure observed in the clay. The result is that a lower factor of safety is obtained than if the net (grain-grain) strength had been determined. The writer also disagrees with the use of the maximum strength value in place of the ultimate or minimum strength value. The result, in this case, is that a higher factor of safety is obtained. Under these conditions, it would appear that these two factors were more or less compensating, thus accounting for the close check obtained.

The stability analysis in such cases should be based on the shearing strength determined from a "consolidated-slow" test, where excess hydrostatic pressure is not allowed to develop in the sample, and the net strength is determined. This would appear to be elementary, since in the analysis the acting forces are divided into two distinct parts: First, the measured hydrostatic pressure;

and, second, the net force, determined by subtracting the hydrostatic force from the total acting force. Then the strength to be used would be the net strength, determined from the "consolidated-slow" test. In addition, the minimum strength should be used, since in all failures of this type there is sufficient progressive movement before the full failure plane is developed. Thus the minimum strength is existing all along the so-called failure plane or zone. The authors recognized this fact but failed to employ it in their analysis.

In 1934 and 1935, the writer had an opportunity to investigate the deformation of clays in connection with the design of the Fort Peck Dam on a deep clay formation.[10] His conclusions were borne out by the satisfactory performance of the dam over this clay strata. Model experiments in the laboratory, combined with previous experience, convinced the writer that the "yield point" strength (about equal to the minimum strength) should be used instead of the maximum strength. Fig. 19 shows typical results of these model experiments. It will be noted that the clay did not develop a true failure plane even though the deformation was sufficient to term the clay mass "failed."

FIG. 19

The circular slide method appears to give results that are satisfactory in this case, and it is generally considered accurate enough for all practical purposes. However, a better understanding of the factors involved in problems of this nature can be obtained by the elastic-theory method as outlined by the writer in the previously mentioned paper[10] and in a subsequent one on the failure of the Fort Peck Dam.[11]

---

[10] "Foundation Investigation of Fort Peck Dam Closure Section," by T. A. Middlebrooks, *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., Harvard Univ., Cambridge, Mass., 1936.

It is hoped that, in their closing discussion, the authors will present data on "consolidated-slow" tests and, if possible, a stability analysis using the minimum strength determined by this method.

D. P. KRYNINE,[12] M. AM. SOC. C. E.—Because of a favorable coincidence, two analogous papers, both very interesting, have been published simultaneously: The paper by Messrs. Fields and Wells, and that on the Chingford, Essex (England), earth dam failure.[6] At the time of failure both structures were approximately of the same height (32 ft at Pendleton and 26 ft at Chingford). The soil conditions are also very much alike. Those at Pendleton are shown in Fig. 1 and those at Chingford are: Soft clay varying between 0 and 12 ft, usually about 3 ft thick; a layer of "river ballast"; and finally the so-called "London clay." The total thickness of both the "river ballast" layer and the upper soft clay layer is from 10 to 30 ft. There was a puddle core at Chingford and no core at Pendleton. In both cases the failure occurred in the same way. A large part of the failure line (shear surface) is practically horizontal and is within the clay layer underlying the structure (Figs. 11 and 20[13]).

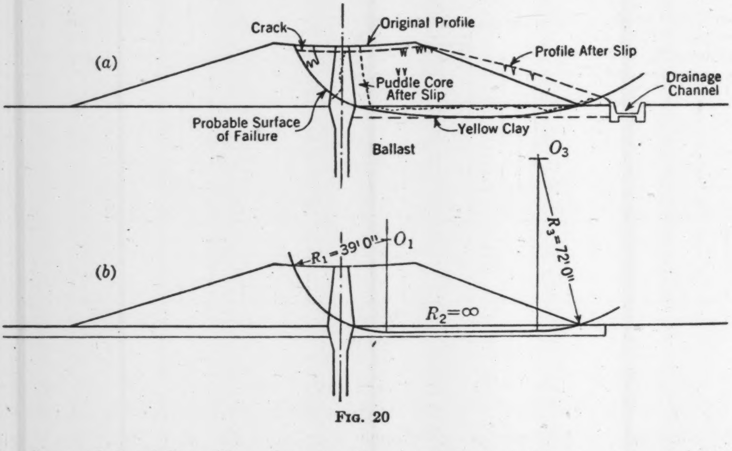

FIG. 20

The slope of the failure line close to the center line of the structure is rather steep, and there is a sinking of the crown in both cases. It may be concluded from the movement of the settlement plates at Pendleton (Figs. 3(*a*) and 5) that the clay compressed between two sand layers was squeezed out toward the toes. Apparently, in Chingford there was an analogous situation.

[12] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

[13] "The Analysis of the Failure of an Earth Dam During Construction," by L. F. Cooling and H. Q. Golder, *Journal*, Institution of Civ. Engrs., No. 1, November, 1942, Figs. 4 and 5*b*.

Horizontal Movement of Pore Moisture.—Fig. 21 represents a hypothetical clay layer between two sand layers. Points A and A′ are on a vertical line very close to the center line of the dam, whereas points A, A″ and A‴ are on a horizontal line. During the process of consolidation, the pore-moisture pressure at point A is greater than at point A′; and the pressure at point A is greater than at point A″ because of the difference in the heights of the dam. In its turn, the pressure at A″ is greater than at A‴. Hence at point A there is a hydraulic gradient in the vertical direction driving moisture from the clay into the sand; and, at point A, there is a hydraulic gradient in the horizontal direction driving moisture from the center of the dam toward the toe. In reality, moisture driven out of the clay layer follows curvilinear paths. For the sake of simplicity, however, vertical and horizontal components of this movement will be considered.

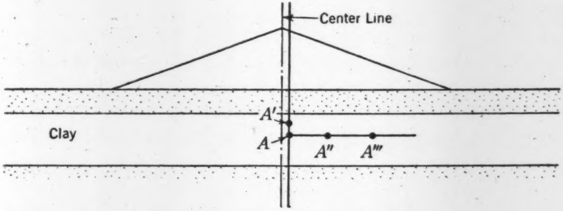

FIG. 21

The behavior of that moisture which moves horizontally depends mostly on the capacity of the sand layers above and below the clay to take up moisture from the clay, especially close to the toes of the structure. If drainage at the toe is poor (saturated sand, or rainy weather, or both), moisture will accumulate close to the toes in an adiabatic way (that is, without leaving the mass).

Difference in Vertical and Horizontal Permeability.—If the coefficient of horizontal permeability in the clay layer (Fig. 21) is considerably larger than the coefficient of vertical permeability, moisture arriving horizontally at the toes will not be satisfactorily drained vertically in the clay layer itself. This can be proved easily by computing the discharge at the toes, in both horizontal and vertical directions, using the Darcy formula with two different coefficients of permeability. All measures tending to relieve pore pressure at the toes—particularly the drainage of the clay mass by vertical sand wells—contribute to the stability of the structure.

Character of the Failure.—Adiabatic pore moisture accumulated at the toe of the dam makes the clay swell. The process of swelling and consequent growth of moisture films gradually relieves original cohesion ($c = 0$ in Eq. 1). At the same time the growing value of the pore-moisture pressure ("neutral stress," u) gradually decreases the second member at the right side of Eq. 1. As soon as the values of u and p are balanced, the clay mass under the toes of the dam becomes an exceedingly soft plastic mass (shearing strength $s = 0$) under pressure. At this stage it breaks through the earth mass to reach the earth surface; and, in this connection, it must overcome what may be called "passive pressure" or "passive resistance" of the earth mass outside the dam. In other words, a shearing surface (failure line), to the right of the toe (Fig. 13), is formed, and a part of the clay material is thrown out to form the "upheaval" (or "mud wave"). As soon as this quasi-liquid mass reaches the earth surface, its pore pressure is lost (in the same way as pressure in the water running from a faucet). The clay gradually hardens; and sometimes one is able to walk on these "mud waves" a few days after failure.

The shape of the failure line (shearing surface) close to the middle of the dam may be circular in a general case (Fig. 13), but it is very possible that, under the given geological conditions, it is much steeper (Fig. 5). In the opinion of the writer (which he does not advance as a definite one, however), the separation of the wedge from the remainder of the dam in the given case is due mostly to tensile stresses.

All that has been said in this discussion about the character of the failure is nothing more than a proof and clarification of an interpretation presented by Messrs. Fields and Wells (see heading, "Analyses of Failure")—"the failure * * * was caused by the building up of pore pressure in the clay stratum near the toes of the structure to values equal to or greater than the overburden pressure at that point." The writer agrees completely with this clear-cut statement since he considers it accurate enough for all practical purposes.

Summary.—Considerable work has been done in this field both in the United States and in England. The writer believes that research along these lines should be continued and that, in this connection, more attention should be paid to quantitative studies of soil permeability and drainage conditions under a dam. This remark is not intended to detract anything from the value of the papers discussed. In the last sentence of their paper, Messrs. Fields and Wells hope that "* * * the Pendleton experiences will assist, in some measure, the future studies of this most difficult question." The writer shares this hope and wishes to extend this statement to the British counterpart of the Pendleton Levee.[6]

KENNETH E. FIELDS,[14] AND WILLIAM L. WELLS,[15] ASSOC. MEMBERS, AM. SOC. C. E.—Professors Peck and Terzaghi suggest that the failure may have been conditioned by the presence of a thin horizontal layer of weak material not disclosed by the borings. It is hoped that it will be possible to obtain continuous cores of the clay stratum at the site at some future date when the demands of Mars have been met.

Professor Peck describes a water-pressure measuring device used in connection with the Chicago Subway project which seems more simple and easy to install than the Pendleton devices.

Professor Terzaghi is of the opinion that failure occurred along a fairly continuous horizontal layer of sand or silt near the middle of the clay stratum. The writers agree that the failure occurred along a horizontal plane within the clay stratum; but all the data obtained indicate that the plane of failure was near the bottom of that stratum. Pore-water pressure was a maximum and effective pressure a minimum near the bottom of the clay stratum on the day of failure at all piezometer locations except those beyond the embankment toes. The pore-water pressure distribution shown in Fig. 8 is typical for all piezometer locations beneath the embankment on the land side. Pore-water pressures were not equal to or greater than total overburden pressures except in zones immediately beneath and beyond the embankment toes. Thus, with strength a minimum near the bottom (assuming homogeneity) and shearing stress a maximum, it is logical to assume that failure occurred along or near the bottom of the stratum.

[15] Capt., Corps of Engrs., U. S. Army, Vicksburg, Miss.

Professor Terzaghi bases his argument for the presence of fairly continuous layers of highly permeable material in the central part of the clay stratum upon Fig. 10 which contains hydrostatic pressure distributions at a point 175 ft land side of the center line, or about 15 ft beyond the land-side toe of the embankment. This value indicates a hydraulic gradient directed toward the central portion of the stratum. Such a distribution of pore-water pressures was exceptional rather than general within the land-side portion of the foundation. Further, at and beyond the toes of the structure, flow would be directed away from the silt or sand partings as illustrated by Fig. 18(*b*) of Professor Terzaghi's discussion, should such partings be continuous beneath the embankment.

Professor Terzaghi then states that the excess pore-water pressures in the clay beyond the toes of the fill can be explained adequately by the sedimentary origin of the clay—that is, by the fact that the permeability of the clay in a horizontal direction is much greater than that in a vertical direction. In the original report[16] on the subject the following three theories were considered as possible explanations of the pore-water pressure distributions observed:

(*a*) Arching in the fill resulting in a spreading of the load laterally;
(*b*) A fluid-like transmission of pressure laterally in the clay stratum;
(*c*) Lateral drainage away from the zone of maximum pressure.

In connection with theory (*c*), Fig. 22 illustrates the stratified nature of some parts of the clay stratum. Some of the other samples taken were much less distinctly stratified.

All these theories were rejected as primary causes of the pore-water pressure distributions noted since they do not explain the large variations of the hydrostatic excess pressure with depth (Fig. 8) and the only theory which apparently explains the phenomenon adequately is that a transference of intergranular pressure to hydrostatic or pore-water pressure occurred within zones of maximum shearing stresses. This phenomenon was called "remolding" by the writers, a term which may be too extreme, as suggested by Professor Peck, since it may occur at relatively small strains. In the Pendleton case, the strain within the clay may not have been so small since the base of the embankment near its center settled a total of about 1 ft up to February 12, 1940, two days prior to failure, and one settlement plate 150 ft land side, near the toe of the embankment, indicated an apparent uplift of about 1 ft as early as January 12.

---

[16] *Technical Memorandum No. 178–1*, U. S. Waterways Experiment Station, Vicksburg, Miss., January 4, 1941.

The abrupt rise in the readings of all piezometers located between points 50 ft river side and 175 ft land side, which commenced one day before failure and continued for one to two days thereafter, appears to be further evidence that, prior to and during failure, a transference of intergranular pressure to pore-water pressure occurred.

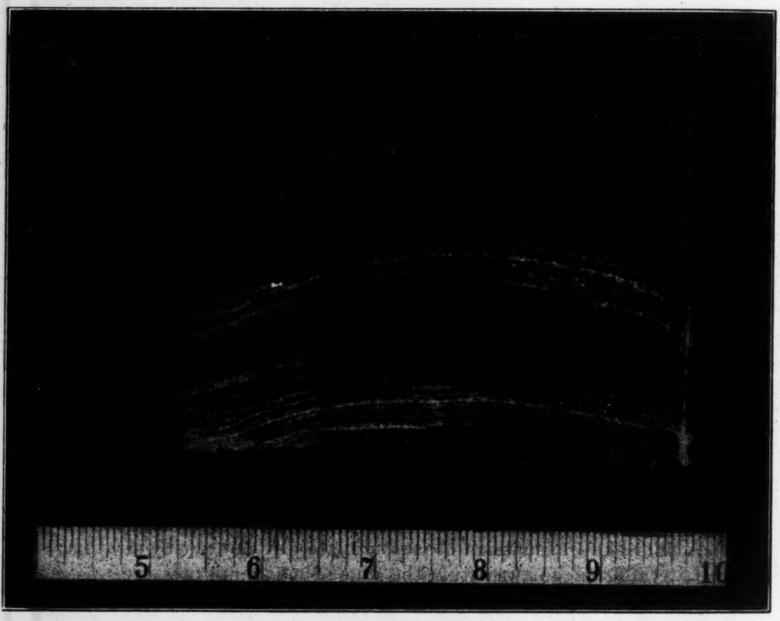

FIG. 22.—CROSS SECTION OF AN "UNDISTURBED" SAMPLE OF FOUNDATION CLAY

Professor Terzaghi inquires as to the type of bentonite used for sealing the drill holes used for the piezometers. The bentonite used was a standard commercial grade having a grain size of 0.3 to 0.5 mm. This material exerts some pressure when confined and supplied with water. In the present case, however, the situation is somewhat different since any water which the bentonite absorbed must be supplied by the pore water within the clay. Six of the piezometers installed were located 225 ft from the center line of the embankment, or about 65 ft beyond the toes. Three of these piezometers, on the river side, did not indicate hydrostatic pressure excesses at any time. The other three, on the land side, indicated only normal hydrostatic pressure up to January 24, at which time they had been in place about one month. This indicates that swelling of the bentonite seal did not create excess pore pressures in the clay. It seems entirely possible for pore-water pressures to become somewhat greater than total overburden pressures over small localized areas, especially in the case where the clay stratum is overlain by sand of appreciable thickness. The upward movement of the column of sand overlying the pressure concentration would be resisted not only by the weight of the column but also by friction along its sides.

Both Professor Terzaghi and Mr. Middlebrooks think that the computations of shearing resistance should have been based upon the results of fully consolidated shear tests rather than "consolidated-quick" tests. The writers are inclined to agree with this viewpoint. Although no such tests on the Pendleton clay are available, slow triaxal shear tests on other clays have shown that the "failure envelope" is a straight line passing through the origin (cohesive strength of zero) and having an inclination of about 30°. If cohesive strength of zero and a true angle of internal friction of 30° is assumed for the Pendleton clay, the computed factors of safety of the land-side portion of the foundation remain practically unchanged; but those for the river side become smaller. The writers hope to investigate this matter more thoroughly at the earliest opportunity.

CHART FOR THE FUTURE

ADDRESS PREPARED FOR THE ANNUAL CONVENTION, CLEVELAND, OHIO, JULY 19, 1944

By Malcolm Pirnie,[1] President, Am. Soc. C. E.

Present recording of the experiences of the past is the tried-and-proved method of making a chart upon which a successful voyage into the future may be plotted. Eternally colorful words of Patrick Henry forcefully express this fact:

> "I have but one lamp by which my feet are guided, and that is the lamp of experience. I know of no way of judging the future but by the past."

Liberty-loving peoples of the earth are now engaged in the greatest of recurrent revulsions against unbearable usurpation of the unalienable rights of all men by powerful human cliques. They were so engaged in the lifetime of Patrick Henry when that New World crisis brought forth enunciation of a great principle, upon which this nation was founded.

The concordant discoveries of the world's most revered scholars and teachers were selected by Thomas Jefferson to guide his task of wording the Declaration of Independence. He said of his work,

> "I did not consider it as any part of my charge to invent new ideas altogether and to offer no sentiment which had ever been expressed before."

Thus, resistance to invasion was cemented in the heat of battle just 168 years ago by defining the cause of the people clearly in a simple 112-word declaration of unalienable rights of men and a recitation of the usurpation of many rights which had been suffered. The representatives of the first thirteen states pledged to each other their lives, fortunes, and sacred honor in signing that Declaration. Victory was finally won by men willing to endure great hardship for a common cause, so clearly defined in the light of their experiences that they were willing to die to establish their declaration as the birthright of their descendants.

---

[1] Cons. Engr., New York, N. Y.

When every effort was being exerted to define the purpose of our Revolutionary War and to support the armed forces from pitifully limited resources, comparable labors were undertaken at the same time to define and implement the peace. A committee to devise a plan for a union of the states was appointed by the Continental Congress on the same day that the committee was appointed to formulate a Declaration of Independence. The resulting Articles of Confederation were reported to Congress eight days after the first Independence Day. Inevitably, the jealous retention by the states of the newly proclaimed rights of their citizens produced a national government with insufficient powers even to give its armed forces the support they so desperately needed. A decade of bitter internal and external experience ultimately resulted in Congress's calling the first Constitutional Convention. Presiding over the deliberations of that convention of distinguished men, representative of their respective states, was George Washington, engineer, military leader, and statesman. In 1791, when the first ten amendments were adopted after the last of the thirteen states ratified the Constitution, a sovereign people had instituted and endowed with just powers the Government of the United States of America to secure the rights of the people.

The Constitution of the United States is figuratively a chart recording the depths, the shallows, and known currents of the age-old struggle for individual freedom among men. Ventures into the future have been plotted on this chart in vast numbers during the century and a half of its existence. They are the voyages of free enterprise into the future, with courses set from known positions on the chart. Promise of security thus made available has been sufficient to justify risk of life and property in the search for new products and services for the use and convenience of man. The unleashed capacity of a people to make effective use of its rights raised living standards within this brief period of time to more than double the standards of living attained during all the preceding centuries.

A veritable avalanche of new conveniences and time-consuming pleasures aroused desires to possess them. This multiplied incentive for constantly increasing production. In the scramble to produce and enjoy such mounting abundance, there was diminishing time given to thought of the source of such freedom and its protection. Developments in education lagged far behind knowledge needed to convert the products of free enterprise into blessings of permanent benefit. So engrossed were the people in the problems of their separate fields of endeavor that the clouds of a powerful reactionary storm to usurp the unalienable rights of all men broke with inhuman force over a large part of the world before our nation began to awake to imminence of its peril.

Not until England's Dunkirk did the flow of outmoded material and equipment start across the Atlantic in relatively insignificant aid of her heroic resistance. We took in exchange grants of sites for defensive bases and proceeded to construct them in feverish haste. In November, 1940, our voters recorded their approval of the proposition that their Army and Navy would not be called upon to fight beyond our national boundaries. Then, thirteen months later, Japanese carrier-borne planes dove out of the clouds on a Sunday morning and destroyed the greater part of our Pacific Fleet snugly tied up in Pearl

Harbor. This assault was patterned on maneuvers of the winning squadron in an earlier American fleet war game. A few hours later our air force was destroyed on the ground in the Philippines. These tragedies had to happen before sound-reasoning common sense could replace comfortable wishful thinking and willingness to let the incompetent do what thinking was done.

There has followed in the succeeding two and a half years an astounding demonstration of the productive capacity of free enterprise energized by almost complete unity of purpose. There was planning and action which vastly accelerated development of transportation and communications, which provided the facilities required to create and implement huge armed forces and a Navy with auxiliary ships strong enough to carry the war to the enemy and to deliver needed supplies to our embattled allies. These developments have conclusively demonstrated that the natural barriers behind which some nations formerly were able to isolate themselves no longer exist.

Now that communications can be instantaneous and commerce can span distances in hours instead of days or weeks, ventures into the future must be planned on this latest radical revision of the chart recording our experiences. The peoples of this new earth must learn to work harmoniously for the common good. Otherwise, they will destroy potential progress and each other. Present speed with which implements of destruction are produced and applied over land, mountains, and oceans warns nations of the future horrible consequences of their failure to live in harmony with their neighbors. The United States of America and allied nations, whose citizens have experienced freedom to use many of their unalienable rights, are now well on the road to force unconditional surrender of the Axis Powers, whose people gave all their rights to government in exchange for its vain promise to make them lords over a subservient world.

There is too little time left before victory for our country to plan adequately to solve its internal problems of reconversion from a wartime to a peacetime basis. There is too little time left to plan with care our foreign relations. The most that can be done within the limited time available is to take the available and demonstrated truths from the chart of experience and express them so clearly that the vast majority of our people can understand the destination of what should be a proud venture into the future and will determine to set forth in that direction. Devious courses undoubtedly will be undertaken, but with the aid of instantaneous communications and interpretations by representatives of the people selected from those best qualified for their respective tasks, our nation can be kept advised of positions reached which are definitely off course and of those most likely to reach our destination.

As great a need for inspired leadership, universal discussion, and prayerful thought by all citizens exists in our nation today as that which led to creation of our birthright in the days of the Continental Congress. We must here and now resolve to give a substantial part of our time for considered thought to rebuild the protections of our rights and reach beyond our borders to offer the aiding hand of true friendship to peoples less fortunate than our inheritance has made us. Of necessity, this must be a continuing process depending upon the development of capacities of peoples to use effectively such rights as they may from time to time possess. Here in this nation we can neither stand still nor regress. We must progress to higher standards of lifetime service to justify to our people our rich inheritance and to other peoples of the earth their sufferance of our existence.

During the past decade, many small units of free enterprise have been forced to go out of existence or to seek protection in affiliation with large units. New obstructions on the chart of recorded experience have appeared to cause this trend. A threat resulting in such demonstrated discouragement of ventures into the future of a formerly greater number of small units of free enterprise also presents dangerous hazards to be navigated by the surviving larger units. The most important immediate assignment for the best qualified among our leaders is to remove these obstructions as fast as possible to re-establish incentive for development of free enterprise.

Where does the engineer stand in the present call for best qualified leaders to interpret the chart of experience, to define the destination of ventures into the future so clearly that the vast majority of his fellow citizens will plot their courses in that direction, and to offer suggestions of courses he believes may be most likely to prove successful? The engineer must admit that he is largely responsible for planning the phenomenal advances made in harnessing power to aid men in the development of mass production, in the acceleration of transportation, and in the accomplishment of instantaneous communications. To accomplish so much in so short a time, he has concentrated his effort almost to the extent of his full capacity for thought within his chosen limited field of applied science.

Taught to plan his creations with due regard to their usefulness related to their costs, he has made more and more material things available to his fellow men in exchange for less and less effort required of them. The engineer has also aided in the development of entertainments to absorb the increasing free time of the people. Recreation time, formerly available for physical exercise, study, thought, and discussion, is competed for by absorbing programs broadcast into every home and by tempting amusements that can be reached by a drive in the family car. The engineer has given too little thought to the social effects of the results of his enterprise. The engineering profession is inarticulate because it is separated into a number of limited specialties. Within each special field, engineers discuss their problems in language which is foreign even to many engineers in other fields and totally uncomprehensible to the general public. On the chart of experience the present position of the engineering profession is a galaxy of isolated spots, only a few of which are on the proper course to a desirable future destination.

Today, standing on the threshold of the greatest opportunity for service that the world has yet offered them, engineers have a grave responsibility in the development of a sound national and international future program. To begin this assignment, engineers must join hands across the boundaries of their specialties and work together to remove unnecessary obstructions to future ventures of free enterprise and to chart a safe course toward lasting peace with organized justice in a free world. They must be adequately represented in the departments of government, on committees of business men advisory to government, and among the delegates who will negotiate a lasting peace. To be entrusted with such responsibilities of representation of their fellow citizens, a majority of these must first approve the principles and propositions for applying them offered by the engineers. It will not suffice to know that an engineer designed the best airplane engine or a bridge to span a great river. The people will always take such qualifications for granted but will need assurance that the engineer understands many of the present problems confronting the nation as a whole, which are in fact engineering or closely related problems. Concrete evidence that engineers, representative of the entire profession, recognize the grave responsibilities of their greatest opportunity for service in world development toward lasting peace, must be formulated now and submitted in comprehendible form for criticism, revision, and majority approval by their fellow citizens.

To this end, let us consider the following four propositions. It is necessary that they should receive considered thought and criticism conducive to clearer expression of principle in each proposition. The development of other propositions equally important is omitted here in the desire to focus initial attention on an obviously important few.

PROPOSITION 1

The Declaration of Independence states in part:

> "We hold these truths to be self-evident, that all men are created equal, that they are endowed by their Creator with certain unalienable rights, that among these are life, liberty and the pursuit of happiness. That to secure these rights, Governments are instituted among men, deriving their just powers from the consent of the governed. That whenever any form of Government becomes destructive of these ends, it is the right of the people to alter or to abolish it, and to institute new Government, laying its foundation on such principles and organizing its powers in such form, as to them shall seem most likely to effect their safety and happiness."

With the authors of the Declaration of Independence we recognize that the statement quoted above is restricted to rights and does not imply present equality in capacity and will of individuals among men to use such rights effectively and for the common good. Rights are equal and unalienable at birth. Use made of such rights by the individual is accountable by him to his Creator and to his fellow men only to the extent that the rights of others are transgressed.

PROPOSITION 2

The American way of life can be continued and improved in an increasing complexity of activities and new developments. This is possible only if a substantial majority of the people believe and will aggressively assert the principle simply phrased by Walter Lippmann:

> "In a free society the State does not administer the affairs of men. It administers justice among men who conduct their own affairs."

Constitutional checks upon natural human tendency to exercise power beyond the boundaries of authority granted by the people must be made equally mandatory upon all agencies established by Congress to direct details of administration of the collective needs of free enterprise within well-defined boundaries of the delegated authorizations.

PROPOSITION 3

Leaders of opinion at the so-called Mackinac Conference (1943) subscribed to the following statement, which Sumner Welles states is unexceptionable and in accordance with the spirit and the letter of the announced plan of President Franklin D. Roosevelt:

> "We favor responsible participation by the United States in post-war cooperative organization among sovereign nations to prevent military aggression and to attain permanent peace with organized justice in a free world."

To start implementing these principles, an international congress representative of the Allied Nations should be inaugurated at the earliest possible date.

The Allied Congress should be directed:

1. To make a declaration of principle.
2. To prepare articles of joint responsibility in undertakings to prevent military aggression.
3. To draft a charter or constitution under which representatives of free peoples can organize justice and support its development to gain majority approval and respect to the end that permanent peace may ultimately be attained.

PROPOSITION 4

A people endowed with reverence for good should be urged to adopt universal education to develop capacity to produce good works.

Facilities for education designed to increase incentive to develop good citizenship and acquire knowledge should be perfected in competitive balance with the productions of the people's enterprise. Incentive to expand production will increase in proportion to unalienable rights entrusted to the people.

In the United States, incentive to acquire good citizenship and knowledge is insufficient to compete with development of time and labor-saving conveniences and time-consuming diversions. Education designed for the tempo of average capacity is productive of lazy mental and disruptive social habits for half of the pupils endowed with greater-than-average capacity to develop qualities of good citizenship and to acquire knowledge.

Free debate upon these four propositions will clarify their wording to convey meanings acceptable to a substantial majority of free citizens. Principles involved are fundamental and must be understood as the foundations upon which millions of special fields for free enterprise developments can be established. Government pronouncement through agencies of new rules that transgress justice, which has earned majority respect and support of a people through past ages, is productive of uncertainty to the point of chaos in the administration of justice.

Never before in history has so dependable a chart been created as that recording the scant two centuries of experience of our nation. It must be a bright lamp by which our feet are to be guided if we are to form sound judgment in directing our future course. Engineers must join in charting a course secured by references to those established landmarks which have assisted in guiding our nation to its present greatness. We must never depart from the course so clearly set forth in the most inspired of all state documents, the Constitution of the United States.

All citizens entrusted with public office and accepted into the armed forces have sworn to support and defend the Constitution. We are united with our allies to defeat the demonstrated end-product of National Socialism. On the home front we must voluntarily swear to understand, defend, and perpetuate the national institutions responsible for the American way of life to the end that the sacrifices we are demanding of our armed forces shall not be in vain.

MEMOIRS OF DECEASED MEMBERS

GEORGE STEWART DAVISON, Past-President and Hon. M. Am. Soc. C. E.[1]

Died October 3, 1942

George Stewart Davison was born on September 21, 1856, in the borough of Lawrenceville, Pa. (absorbed by Pittsburgh, Pa., in 1868). His father, Edward Davison, came to America from England in 1816; his mother, Isabella Kennedy, born in Scotland, came to Pittsburgh from Canada in 1832. The family of Edward and Isabella (Kennedy) Davison consisted of seven sons and three daughters. With the death of his younger brother Charles in 1937, George Stewart Davison was the sole surviving member of that large family.

Completing his preparatory education in the schools of his birthplace, Mr. Davison entered Rensselaer Polytechnic Institute, at Troy, N. Y., in 1874, being graduated in 1878 with the degree of Civil Engineer. From the day of his graduation throughout the remaining sixty-four years of his life he was deeply interested in the "Institute" and served as one of its Trustees from February, 1909, until his death. In 1926 Rensselaer Polytechnic Institute conferred upon him the degree of Doctor of Engineering. In the same year the University of Pittsburgh honored him with the degree of Doctor of Science.

In spite of the pressure of business and the cares that accompany responsibilities, Mr. Davison found time to take an active part in movements that would benefit his fellow man and his community. Seldom is seen such devoted service as he gave to the institutions on whose boards he served. No one person could tell a complete story of his generosity. At the beautiful service held in the Edgewood Presbyterian Church in Pittsburgh on October 5, 1942, every station in the community's life was represented. All were there because of a profound sense of loss.

In character George Stewart Davison was everything that was fine and noble. He impressed everyone with his sincerity and his absolute integrity. He was a man of the highest moral standards—generous, kind, friendly, truly a Christian gentleman. His death on October 3, 1942, coming most unexpectedly, inflicts upon his family, his friends, and his community no ordinary loss. Death has made vacant a place that cannot be filled.

His civic and humanitarian interests were many. In 1893 he was a member of a committee to study the ravages of typhoid fever, and, as a result of the findings of that committee, the City of Pittsburgh built its sand filtration plant which practically eliminated that dread disease. Mr. Davison was an active member of the Chamber of Commerce of Pittsburgh for twenty-seven years; a member of the Pittsburgh Flood Commission for thirty years, becoming its president following the disastrous flood of 1907. He was chairman of the City Transit Commission for ten years, of the City Planning Commission for three years, and of the Citizens Committee on City Plan for twelve years. He was the originator of the Metropolitan Plan for Allegheny County (Pennsylvania). This plan was approved by 70% of the votes cast, but the will of the voters was thwarted when a few members of the Legislature tampered with the Enabling Act which provided for the election.

---

[1] Memoir prepared by J. N. Chester, M. Am. Soc. C. E., and Allen S. Davison, Assoc. M. Am. Soc. C. E.

In 1927, with twenty-three other leading industrialists, he shared the authorship of a book entitled "Pittsburgh and the Pittsburgh Spirit," published by the Chamber of Commerce. The title of Mr. Davison's contribution to that work was "Petroleum from the Earliest Days."

For almost a quarter of a century Mr. Davison served as a director of The Western Pennsylvania Hospital, one of the largest hospitals in Pittsburgh. He was elected a vice-president in 1933 and president in 1940. To the day of his death this institution was the object of his untiring devotion.

Those who knew him well were aware of his amazing memory and his deep sentiment. He was unashamed of the tears that came to his eyes as he recounted his rare experiences or those of his family, and he had the faculty of relating in a fascinating way his seemingly inexhaustible fund of stories. Measured by years, his life was a long one. Measured by achievements, he might have been regarded as a patriarch. He lived to realize his oft expressed hope—that the world might be bettered because of his living in it.

Mr. Davison entered the practice of engineering on July 1, 1878. Like so many prominent engineers of his day, he began his career in railroad engineering. No attempt will be made to dwell upon his business and professional achievements; they are recorded quite fully in *Civil Engineering*[2] upon the occasion of his election to Honorary Membership. On January 1, 1890, Mr. Davison joined the late William Glyde Wilkins,[3] M. Am. Soc. C. E., in his already established general engineering practice. That partnership came to an end in 1900 when he entered into a contract with A. W. Mellon and R. B. Mellon to serve as manager and executive of corporations and other interests under their control. The greatest of these corporations later became the Gulf Oil Corporation. When Mr. Davison retired from the oil industry in 1929, he was vice-president of the Gulf Oil Corporation and president of the Gulf Refining Company and its eight or ten affiliated companies which engage in every phase of the oil business from production to marketing, including the intermediate transporting and refining. In the latter part of 1906, Mr. Davison initiated locations for an oil pipe line extending from Tulsa, Okla., to the Gulf coast at Port Arthur, Tex., a distance of five hundred miles, designing and constructing its pump stations. In this connection Mr. Davison is believed to have played the rôle of pioneer in the use of large internal combustion engines as the power source for pumping oil through pipe lines. In 1910, he designed and had direct charge of the construction of the one-and-one-half mile extension of the Port Arthur Ship Canal to the refinery of the Gulf Refining Company at Port Arthur, which improvement included a concrete wharf 1,000 ft long. In September, 1941, Mr. Davison made the round trip by plane from Pittsburgh to Beaumont, Tex., to witness the unveiling of a monument to the Lucas Well in Spindle Top Field which came in on January 10, 1901, the largest producer in this continent, reported as 100,000 bbl a day. The inability of the original owners to control and store this tremendous volume of oil caused their bankruptcy and out of this situation was born a few years later the present Gulf Oil Corporation. On September 30, 1929, Mr. Davison's contract with the Mellon interests was terminated at his request, although he continued to manage the Pennsylvania Water Company of which he became executive vice-president in 1902 and president in 1933 upon the death of R. B. Mellon.

---

[2] *Civil Engineering*, January, 1938, p. 54.

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1742.

In 1880 Mr. Davison became a member of the Engineers' Society of Western Pennsylvania, a few months after its organization, and for the first twenty years of his membership he left no stone unturned to advance its interests. He was a director in 1891–1892, vice-president in 1896–1897, and president in 1898. On May 23, 1942, this society conferred honorary membership upon him for his "outstanding contributions to the engineering profession, to the community, and to the society."

On April 2, 1890, Mr. Davison was elected a Member of the American Society of Civil Engineers. To quote from a statement he made in 1920 before a meeting of the Pittsburgh Section, "I made application for membership with the selfish idea that my connection with the Society would pay me large dividends. In this I have not been disappointed. In fact, there came a time when I became convinced that the rate upon which my dividends were being received entitled me to a place in the profiteering class." In 1903–1905 he served the Society as a Director. He was elected Vice-President in 1923–1924; became a Life Member in 1925; was elected President in 1926; and, on October 4, 1937, was elected to Honorary Membership. He represented the Society as a delegate at the dedication, on July 4, 1928, of the $80,000 memorial carillon, given by the engineers of America, in the new fire-proof library of the University of Louvain, at Louvain, Belguim, and was its official delegate at the World's Engineering Congress in Japan in 1929. In the years that intervened between 1905 and 1923, Mr. Davison's business activities and civic interests occupied his time, but he never lost sight of his obligations to the Society. He was proud of his profession, and, whether in the conduct of his employers' affairs or of his own, he constantly kept in mind the thought that he was a member of an honorable profession, that he should do nothing that would bring disgrace to himself or discredit to that profession, and on occasions he vigorously protested instances of their misconduct with violators of professional ethics.

In 1926 Mr. Davison became a member of the American Institute of Consulting Engineers and was always active in promoting its interests. Mr. Davison was a member of Delta Phi and Sigma Xi fraternities. He was also a member of The Historical Society of Western Pennsylvania, the Duquesne Club of Pittsburgh, and the Pittsburgh Athletic Association.

In World War I, Mr. Davison was engaged in war work one week before the United States declared war on Germany, and for two years he devoted practically one third of his time to the problems of the war. One of these problems was to supply gasoline and fuel oil to the Allied armies and navies—the duty of the National Petroleum War Service Committee which was composed of presidents of oil companies.

In religion, Mr. Davison was a Presbyterian and, at the time of his death, was a member of the Edgewood Presbyterian Church, which he served as a Trustee from 1910 to 1926. He was elected president of that Board in 1911 and continued in that office until his resignation in 1926.

Politically, he was a staunch Republican.

On May 19, 1881, he was married at Melrose, N. Y., to Clara Elizabeth Lape, daughter of Pamelia Simmons and Frederick Allen Lape, of Troy. Mrs. Davison died in Pittsburgh on September 3, 1916. They had one son, Allen Stewart Davison, who, with six grandchildren and two great-grandchildren, survives. To them George Stewart Davison has left a wonderful heritage.

As previously stated, Mr. Davison was elected a Member of the American Society of Civil Engineers on April 2, 1890.

JOHN FRANK STEVENS, Past-President and Hon. M. Am. Soc. C. E.[1]

DIED JUNE 2, 1943

John F. Stevens lived thirty-eight days beyond the age of 90. His professional career, too, was a long and varied one. It extended from 1873 to 1931—fifty-eight busy years; and it included distinguished achievements in three well-defined fields: First, that of railroading, which he never gave up and in which his greatest contributions probably were made during the decade 1889 to 1899; second, his work in Panama from 1905 to 1907; and third, his Russian service from 1917 to 1923.

John Stevens was born in West Gardiner, Me., on April 25, 1853, the son of John and Harriet (French) Stevens. He attended the Maine State Normal School, and this was the end of his formal education. In his address at Boulder, Colo., on May 22, 1925, Mr. Stevens had this to say regarding his training:

> "So being endowed by Nature with a bull dog tenacity of purpose, I started on the acquisition of engineering knowledge, at the same time I was working for a bare livelihood for my family and myself. In this sense I became, in a measure, self educated, as I never attended a day at a technical school, or even listened to a technical lecture in my younger days."

After leaving normal school, he went west. He served as assistant city engineer of Minneapolis, Minn., for two years, and then went into railroad work in which he was remarkably successful. Eventually he became System Operating Officer of such large railways as the Great Northern Railway Company; Chicago, Rock Island and Pacific Railway Company; and the New York, New Haven and Hartford Railroad Company. He was President of the Spokane, Portland and Seattle Railway Company, and the Oregon Trunk Railway, subsidiaries of the Great Northern and the Northern Pacific railway companies when they were rounding out the so-called Hill Lines in the Pacific Northwest. Under Stevens they reached Portland, Ore., by an advantageous route down the Columbia River and entered central Oregon, the gateway to California, by building up along the Deschutes River. His administration of these high offices was notably efficient, so that, in addition to the distinction he attained by other more unique accomplishments, he is rightfully accorded a place in railway history as a successful major executive of important railways.

---

[1] Memoir prepared by Ralph Budd, Hon. M. Am. Soc. C. E.

Stevens' most valuable contribution to the railways of America, however, was as a civil engineer, more particularly in reconnaissance, location, and construction work. He was fortunate, and so was the industry and indeed the public generally, in that the period of most rapid railway expansion in the United States and Canada coincided with his young manhood when he was at that stage of his developing experience and ability which made railway reconnaissance and location especially attractive to him. From 1876, when he was 23, until 1899 when he reached 46 years of age, 140,000 miles of railway were built in the United States. He was in the thick of that work, more or less in the following order: The Sabine Pass and Northwestern Railroad Company; Denver and Rio Grande Railway Company; Chicago, Milwaukee & St. Paul Railway Company; Duluth, South Shore & Atlantic Railway Company; Canadian Pacific Railway Company; and Great Northern Railway Company.

There were many locating engineers in those days, and it would be pleasant to state that all railway lines were well and properly laid out. They were not, however, and the cost of operating many poorly located routes, as well as the cost of extensive rebuilding, ran into millions of dollars. There were, of course, numerous instances in which the cost of the lowest grades and easiest alinement would have been prohibitive, and where the first track built was known to be temporary, a permanent route being selected for later development.

The principles of railway location were thoroughly understood by some railway engineers from the early '70's, although the great work by Arthur Mellen Wellington,[2] M. Am. Soc. C. E., was not published until 1877. Every engineer well knows, however, that the best of formulas requires the exercise of good judgment to yield the best results. It would be difficult to find a better illustration of this truth than that found in the choice of ruling grades and other physical standards when laying out a railway. Assumptions as to the future volume of traffic, the speed requirements from the standpoint of adequate service and competition, the cost of maintaining the line in alternative locations, possible floods, slides, snow troubles, etc., are some of the factors that must be based upon judgment. The commonest error was failure to realize the extent to which railroad cars and locomotives would increase in weight and the high train speeds which would be attained; another was to underestimate the heavy future traffic on some of the lines.

---

[2] For memoir, see *Proceedings*, Am. Soc. C. E., Vol. XXI (1895), p. 199.

James J. Hill,[3] F. Am. Soc. C. E., and John F. Stevens were notable collaborators. Hill had such faith in the future and knew so well the importance of favorable physical characteristics that he was willing to spend large amounts to secure the best route, and, when the cost of the ultimate was prohibitive, he approved of a makeshift line that would tie in to the future location with least waste. The inestimable value of proper location of a railway was admirably summarized by Justice Pierce Butler at the unveiling of the statue of John F. Stevens at Marias Pass in July, 1925,[4] when he said:

> "Who can appraise the thing accomplished? It is impossible to estimate the value of such a pass for the transportation of transcontinental commerce in ever-increasing volume. The saving of power, labor, and equipment results directly to the great benefit of the company and of the public served. The shortest line fixes the distance, and the best grades establish the standard of efficiency that competitors must meet. So, indirectly, the use of this pass results to the advantage of all interested in transcontinental transportation by whatever route."

The science of railroading was advancing very rapidly during the period under discussion. In the progressively higher positions he held, Stevens exerted a great and growing influence upon the improving standards of construction and operation.

When in 1905, succeeding John F. Wallace,[5] M. Am. Soc. C. E., Stevens became chief engineer of the Panama Canal, he was undoubtedly the world's foremost railway civil engineer. This was true in spite of the fact that he was then not in engineering but in executive work, having been advanced to the position of vice-president of the Chicago, Rock Island and Pacific Railway Company, following his general managership of the Great Northern. It is significant that in the professional, in distinction to the administrative, field, the first and most important question which had to be decided after he took charge was the type of canal to be built. The problem was elementary. The considerations for and against the sea level and the lock types of canal were essentially the same as those which a railway locating engineer must weigh over and over again in the course of his duties. The difference in the case of the canal problem was in its magnitude.

A Board of fourteen noted consulting engineers decided 9 to 5 for the sea-level route. The minority five were Alfred Noble,[6] Past-President, Am. Soc. C. E., Henry L. Abbott, Frederic P. Stearns,[7] Past-President, Am. Soc. C. E., Joseph Ripley, M. Am. Soc. C. E., and Isham Randolph,[8] M. Am. Soc.

C. E. Stevens agreed with them in favor of a lock canal, and through his influence Congress adopted that plan on June 29, 1906.[9] His letter of January 26, 1906, to the Isthmian Canal Commission was characteristic:

> "Prior to the receipt or inspection by myself of any report from the Consulting Board, my judgment was and is yet in favor of a high-level canal, and it has only been strengthened by the very able presentation of the facts and deductions made therefrom in the minority report.
>
> "I can therefore conscientiously and fully approve the adoption of the high-level type, and strongly recommend that the Commission give its official voice in favor of such a type as is described in the minority report, and there seems to be nothing that I can add to such report, in view of its clearness and completeness, more than that I am heartily in favor of its adoption."

This decision was basic, just as is the choice of a route for a railway when it is to be constructed. The government of the United States never gave John F. Stevens any special credit or any reward for this momentous decision, but if he had joined the majority for a sea-level canal there scarcely can be any doubt of the criticism which would have come his way when the mistake was realized. When the lock level had been chosen and fixed at 85 ft above the sea, the organization of forces and prosecution of the work followed with great vigor. The American public was clamoring for progress and speed and soon had reason to be satisfied.

Two general types of engineering work were involved: (1) The digging of Culebra Cut and other dry excavation between the Gatun Locks and those at Miraflores, and (2) the building of the locks and dams and approaches thereto from tidewater. The first of these undertakings was like a huge railroad construction project—nothing else. The Culebra Cut was 8 miles long, more than 300 ft deep on the slopes, 300 ft minimum width at the bottom, and more than half a mile across the top, but digging it out was essentially a matter of steam-shovel operation at various levels and hauling the excavated material away by train.

There was a job in the United States which was and still is much like Culebra Cut (later called Gaillard Cut) in many respects. That is the stripping and mining of iron ore at the Mahoning and Hull Rust open pits on the Mesabi Range in Minnesota. There are, of course, several other similar operations. John F. Stevens once protested the assertion that the canal excavation was patterned to some extent on what he had seen and had a part in doing on the Mesabi Range, but it is difficult to believe that Culebra could have been organized so promptly and perfectly without that experience. The locks, dams, and sea-level approaches were of course the kinds of projects that the army engineers and their civilian associates were more familiar with, except for the unprecedented magnitude at Panama. These were placed in the hands of those engineers who had had wide experience in such construction.

There were literally all manner of collateral organizations and engineering activities involved in carrying on such an extensive undertaking as the Canal so far from sources of supplies. Most vital was the matter of housing and caring for the many employees of various nationalities, including especially that of making it safe to live there. Ridding the Canal Zone of yellow fever, reducing malaria to the minimum, and cleaning up the area were given preference by Stevens. This pioneer project in sanitation not only was necessary to the successful production of the canal but was an humanitarian act of first magnitude. Its brilliant accomplishment was under the direction of Col. William C. Gorgas, who enjoyed Stevens' full confidence and support.[10]

---

[9] "Report of the Board of Consulting Engineers for the Panama Canal," Government Doc., 1906; also "Best Type of Canal for Panama," *H. R. Doc. No. 10,* March 26, 1909.

The record at Panama is that by April, 1907, when Stevens turned the job over to Col. George W. Goethals,[11] M. Am. Soc. C. E. (later General), the entire work was planned and organized; construction was under full headway and proceeding at a rapidly accelerating rate. After Stevens left there were no substantial changes and his plans were carried forward to successful conclusion and on his time schedule.

Upon returning to the States from the Canal Zone in 1907, Stevens spent four years in active railroad administration and then six years as a consulting engineer. During this period he served two years as vice-president of the New Haven and two as president of the Hill Lines' subsidiaries in the Pacific Northwest.

It is a notable feature of Stevens' life story that he never remained long in one place or with one concern. The nature of his work would account for this until he became so firmly entrenched with Mr. Hill after 1889. Then for ten years he handled the Great Northern's expanding construction as chief engineer and in 1901 became general manager as well. He went to the Rock Island in 1903 and stayed there two years, when he assumed charge of the Panama Canal construction.

Stevens' frequent changes after leaving the Great Northern were not because he was ambitious to better his position, or because he did not make good in the high places he held, but rather were due to some other traits of his character. He was possessed of a New England conscience, an unfailing ability to detect sham or pretense, and was frank in showing his feelings about such things, especially in the case of those holding higher positions. He was a debunker by nature and environment. Handsome, prepossessing, and impressive in every way, Stevens was at the same time modest almost to the point of being shy. His years of struggle and lack of privileges in his youth might account for this. Yet another characteristic was his sensitiveness to criticism. Possibly it reflected a mindfulness of his lack of formal engineering education, although he must have known that any such deficiency had been more than compensated by his study and his wide experience in the field.

Mr. Stevens had a good sense of humor which manifested itself in dry Yankee fashion, never in the form of practical jokes. His response on the unveiling of his statue at Marias Pass was considered by many a model for such an occasion and he livened the occasion by saying:

---

[10] "William Crawford Gorgas, His Life and Work," by Marie Cook Gorgas and B. J. Hendrick, Doubleday, Page and Co., New York, N. Y., 1924.

[11] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1813.

> "As these proceedings have been a little bit sober, to say the least, I want to illustrate, if you will pardon my levity, why I might not properly express my appreciation by a lengthy address. Many years ago, probably longer back than many of you remember, there was an eminent Irish author and actor and one of his famous characters was Con Carney. Con Carney was a worthless, happy-go-lucky fellow. He was supposed to die and at the funeral there was, of course, lots of whiskey and lots of fighting. When his friends went to pay their final respects to Con, to their surprise he rose up in his coffin and they exclaimed: 'Are you alive—why didn't yez spake?' and Con said: 'Spake! Do yez think I would spile a good wake?'
>
> "So perhaps, while this is not a wake, it is better that I do not 'spake.' "

Outstanding in Stevens' relationship with other men was the universal affection in which he was held by subordinates and the loyalty of those who worked under his direction. He was most considerate of them, while they thoroughly believed in him and gave unstintingly their fullest and best efforts. His unlimited respect and admiration for Mr. Hill endured through the years and it is only fair to state that the regard was mutual. It was Mr. Hill who convinced William H. Taft, then Secretary of War, that Stevens was the best man to build the Panama Canal. As has been implied, Stevens was not so happy in his relationships with men holding coordinate positions, nor always with his superiors. This was recognized among some of his closest friends, including Mr. Hill, and it may have interfered with his advancement to the presidency of one of the larger railroads. Stevens felt that he had reason to expect such promotion about 1903 and again in 1911, and its failure to materialize hurt him deeply.

The married life of John F. Stevens and his devoted wife (Harriet T. O'Brien Stevens) was ideal. Mrs. Stevens enjoyed having people around her, and she had many friends wherever she went. Mr. Stevens had great affection for her and left to her care and judgment everything pertaining to the home. Her death in 1917, ending forty years of happy married life, left him disconsolate. Surviving are three sons, Donald French, John F., Jr., and Eugene C.

Although his sons made him welcome at all times and were a great comfort he was never again to enjoy a real home of his own where he could mingle extensively with his friends.

All personal ambitions and any disappointments concerning them had no doubt been completely outlived before Stevens went to Russia[12] during World War I in 1917. He was 64 years of age then, and possessed neither political nor personal aspirations. His years of experience in many fields had made him cosmopolitan and philosophical. The service he was to render in Russia was wholly disinterested and devoid of guile either on the part of his country or himself. He represented a friendly nation, desirous only of assisting a people who were traditionally our allies at a time when they had become helpless through the ravages of civil strife.

The Russian government under Alexander Feodorovitch Kerensky constituted an attempt to reorganize a weary populace and restore order out of the chaos following collapse of the Czar's regime. Railway service was essential to success, and the United States sent a Transport Board to assist the Russian officials in their efforts. The Kerensky government fell and then for nearly two years Russia was torn with the struggles between the Bolshevists under Nikolai Lenin and Leon Trotsky and the White Army under Alexander Kolchak and other leaders.

---

[12] "America's Siberian Adventure," by William S. Graves, Jonathon Cape, and Harrison Smith, 1931.

The United States and its allies were concerned with keeping open the Trans-Siberian Railway as an artery for necessary travel and the movement of vital supplies from one part of Russia to another. The policy of the United States was to remain strictly neutral concerning internal affairs of Russia. To carry out these good intentions there was organized the Inter-Allied Technical Board of eight nations: China, Great Britain, France, Italy, Czechslovakia, Japan, Russia, and the United States. John F. Stevens was the United States member and Chairman. At least so far as the conduct of the United States was concerned, there cannot be any doubt that the principles laid down were strictly observed.

To assure compliance with the Board's policies the property and operations of the Trans-Siberian Railway were safeguarded by the military of several nations for about two years, Maj.-Gen. William S. Graves being in charge of the United States troops. Stevens also had a carefully selected group of nearly three hundred railway operating men, with northern United States railway experience. These men were under the leadership of Col. George H. Emerson, general manager of the Great Northern. They actively supervised the railway operations from Vladivostok as far west as Omsk. The property was kept intact and service maintained, although not always with much regularity. Some critical raw materials were brought out, and much needed supplies taken in. The greatest and most spectacular movement over the Trans-Siberian during this period was that of the Czech Army. There were several Divisions of these soldiers who found themselves so far east of the eastern war front that they could not return as they had come and were taken over the Russian railways all the way east to Vladivostok, thence home by sea.

About as much tact was required to handle the Inter-Allied Board as to keep in hand the situation along the Siberian Railway; and the successful administration of this assignment no doubt was the most difficult undertaking of Stevens' whole life. He achieved real greatness in its discharge, and such men as William H. Taft, Elihu Root, and Newton D. Baker were enthusiastic in their praise. Both the military protection and the railway contingent withdrew in 1921, after which Stevens, with only one or two assistants, continued in an advisory capacity until 1923.

In 1935, Stevens made a noteworthy contribution to engineering literature by writing about his life and work, omitting, however, any reference to the years he spent in Russia. A final chapter of this series of "recollections,"[13] as he called them, is addressed "To The Young Engineers Who Must Carry On." This chapter of counsel and advice doubtless reflects his final judgment of values at the close of his long and brilliant career. It contains not only admirable counsel for engineers of all ages, but affords a revealing glimpse into the character of the author. It is a declaration of ideals and of faith in the future with a closing word on rewards—

---

[13] "An Engineer's Recollections," by John F. Stevens, *Engineering News-Record,* March 21 and November 28, 1935; also published by McGraw-Hill Book Co., Inc., 1936.

> "While the rewards are not always in the shape of great material wealth as the world regards wealth, they will come in the knowledge that we can leave a good name to our posterity, and that we have contributed something to the comfort and happiness of succeeding generations."

Stevens received the following governmental honors: Distinguished Service Medal, United States; Officer of the Legion of Honor of France; Second Class Order of the Rising Sun, Japan; Order of Chia Ho (Golden Grain), China, highest civil decoration; Order of Wen Hu (Striped Tiger), China, highest military decoration; and the Czechoslovak Military Cross. He was an honorary member of the Association of Chinese and American Engineers and the Northwestern Society of Engineers. In 1922, he received the degree of Doctor of Laws from Bates College, at Lewiston, Me. He served as chairman of the U. S. Commission of Railway Experts to Russia, and as President of the Inter-Allied Technical Board. He was elected an Honorary Member of the Western Society of Engineers in 1935.

He received the John Fritz Gold Medal on March 23, 1925, for "great achievements as a Civil Engineer, particularly in planning and organizing for the construction of the Panama Canal; as a builder of railroads, and as administrator of the Chinese Eastern and Siberian Railways." The Hoover Gold Medal was given to him in 1938.

Mr. Stevens was elected a Member of the American Society of Civil Engineers on June 6, 1888, and an Honorary Member on June 19, 1922. In 1927 he served as President of the Society.

JOHN WATSON ALVORD, Hon. M. Am. Soc. C. E.[1]

Died July 31, 1943

John Watson Alvord, son of the Rev. John Watson and Myrtilla Mead (Peck) Alvord, was born at Newton Center, Mass. (later a section of Boston, Mass.), on January 25, 1861, from pioneer Colonial New England stock on both sides of the family.

He was educated in private schools, including Howard University Preparatory School in Washington, D. C., where the family moved when he was a young child. At the age of 17, he struck out for himself, and, after a short experience as a law clerk in New York, N. Y., he went west and entered the employ of the Denver Pacific Railway and Telegraph Company as a brakeman and fireman running between Denver, Colo., and Cheyenne, Wyo., in the mining boom days. A framed letter hanging on the wall of his office certifies his fitness as a railroad man. In 1879 he went to Chicago, Ill., and entered the employ of his brother-in-law, the late John A. Cole,[3] M. Am. Soc. C. E., at that time a practicing civil engineer engaged on the municipal improvements of the suburban towns immediately surrounding rapidly growing Chicago. He studied surveying, became a good draftsman, learned to design under direction, to supervise the construction of water works and sewers, and to lay out the villages and subdivisions later to become part of Chicago. This work included the construction of the water works system for the Village of Hyde Park, including an inlet lake tunnel under Lake Michigan on which he was assistant engineer. In 1883 his employer admitted him to partnership under the firm name of Cole and Alvord. During this year he was principally engaged in the design of a sewer system for the town of Lake View (a suburban area later part of Chicago).

---

[1] Memoir prepared by Charles B. Burdick and Louis R. Howson, Members, Am. Soc. C. E.

From 1884 to 1887 Mr. Alvord served as city engineer of Lake View, designing and executing municipal work—water supply, sewer extensions, street improvements, and lake shore protection—costing $3,500,000. During this period at Lake View he profited greatly by meeting Benezette Williams, an able consulting engineer who was employed to advise on the Lake View improvements. His association with Mr. Williams so inspired Mr. Alvord's desire for knowledge that he spent the greater part of the year 1888 on an engineering inspection trip to the eastern United States and Europe, studying hydraulic and sanitary engineering works in England, France, Germany, Austria, and Italy—frequently traveling from town to town on foot.

Returning to the United States, he resumed his engineering connection with Mr. Cole, under the firm name of Cole, Alvord and Shields and for a year was engaged in additional suburban work including an adventure as a contractor on two Lake Michigan water works intakes involving considerable hazard. In 1890 he became town engineer for Cicero, Ill., and designed the sewer system for 17 square miles of territory (part of which now is within the City of Chicago).

Late in 1890 Mr. Alvord accepted a position with the Worlds Columbian Exposition (Chicago) heading the Department of Surveys and Grades which employed a large force of engineers on the layout of the Exposition, the lake shore protection, and the system of lagoons that was an important feature of the landscaping operations. This was a valuable and inspiring experience during which he had intimate contact with many experts in all branches of architecture, art, and engineering including close association with Daniel H. Burnham, the director of works.

When his work at the Exposition was completed in 1894, Mr. Alvord again visited England and France for further study of engineering works. Upon his return to Chicago, he opened an office as consulting engineer which continued without interruption until his death, although his responsibilities were minor for the last twenty years of his life. For about two years following 1896, he operated in partnership with William S. Shields who had been an associate during his early experience. In 1902 he formed the partnership of Alvord and Burdick, which in 1922 became the firm of Alvord, Burdick and

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1634.

Howson. During this time, the engineering work of the firm extended widely throughout the United States.

Mr. Alvord was particularly interested in the subject of sewage treatment, designing several of the early plants utilizing sand filtration after preliminary treatment in septic tanks then coming into use. In 1897 he was employed by the City of Columbus, Ohio, and made a study and report on all methods of treatment available at that time. He early recognized the disadvantages of the septic tank and in 1913 designed one of the earliest plants for sedimentation with sludge digestion in separate tanks, which shortly before had come into use in England and which were the antecedents of separate digestion effected through mechanical equipment in modern plants. In 1907 Mr. Alvord was employed by the U. S. Steel Company to design the water works and sewers for the new steel town of Gary, Ind., planning the works for a population of 100,000 people, including a water works tunnel and intake from Lake Michigan, supervising the original construction and planning numerous additions, including sewage treatment, to these public works in subsequent years. He also designed and supervised similar works for the new but smaller coal town of Kincaid, Ill.

In 1910 he became a member of an engineering commission which reported on sewage disposal for Milwaukee, Wis., the beginning of the treatment works later completed. He was also a member of the engineering commission which outlined plans for sewage collection and treatment of the North Shore Sanitary District prior to the annexation of this territory to the Chicago Sanitary District. Through his connection with the Chicago Real Estate Board, he took an active interest in sewage treatment for Chicago. He was instrumental in an early study of this problem by independent experts in a privately financed investigation, and later in 1925 he thoroughly studied and reported to the Secretary of War on the disposal of the sewage of the Sanitary District of Chicago, reviewing the possibilities of sewage treatment and the subject of sewage dilution.

Mr. Alvord also specialized in flood protection methods. In 1913 he became a member of the Consulting Engineering Board to devise flood protection for Dayton, Ohio, and its vicinity following the great 1913 flood. In the same year he and his organization were appointed to do similar work by the Franklin County Conservancy District at Columbus, Ohio, and during the ensuing two years made a thorough study and report for protective works on the Scioto River (only partly finished). At about this time, he was also engaged on numerous other investigations for relief from floods on the Illinois River for the State of Illinois and elsewhere. In addition, he was employed by numerous railroads and other organizations on matters relating to floods. He was coauthor of a book on this subject published in 1918.

During World War I, Mr. Alvord served at Camp Grant, Rockford, Ill., as supervising engineer for the Quartermaster in charge of water supply, sewers, and roads. Upon the completion of that work, he became chief engineer of the U. S. Housing Corporation, U. S. Department of Labor, Washington, D. C., heading a force of engineers, until the Department was liquidated after the Armistice. He then returned to Chicago and resumed his practice.

In the later decades of Mr. Alvord's active work, he devoted much attention to the valuation of water works properties. In 1899 he was employed by the Dubuque Water Company to inventory their property and to be a witness in the valuation proceedings conducted by a layman-lawyer-engineer commission. In this case, many of the procedures were inaugurated which have been followed on later work. He was subsequently a member of many commissions and boards which transferred the ownership of such property. In numerous cases, on account of a reputation for judgment and fairness, he was selected by appraisers as third man. He is the author of several engineering papers on the subject of valuation, depreciation, and going value.

Although Mr. Alvord never held public office, he frequently gave his services to boards and commissions serving the public. In 1910 he became a member of the Chicago Commission on Public Expenditures, a privately financed organization which operated for several years with a staff of assistants. In 1914 he served as a member of the Citizens Terminal Plan Commission. For many years, he was a member of the Chicago Real Estate Board, serving as chairman of the Committee on Rivers and Harbors and on various other committees and commissions dealing with health, taxation, and other local problems. In 1914 he became a member of the State Board of Natural Resources and Conservation, an Illinois state advisory and administrative commission on which he served for many years.

Mr. Alvord always felt keenly his lack of a technical university education. It made him a student all his life, and he had a special aptitude for study. His library was extensive and included papers and reports on the engineering subjects in which he became interested. He had a high regard for the help of others and was quick to appreciate the services of experts on the special problems. Nearly every one with whom he came in close contact became a valuable friend. He had the habit of commending good work wherever he saw it by an appropriate letter which made friends, with some of whom he maintained occasional correspondence for many years. This practice ultimately led in 1916 to his founding and endowing the Washington Award named in honor of George Washington who was one of the earliest American engineers, an honor administered by the Western Society of Engineers in cooperation with the four national Founder Societies and conferred annually upon some engineer in recognition of preeminent services in promoting the public welfare. Twenty engineers in widely different lines of endeavor have been thus honored at dinner meetings in Chicago.

Mr. Alvord was granted the degree of Civil Engineer by the University of Wisconsin, at Madison, in 1913. He was an honorary member and past-president of the Western Society of Engineers, American Water Works Association, and the Illinois Society of Engineers; a fellow of the American Society for the Advancement of Science; and a member of the Institution of Civil Engineers of Great Britain, American Institute of Consulting Engineers, New England Water Works Association, Sons of the American Revolution, Society of Mayflower Descendants, Chicago Engineers Club, Union League Club of Chicago, and University Club of Winter Park, Fla.

Mr. Alvord was married to Helen C. Cornell of Chicago on September 4, 1889. She died in 1926. In 1927, he was married to Lucy Bicknell Pitkin of Oak Park, Ill., who survives him.

Mr. Alvord was elected a Member of the American Society of Civil Engineers on January 4, 1893, and an Honorary Member on October 14, 1935. He served as a Director in 1917–1918 and in 1919–1921.

JOHN DEBO GALLOWAY, Hon. M. Am. Soc. C. E.[1]

DIED MARCH 10, 1943

John Debo Galloway, the son of James and Emily Meyers (Hoover) Galloway, was born on October 13, 1869, at San Jose, Calif. His ancestors were residents of Maryland, New Jersey, and Pennsylvania prior to the American Revolution. His parents died when he was still quite young. Left to his own resources, one of his dominant characteristics, self-reliance, early came to the fore. His boyhood experiences, some of which were acquired at Virginia City, Nev., when that city was the center of the great mining activity incident to the discovery and development of the famous Comstock Lode, made a deep impression upon him. At the age of eight he was taken to live with friends in Napa Valley, California.

His technical education was gained, not without some financial struggles, at Rose Polytechnic Institute, Terre Haute, Ind. There originated lifelong friendships with others who, like himself, later proved to be leaders in the Society. Mr. Galloway was graduated from Rose Polytechnic Institute in 1889. His attendance there had been inspired by his brother Mason Galloway, who was graduated in 1890.

Next, he was employed in railroad work in the Pacific Northwest. Recalling these days, he later enjoyed telling the late John F. Stevens, Past-President and Hon. M. Am. Soc. C. E., of a good turn he received from him. Although Mr. Stevens had not met Mr. Galloway, through a consolidation of railroad interests, Mr. Stevens, directing the affairs of his company, released Mr. Galloway to (it later proved) better and more congenial employment. After a short stay in the Pacific Northwest, Mr. Galloway returned to California and throughout the remainder of his career maintained his headquarters in San Francisco although his practice often took him far afield.

From 1892 to 1896 he was chief engineer for Healy-Tibbitts Construction Company of San Francisco. In this capacity he personally directed the construction of important bridges, harbor works, sewers, and difficult foundation work. From June, 1896, to September 1897, he was employed in the engineering department of Pacific Rolling Mill Company of San Francisco, on designing and detailing steel building frames.

---

[1] Memoir prepared by a Committee consisting of Walter L. Huber, *Chairman,* Henry D. Dewell and A. Kempkey, Members, Am. Soc. C. E.

From September, 1897, to October, 1899, he was an instructor in drawing and mechanics at California School of Mechanical Arts in San Francisco. In this capacity he made a deep impression on his students, many of whom became leaders of the engineering profession. Among them was the late Arthur H. Markwart,[2] M. Am. Soc. C. E., who later became Mr. Galloway's partner. From October, 1899, to May, 1900, Mr. Galloway was chief engineer for Colusa Stone Company. After May, 1900, he maintained an independent practice as consulting engineer, although on two occasions, covering several years, he was associated in partnerships.

For the California Gas and Electric Company, predecessor of the Pacific Gas and Electric Company, he directed the design and construction of the cable span across the Straits of Carquinez. This span, which was a part of the world's then longest transmission line, was also the then longest cable span. It is still in service as an important part of this company's great system.

From 1900 to 1906, the period just prior to the San Francisco earthquake and fire of April 18, 1906, he designed and supervised hydraulic and structural construction for several hydroelectric plants which were later absorbed in the system of the Pacific Gas and Electric Company. He also designed the hydraulic and structural features for the first two hydroelectric plants of the system later owned by California Electric Power Company; and the structural elements of some of the city's principal buildings including the Mutual Savings Bank Building, the St. Francis Hotel, the Shreve Buildings, the Schroth Building, the Syndicate Building of Oakland, etc. He was one of the earliest advocates of earthquake-resistant design, and the merit of his reasoning was fully demonstrated by structures designed by him, when they were subjected to the effects of the great earthquake.

Immediately after the earthquake he formed a partnership with John Galen Howard, as Howard and Galloway, Architects and Engineers. William C. Hays and Mr. Markwart were junior partners. This firm took a leading part in the design of San Francisco's reconstructed commercial district. Many of the city's most important office and commercial buildings were designed under Mr. Galloway's direction. In spite of the exacting demands of his professional work at this critical time, he devoted much personal effort to the revision of the city's building ordinance and to relief work. His firm also designed and supervised the construction of buildings and grounds for the Alaska-Yukon-Pacific Exposition at Seattle, Wash., and the auditorium, chemistry and engineering buildings, and a steam-electric power plant for the University of Washington at Seattle.

At this time he served with Charles D. Marx,[3] Past-President and Hon. M. Am. Soc. C. E., and Wynne Meredith, M. Am. Soc. C. E., on the Board of Advisory Engineers on the design and construction of the Stanislaus Hydro-Electric Power Plant, California.

From 1908 to 1920 he was associated with Mr. Markwart on consulting work. However, this partnership had a number of intermissions. From

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 105 (1940), p. 1877.

[3] For memoir, *ibid.*, p. 1785.

July, 1912, to April, 1915, Mr. Markwart was absent while in charge of the design and construction of the Panama Pacific Exposition at San Francisco. From November, 1917, to February, 1919, Mr. Galloway served as an officer with the American Expeditionary Force in France. In November, 1920, Mr. Markwart became head of the engineering department of Pacific Gas and Electric Company and the partnership was then dissolved. After this Mr. Galloway continued in independent practice.

With Mr. Markwart, he designed and built several railway and combined highway and railway bridges in the Sacramento Valley, California, a hydroelectric power plant in Yosemite National Park, and a number of important buildings. The firm made many investigations and reports upon utility properties, including those of the Oro Electric Corporation, Butte and Tehama Power Company, City Electric Company, Yolo Water and Power Company, and Santa Barbara Gas and Electric Company. Mr. Galloway investigated and reported on the steam and hydroelectric plants of Treadwell Mines in Alaska; on proposed power development on the Potomac River and Shenandoah River at Harpers Ferry, W. Va.; on existing and possible additional power developments on the Menominee River, Michigan and Wisconsin; on power possibilities on Deschutes River in Oregon; on power developments on Feather River and Yuba River in California; on development of hydroelectric power on Vancouver Island, B. C., Canada; and on power projects on Pit River, California. He also conducted extensive examinations and reports, in many instances including appraisals of irrigation systems. Among the properties concerned were those of Turloch Irrigation District and Modesto Irrigation District; Fresno Canal and Land Corporation; James Irrigation District; Honcut-Yuba Irrigation District; Mendota Irrigation District; Tulare Lake Basin Water Storage District; and Sutter Butte Canal Company. With Mr. Markwart, he made surveys and prepared designs for the irrigation system which, with some modifications, was built by Merced Irrigation District at a cost of approximately $16,500,000. With the late J. B. Lippincott,[4] Hon. M. Am. Soc. C. E., B. A. Etcheverry, F. C. Herrmann, W. L. Huber, and the late F. H. Tibbetts,[5] Members, Am. Soc. C. E., he was a member of the Board of Advisory Engineers on the Sacramento Valley Division of the Central Valley Project in California. This board made studies of dams on the larger rivers giving special consideration to the Shasta (Kennet) Dam and the use of water in the Sacramento Valley.

Mr. Galloway rendered extensive service to Great Western Power Company: First in connection with the design and construction of extensions and additions to its Las Plumas Plant on Feather River; and later in connection with the design and construction of its Caribou Plant on the same stream. As consulting engineer, he represented this company on the construction of the Bucks Creek hydroelectric power plant, a plant with 2,660-ft head.

With Frank G. Baum,[6] M. Am. Soc. C. E., and W. F. Durand, Mr. Galloway was a member of the Board of Consulting Engineers on the location and design of the Moccasin Creek hydroelectric plant on the Hetch Hetchy Aqueduct of the City of San Francisco. For Pacific Gas and Electric Company he served as consulting engineer in connection with the concrete masonry dams for Pit No. 3 and Pit No. 4 power plants on Pit River, the enlargement of Fordyce rock-fill dam on Yuba River, and the design and construction of the 328-ft Salt Springs rock-fill dam on Mokelumne River. With Robert Ridgway[7] and Arthur N. Talbot,[8] Past-Presidents and Honorary Members, Am. Soc. C. E., and M. M. O'Shaughnessy,[9] M. Am. Soc. C. E., Mr. Galloway was a member of the first Commission of San Francisco on the location of the San Francisco-Oakland Bay Bridge. The foregoing list of his professional engagements is necessarily incomplete. As one of his colleagues recently stated, he had a part in practically every major engineering project in northern California during a period of forty years.

---

[4] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 108 (1943), p. 1543.

[5] For memoir, *ibid.*, Vol. 105 (1940), p. 1924.

[6] For memoir, *ibid.*, Vol. 99 (1934), p. 1407.

As previously noted, his professional career was interrupted by World War I. In 1917 he was chairman of a temporary organization of about 750 engineers for the study of war work and for supplying information preparatory to army service. In November, 1917, he was called to active duty and ordered to France, arriving in December, 1917. He served as Major of Engineers in G-2 Section of the General Staff at Headquarters of the American Experitionary Force at Chaumont, France.

In 1942, during World War II, he was board member of the Price Adjustment Section for the Pacific Division, Corps of Engineers, U. S. Army. He was Director of Defense Transportation (Office of Civilian Defense) for Berkeley, Calif., until the time of his death.

He was married on April 19, 1894, to Nettie Mabel Barnes whom he had known since early childhood in Napa Valley. Mrs. Galloway died on June 14, 1941. Two daughters, Mrs. E. Ronald Foster and Mrs. Alice Wilder; three grandchildren, John D., Margaret Ellen, and Rosemary Foster; and a brother, Mason Galloway, survive him.

Mr. Galloway was a life member and past-president of the Astronomical Society of the Pacific, a member of the Society of Military Engineers, a member of the Seismological Society of America, a member of the California Historical Society, a charter member and life member of the Commonwealth Club of California; and a director of California School of Mechanical Arts and past-president of its Board of Directors. San Francisco's noted Bohemian Club, a group of professional and civic leaders, learned to appreciate his ability as he was charged with upkeep of its summer retreat in the Redwood Country—the locale of events famous for their originality and convivial atmosphere. Mr. Galloway was particularly proud of the fire-protection system which was installed there under his direction.

His was a rich life filled with interests beyond his professional practice. He had a passionate fondness for historical research, particularly when it related to the early development of the West such as the Pacific railroads, the utilities which served the western mining regions, and early explorations in general. He made a fine collection of rare prints. Gardening gave much pleasure to him and his wife.

[7] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 106 (1941), p. 1527.

[8] For memoir, *ibid.*, Vol. 108 (1943), p. 1530.

[9] For memoir, *ibid.*, Vol. 100 (1935), p. 1710.

He wrote many authoritative articles, especially for the Society. For his paper on "The Design of Rock-Fill Dams,[10] he received the Thomas Fitch Rowland Prize in 1941, and, at the same Society meeting, he was awarded Honorary Membership. The dual honor was a significant tribute to the depth and catholicity of his interests. His splendid article, "Theodore Dehone Judah—Railroad Pioneer," [11] is, so far, the only printed evidence of the great amount of study and research which he devoted to the subject of the building of the Central Pacific Railroad. It is hoped that some of his manuscripts on this subject will yet be printed.

Among many important assignments which he filled for the Society one stands out in bold relief—his chairmanship of the Society's Earthquake Committee which was instituted following the Japanese disaster of 1923. After years of study this committee produced a monumental report, which is still consulted for authentic information on a wide variety of earthquake problems.

Besides the papers mentioned he was the author of many other papers and discussions, among them: "Report of Committee on Fire and Earthquake Damage to Buildings" [12] (chairman of committee), "The Design of Hydro-Electric Power Plants," [13] "Hydro-Electric Developments on the Pacific Coast," [14] and "Earthquakes and Structures," [15] in collaboration with L. M. Hoskins. He contributed valuable discussions to a great many papers published by the Society. He was the author of "Hydraulic Power Development and Use" presented at the International Engineering Congress in San Francisco in 1915. He also contributed a discussion of a paper entitled "The Subsidence of a Rockfill Dam and the Remedial Measures Employed at Eildon, Australia" to the *Journal* of the Institution of Civil Engineers, London. Among his numerous papers presented to the Commonwealth Club of California may be mentioned "The Hetch Hetchy Water Supply for San Francisco," "The Bay Cities Water Problems," "Reception to Members from the Front," "Water Power and Irrigation in California," "California Water and Power Act," "Hetch Hetchy Power," and "The Swing Johnson Bill."

Mr. Galloway had a capacity for genuine friendship but when occasion demanded he could be a frank critic. Whatever decision his logical mind led him to take, he defended it strongly. This independence combined with his great kindness made him greatly admired and loved. As noted in *Civil Engineering,*[16] "No civil engineer on the Pacific Coast has enjoyed a more secure place in the esteem and affection of his fellows." One of his loyal friends of many years recently made a statement which is offered here because it describes Mr. Galloway's personality so truly.

[16] ***Civil Engineering,*** **April, 1943, p. 190.**

> "Personally, I not only respected but also appreciated 'J. D.' both as a student and as a scholar, and I certainly did look up to him as a genuine engineer—sound as to judgment and eminently practical as regards the application of engineering knowledge and skill.
>
> "My very deep affection for him, however, was founded upon his humanitarian traits, for after all he was a man both human and humane.
>
> "I did so enjoy his little 'bark' which never could become anything even remotely resembling a 'growl' because of the smile that at such times always lingered at the corners of his mouth, and the ever present bright twinkle in his eye.
>
> "The structures which he designed and the projects in which his influence is so clearly shown will endure as physical mementos to his worth as an engineer; but as a man and as a friend, his memory ever bright will live always in my heart."

Mr. Galloway was elected a Member of the American Society of Civil Engineers on December 6, 1905, and an Honorary Member on October 14, 1940. He became a Life Member on January 1, 1940. He was a Charter Member and Past-President of the San Francisco Section of the Society.

JOSEPH RUGGLES WORCESTER, Hon. M. Am. Soc. C. E.[1]

DIED MAY 9, 1943

Joseph Ruggles Worcester, whose membership in the Society dates from the year 1895, and who was elected to Honorary Membership in 1937, passed away on his eighty-third birthday, May 9, 1943, at his home in Waltham, Mass. Waltham was the city of his birth and he resided there throughout his life.

He was born on May 9, 1860, the son of Benjamin and Mary Clapp (Ruggles) Worcester. His early educational and preparatory training was acquired at what was then called the Waltham New Church School (later known as Chapel Hill School), a private institution founded originally in 1860 by his father to serve a neighborhood group, and later opened to all suitable applicants. As a result of the splendid instruction received at this school, Mr. Worcester was enabled to enter Harvard University in Cambridge, Mass., in 1878 with advanced standing in mathematics and the classics.

In 1882 Mr. Worcester was graduated from Harvard University with the degree of Bachelor of Arts, and immediately entered the employ of the Boston Bridge Works, engineering department. At the end of two years of service with that company, he had become its chief engineer, in which capacity he soon acquired a widespread and favorable reputation as an outstanding authority on the subject of structural design.

The persistent demand for his services as consultant on important engineering projects, both public and private, led him to resign his position with the bridge company in 1894 and to open an office in Boston for the practice of consulting engineering exclusively. Twelve years later, he organized the business under the firm name of J. R. Worcester and Company, and assumed the position of senior partner. He continued his association with this concern until his death, although for the last seventeen years of his life his contribution was largely of an advisory character.

---

[1] Memoir prepared by Charles R. Gow and John P. Wentworth, Members, Am. Soc. C. E.

In the course of his experience as a consulting engineer, he was called upon to prepare the designs for many important engineering projects, among them the original Boston subway, together with various features involved in its later extensions; the elevated structure of the Boston Elevated Railway; the East Boston and Cambridge tunnels; the South Terminal Station train shed; and the Cambridge Viaduct. He likewise designed and supervised the erection of the steel arch bridge over the Connecticut River at Bellows Falls, Vt., the Harvard University Stadium, and the reinforced concrete bridge connecting the municipalities of Portland and South Portland, Me. He similarly collaborated with the late John R. Freeman,[2] Past-President and Hon. M. Am. Soc. C. E., in designing and constructing the Aluminum Reduction Plant at Niagara Falls, N. Y. These undertakings constituted but a few of the numerous projects of note with which he identified himself in the course of his long and active professional career.

Mr. Worcester was an early pioneer in the United States in developing the technique and principles of reinforced concrete design, and for a period of several years after its introduction he was recognized as a leading authority in that branch of engineering science. Most of the earlier structures of this character which were built throughout the New England territory were the product of his office.

At an early period of the present century, he acquired a reputation as a leading authority on the subject of foundation design, and his advice in this respect was widely sought and accepted throughout his entire engineering career. His elaborate paper on "Boston Foundations" published in 1914[3] has been considered a classic in that field and is still regarded as a most authoritative treatise on the subject. In recognition of its superior merit, the Desmond Fitzgerald Medal was awarded to its author by the Boston Society of Civil Engineers.

In the course of his active participation in the engineering field, Mr. Worcester was a prolific contributor of papers and discussions before the many technical organizations in which he held membership. The 1867 to 1920 "Index" of the Society alone lists twenty-one instances of his participation. He likewise contributed liberally of his time and knowledge in the delivery of student lectures covering the various phases of engineering science and practice upon which he was competent to speak with authority.

From 1904 to 1917, Mr. Worcester served as a member of the Society's Joint Committee on Concrete and Reinforced Concrete, and for several years as its chairman. He was likewise a member of the Society's Special Committee on Structural Columns and Struts. He similarly placed his exceptional talents at the disposal of many other professional organizations of which he was a member, and devoted himself generously to the propagation of sound engineering knowledge for the benefit of his contemporaries.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 1471.

[3] *Journal*, Boston Soc. of Civ. Engrs., Vol. 1, No. 1, January, 1914.

His contribution to the public service was also noteworthy. In 1921, Herbert Hoover, Hon. M. Am. Soc. C. E., then serving as Secretary of Commerce, selected Mr. Worcester as a member of the Federal Building Code Committee to which he rendered a conspicuous and invaluable contribution. Upon another occasion, the Governor of Massachusetts selected him as one of three citizens of the Commonwealth to serve as a Special Commission for constructing the six-million-dollar Memorial Bridge spanning the Connecticut River and joining the municipalities of Springfield and West Springfield in that state. His loyalty and devotion to his native city of Waltham were manifested on innumerable occasions by the advice and counsel which he frequently gave in connection with its various problems of an engineering or economic nature. He was a trustee and vice-president for many years of the Waltham Savings Bank, as well as president and trustee of the Waltham Hospital, to both of which institutions he devoted himself and his talents without stint. In addition, he served as a member of the City Hall and Library Commission of his native city. He was a member of the Piety Corner Club of Waltham, the Choral Society, and the Boston Handel and Haydn Society. He served as clerk of the Waltham Society of the Church of the New Jerusalem from 1883 until his death, a period of sixty years.

Because of his highly developed sense of fairness, his pronounced intellectual honesty, and his faculty of clear thinking and ready grasp of essentials, he was in constant demand for service as an expert court witness, as well as for arbitration proceedings. Few men of his time commanded greater respect and confidence than that which attended his statements and decisions in those capacities.

He was an inspiration to the younger members of his profession who constantly sought his opinion on problems entrusted to their care. He invariably took a kindly interest in their welfare and endeavored always to guide them along lines of sound and conservative engineering practice. He was extremely proud of his profession and devoted himself wholeheartedly to its advancement.

Throughout his lifetime, he retained a deep interest in the school which his father had founded and from which he had derived his early education. For a period of forty-three years, he served as a member of the governing board of the New Church Institute of Education. He was clerk of the Institute for twenty-five years and gave courses in the subject of astronomy in which he was deeply interested. His sound judgment and unusual foresight were continuously applied to guide the fortunes of the school through both good times and bad.

Mr. Worcester was extremely fond of outdoor life, particularly mountain climbing, bicycling, swimming, and sailing. An item in his mother's diary relates the fact that he climbed a mason's ladder to the piazza roof on his third birthday.

From early childhood, he always evinced a deep interest in some incidental activity. In the course of his younger school experience, he and some other boys built sextants for their own amusement and later on acquired a printing press from which he developed a hobby that he retained throughout his lifetime. To every such interest he devoted himself assiduously, never undertaking a task without completing it.

Among the pupils who attended the Waltham New Church School in his time was Alice Jeannette Wheeler, of Lincoln, Mass., who became Mr. Worcester's wife on January 2, 1889. Mrs. Worcester died on November 24, 1934. Five children were born to them, four of whom survive their parents. They are Alice Martha (Mrs. Clarence D. Howe), Barbara (Mrs. Charles T. Porter), Thomas, and Ruth Hunt.

To his many friends who had learned to love and admire his splendid personal qualities, Mr. Worcester's loss will be irreparable. His was a soul that knew no vanity, nor was he ever captivated by any sense of self-importance. He was inherently gracious, generous, and just, gifted with indomitable consistency and courage and absolutely unswerving and unselfish in his fidelity to his honest convictions. He worshipped at the altar of impersonal loyalty of principle and ever spoke the promptings of a heart to which guile and hypocrisy were total strangers.

His body, mind, and soul were unceasingly devoted to the service of others whether poor or rich, grand or obscure. With even temper, humility, and good nature he sought always to lighten the burden and trials of those about him. His aptitude of comprehension, his richness of imagination, and the rounded measure of his many splendid faculties were freely and lavishly bestowed upon all who sought his aid and counsel.

He stood uncompromisingly for independence, for courage, and above all, for absolute integrity. With unfaltering lip and heart, with a soul aflame for truth and righteousness, and yet entirely free from any trace of bitterness, he proved himself worthy of every confidence reposed in him by those who sought his guidance. His entire life, rich as it was in unselfish service, untinged by any prejudice and unconscious of a single unworthy motive, is entitled to wide emulation by those who follow after him.

Those who were privileged to benefit from the influence of his genial nature and to enjoy the blessings of the peaceful atmosphere of good-will which he invariably created will acknowledge freely the unusual debt of gratitude which they owe to one who contributed so much to their welfare in helping to make this world a brighter and better place in which to live, to labor, and to learn.

Joseph Worcester was elected a Member of the American Society of Civil Engineers on January 2, 1895, and an Honorary Member on October 4, 1937.

THOMAS DAVID ALLIN, M. Am. Soc. C. E.[1]

DIED OCTOBER 17, 1942

Thomas David Allin was born near West Branch, Iowa, on January 13, 1864, the son of John and Jamima (Townsend) Allin. Both his parents were of English ancestry, his mother's family having come to America prior to the Revolutionary War. The Allin family remained in Iowa until 1882, then moved to Southern California and settled in the new community which later was to become Pasadena, Calif.

---

[1] Memoir prepared by Morris S. Jones, M. Am. Soc. C. E.

Mr. Allin received his early education at the Iowa City Academy, Iowa City, Iowa. After arriving in Southern California he attended the Columbia Hill Academy in Pasadena for two years and in 1886 entered the University of California at Berkeley, the first boy to attend the State University from the Pasadena area. At Berkeley he completed a special course in civil engineering in two-and-one-half years. He took an active part in University affairs and was one of the charter members of the University of California Chapter of Phi Gamma Delta fraternity.

After leaving college in 1889 Mr. Allin spent several years in irrigation work as assistant engineer on the Elsinore Irrigation District Project in Riverside County, California, and later was assistant engineer on the Bear Valley Irrigation Company's development in San Bernardino County, California.

In 1891 he returned to Pasadena to enter private engineering practice and for the next fifty years was closely identified with the development of Pasadena and the neighboring communities of South Pasadena, Calif., and Alhambra, Calif. At one time or another, he served all three communities as city engineer.

In his professional work, Mr. Allin conducted a general engineering practice, specializing in land subdivision. He also was in charge of most of the water development for private water companies which supplied the Pasadena area during this period. As engineer for the Pasadena Lake Vineyard Land and Water Company, principal company serving water in the city, he laid out its pipe distribution system and built two large reservoirs of 19,000,000-gal and 16,000,000-gal capacities. He also directed its Devils Gate water development, which included an intercepting tunnel one-and-one-quarter miles long, which for many years was the major water supply of the city. He also was retained from time to time by the Pasadena Land and Water Company, the North Pasadena Land and Water Company, and many of the other smaller companies operating in Pasadena and adjacent territory.

Mr. Allin was city engineer of Pasadena from 1901 to 1905. During this time he laid out and supervised the enlargement of a sewage system, paved many miles of streets, and planned a city-wide system of drains to carry away storm waters. From the engineering viewpoint, this work helped to place Pasadena in the category of a modern city.

After leaving the city engineer's office, Mr. Allin returned to private practice, opening an office in partnership with his brother, Charles. In addition to his private work, he was consultant for the city on the planning and construction of the storm-drain system. He also reported on the type of sewage treatment plant best suited to the city and was instrumental in the selection of the activated sludge method of disposal. This plant was built at a cost of $500,000 and is used by the four cities, Pasadena, South Pasadena, Alhambra, and San Marino, Calif.

In 1913 he was elected commissioner of public works under the commission form of government and served until 1919. He was vice-chairman of the commission for the last four years of this period. Subsequently, from 1922 to 1938, he was a member of the Pasadena City Planning Commission, for four of those years as chairman.

Interested in many other civic, community, and welfare activities in Pasadena, he was honored by his fellow citizens by being given the Arthur Noble Award, an annual recognition granted to a Pasadena citizen for outstanding service to the city.

Mr. Allin had a gift of real friendship. He knew thousands of people by name, and they in turn called him "T. D." or "Tom." With pride and love, almost of a father, Mr. Allin saw Pasadena, the community of his choice, grow from a dusty settlement into a beautiful city. He helped in large measure to shape the city's destiny, yet his thoughts were never of any personal achievement but rather of wholehearted affection for his home town.

He was a loyal worker in the Methodist Church. He was a Thirty-Second Degree Mason and a Shriner. He was a member of the Pasadena Pioneers Association, the Pasadena Historical Society, New Century Club, and the Pasadena Chamber of Commerce.

On October 18, 1892, Mr. Allin was married to Jessie E. Patterson in Pasadena. Mrs. Allin survived her husband by only a few months. Their two children are Hazel (Mrs. Bert Rolfe) and Ralph Walter Allin.

Mr. Allin was elected a Member of the American Society of Civil Engineers on January 3, 1906.

THOMAS WARD BAILEY, M. Am. Soc. C. E.[1]

DIED NOVEMBER 18, 1942

Thomas Ward Bailey was born in Kingston, Mass., on February 19, 1874, the son of sea captain Frederick Coggswell Bailey and Helen May (Peterson) Bailey, of Kingston. He was born in the house built by David Bradford, grandson of William Bradford, an early governor of Massachusetts Bay Colony, and purchased in 1832 by Thomas Bailey, the grandfather of Thomas Ward Bailey.

At the early age of six years young Bailey enrolled in the Stony Brook District School of Kingston. There was one departure from routine during his grammar school years—at the age of nine he went on a sea voyage with his mother and father in the American bark *Nehemiah Gibson,* of which his father was captain. During the voyage, which lasted many months, the vessel touched at Batavia, Java, and Hong Kong, China. In later life Mr. Bailey recalled many interesting pleasures and educational features of this trip. He always regretted that he had not been older so that the voyage would have been even more interesting to him.

---

[1] Memoir prepared by Gibb Gilchrist, M. Am. Soc. C. E.

Upon finishing grammar school, Mr. Bailey entered Kingston High School, being graduated with honors as valedictorian of his class at the age of seventeen. He had not reached the minimum age requirement of his chosen college, the Massachusetts Institute of Technology at Boston, and as a result he spent a year in home study and in tutoring other less fortunate boys who desired to enter college with him. In September, 1892, Mr. Bailey entered Massachusetts Institute of Technology for the course in civil engineering, and was graduated with the degree of Bachelor of Science in June, 1896. Throughout his life Mr. Bailey improved himself by reading and study. In his mature years he was well known not only as a successful engineer, but as one who by much study and self-improvement had achieved for himself a well-rounded education in cultural subjects, the possession of which made him a more valuable engineer.

Immediately after graduation for two years, Mr. Bailey was with the Boston Transit Commission as rodman, instrumentman, and inspector, gaining much valuable experience in excavation, concrete, sewers, pile-driving, waterproofing, stonework, brickwork, and steel construction.

In 1898 he worked for the United States Government Engineers in connection with the fortification work in Boston Harbor during the Spanish-American War. From 1898 through 1904 Mr. Bailey was employed in various capacities, advancing to assistant engineer with the Massachusetts Harbor and Land Commissioners. During this period his experience in marine matters was enhanced, and, in addition, he became experienced in water terminal construction and operation which was an asset to him throughout his life. His last specific employment in connection with Boston Harbor, as superintendent of the dredging company, was terminated upon the completion of important dredging work in the main channel with the disposition of the dredge material at sea.

From 1904 through 1917 Mr. Bailey was in business as a civil engineer in Plymouth, Mass. In addition to the consulting service, he directed surveying and mapping crews on various civil engineering projects in that vicinity. This work involved investigation and reports on agricultural, power, timber, irrigation, and reclamation projects; building electric transmission lines; construction of municipal works including bridges, sewers, and water works; and evaluations, as well as research on land titles and subdivisions.

Mr. Bailey served on the Mexican border in 1916 as a non-commissioned officer in the Second Brigade, Massachusetts Voluntary Militia.

Immediately upon the declaration of World War I in 1917, Mr. Bailey entered the first officer training camp at Plattsburg, N. Y. He was ordered to active duty as First Lieutenant in the Corps of Engineers on July 13, 1917, and went to France with the 101st Regiment of Engineers, 26th Division, in September, 1917. He served with his regiment in the combat areas until August, 1918, when he was ordered back to the United States pursuant to an order sent by the Adjutant General to Gen. John J. Pershing, from which the following is quoted:

> "In order to provide officers and noncommissioned officers for new divisions about to be organized it is necessary to have some of the officers and noncommissioned officers selected from your forces who are efficient, who have had training in France in the latest methods of warfare, experience in the face of the enemy and who are deserving of promotion."

When he returned to the United States, Lieutenant Bailey was commissioned a Captain of Engineers on August 20, 1918. From that time until January, 1919, he served with the 7th Engineer Training Regiment at Camp Humphreys, Virginia, and, from January, 1919, until August, 1919, he was with the Statistics Branch of the General Staff at Washington, D. C.

Upon leaving the army Captain Bailey retained his reserve commission. It is not known when this was terminated, if at all, but he was on reserve status with the United States Army at least through 1934 and perhaps later. In person and in official correspondence he was designated by his military title; always it seemed the right and proper designation for him.

On November 4, 1910, Thomas Ward Bailey was married to Mary I. Perkins, of Plymouth. He is survived by his widow and one son, Harold Thomas Bailey, who was graduated from The Agricultural and Mechanical College of Texas, at College Station, in 1935. Kingston and Plymouth are only a few miles apart, and both Captain Bailey's antecedents and those of his wife trace back to the Pilgrim fathers who first landed at Plymouth in 1620. The staunch integrity of these pioneer Americans was in evidence in the character of Captain Bailey throughout his life wherever he lived and also in the character of his wife and son.

In 1921 through 1924 Captain Bailey was with the Holway Engineering Company on the Spavinaw Water Project at Tulsa, Okla. He served throughout this project, first on the preliminary survey and finally as division engineer on the construction of the 54-mile conduit, costing $4,000,000. From 1924 through 1926 he was with the Oklahoma State Highway Commission as resident engineer on state highway projects in Rogers County, with headquarters at Claremore, Okla. During this period he was in charge of highway location and design, as well as construction and maintenance. In November, 1926, he was appointed division engineer of the Oklahoma State Highway Department, with headquarters at Tulsa. In this capacity, he supervised construction and maintenance in seven Oklahoma counties.

In September, 1927, Captain Bailey accepted a position as division engineer for the Texas State Highway Department, Division No. 16, with headquarters at Corpus Christi, Tex. At that time the division comprised twenty-one counties. He continued in this position until the latter part of 1938, when he was transferred to Del Rio, Tex., as division engineer of District No. 22. At Corpus Christi, Captain Bailey was close to the sea, and to the end of his life he loved the water and all that pertained to marine activity. In 1933 a coastal storm washed away the deck of the 2-mile wooden trestle across Corpus Christi Bay, linking his headquarters city with the coastal towns to the east. Because of his knowledge of coastal storms and the inflow and outflow of storm tides, Captain Bailey was able to recover 90% of the timber decking, much of which had floated back to sea after subsidence of the storm, and in 60 days the bridge was reconstructed and in use.

After his family, his country, and his profession, it is evident that Captain Bailey's chief interest was in the sea. He was familiar with every nook and cranny along the Texas coast from Rockport to Boca Chica. He always knew where the best duck hunting and fishing might be found; he always owned a boat; and he was never happier than when he could be on or near the water.

As a professional man, Captain Bailey was respected for his ability. His knowledge and training were such that he could be depended upon to solve any problem, major or minor. His work in south Texas exemplifies this ability. He found time to make friends with almost every one in his district, including both those who worked under his direction and those for whom he toiled.

Thomas Ward Bailey was elected a Member of the American Society of Civil Engineers on July 15, 1929.

BERNARD BENFIELD, M. Am. Soc. C. E.[1]

Died March 4, 1943

Bernard Benfield, the son of Elias and Bertha (Kunreuther) Benfield, was born in New York, N. Y., on December 11, 1861. In 1862, his family moved to California. His early education was obtained at the San Francisco (Calif.) Boys' High School, from which he was graduated in 1878. He attended the University of California, at Berkeley, and was graduated with the degree of Bachelor of Science in Civil Engineering in 1882.

Immediately after graduation, Mr. Benfield became a rodman for the Oregon Railway and Navigation Railroad Line and also assistant engineer on construction and in the office. During 1883 he was engaged on irrigation canal work in southern California and later was office man and levelman on railroad location with the Southern Pacific Railroad Company from Redding, Calif., north. During this period the so-called "Hood Taper" or transition curve for railroads, was developed, and he collaborated with the late William Hood,[2] M. Am. Soc. C. E., of the Southern Pacific Railroad Company, in preparing the tables. In 1884 as assistant engineer with the Southern Pacific Railroad Company, he had charge of railroad reconstruction work in western Texas.

From 1885 to 1890 Mr. Benfield was on independent work in California. In 1890 he returned to the Southern Pacific Railroad Company as assistant engineer on railroad construction in California and Arizona. In 1893 he became associated, as assistant engineer, with the Pacific Improvement Company, a branch of the Southern Pacific Railroad Company. While holding this position, he discovered and developed an extensive vein of asphalt and introduced and actively promoted the use of California asphalt throughout the United States. He managed the business of the Standard Asphalt Company, a subsidiary of the Pacific Improvement Company, for many years and was president of the former company in 1900.

---

[1] Memoir prepared by a Committee of the San Francisco Section consisting of Walter H. Kirkbride, Chairman, E. T. Thurston, and Charles B. Wing, Members, Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 1096.

In 1901 Mr. Benfield was appointed on a commission of engineers to appraise the Kern River Oil Fields in California. At the same time, he was engaged as geologist by the Associated Oil Company, in which capacity he visited and reported on the oil fields of Borneo and other islands of the Dutch East Indies. Thenceforth, his professional work covered a wide field, including chemistry and geology as well as civil engineering.

Mr. Benfield maintained a constant and active interest in the welfare of the community in which he lived, and belonged to the Commonwealth Club of California and other organizations for civic betterment.

One of Mr. Benfield's particular hobbies was astronomy. Becoming an affiliate of the Astronomical Society of the Pacific in 1916, he at once became interested in the affairs of that society and served it in many ways—as a member of its board of directors, as vice-president for several years, and as president in 1925. At his suggestion, the Astronomical Society of the Pacific began the publication of *Leaflets,* and he personally financed and helped to edit the earlier numbers. Throughout the years he contributed generously to the support of lectures sponsored by this society. The directors named him a "Patron of the Society." He was also a "Fellow" of the Royal Astronomical Society of England.

Mr. Benfield was never married; he was a kindly man, and a devoted son and brother.

Mr. Benfield was elected a Member of the American Society of Civil Engineers on May 6, 1903.

REGINALD PELHAM BOLTON, M. Am. Soc. C. E.[1]

DIED FEBRUARY 18, 1942

Reginald Pelham Bolton, a member of the Society for more than forty years, who died on February 18, 1942, at his home in the Washington Heights section of the Borough of Manhattan, New York, N. Y., led a life of great usefulness not only as an engineer but as an American citizen interested in the social and political life of the community.

Although he was born in England, October 5, 1856, he had a line of American ancestors extending through five generations from Robert Bolton, a native of Yorkshire, England, who emigrated to America in 1718, settling first in Philadelphia, Pa., and later at Savannah, Ga. Reginald's father was the Rev. James Bolton, connected for a time with the Pelham Priory in Westchester

---

[1] Memoir prepared by Rudolph P. Miller, M. Am. Soc. C. E.

County, New York. His mother was Lydia Louisa Pym of Hertfordshire, England. The ancestry of the Bolton family has been traced to Oughtred de Bolton (1100–1135) among whose descendants was the late Channing Moore Bolton,[2] M. Am. Soc. C. E.

Mr. Bolton's early education was obtained in the private schools of Wimbledon, England, referred to as "ordinary home schools" in his application for membership in the American Society of Mechanical Engineers. His engineering education was begun at the age of seventeen at the shops of James Waite in Epsom, Surrey, England. At nineteen he was apprenticed to Messrs. Powis, James and Company of Lambeth, London, England, where he worked in the designing department. In 1878 he was a draftsman with Davey, Paxman and Company of Colchester, England, a firm of agricultural and mining engineers. In December, 1879, a desire for wider experience brought him to the United States, where he found employment as assistant engineer in the Edgemoor Iron Works at Wilmington, Del. About two years later he was assistant to the late Erasmus D. Leavitt,[3] M. Am. Soc. C. E., of Boston, Mass., consulting engineer to the Calumet and Hecla Mining Company on the design of engines and mining machinery. In November, 1881, ill health caused Mr. Bolton to return to England, where he established his own business as a consulting engineer. In 1888 this was interrupted for about a year when Mr. Bolton became general manager for Appleby Brothers Limited of Greenwich, London, England, a firm of prominent crane engineers.

In connection with his professional practice he traveled extensively in England and on the European continent, designing and supervising the erection of machinery and special machine tools. At the Elmore Company's works at Leeds, England, he introduced electric hoisting machinery. He designed and installed the first mining plant for the Gordo sulfur mines at Caltanissetta, Sicily. Other works designed and installed by him included a dredging plant at Taranto, Italy; a mining plant for contractors at Naples, Italy; electric light plants in the Asturias, Spain; and a large gantry crane at Rotterdam, Holland. For the Italian Transport Commission he designed marine engines, and for the governments of Spain and Mexico he designed stern-wheelers and other boats.

Mr. Bolton had a number of inventions to his credit. His earlier products, developed before he came to the United States, included a hydraulic governor (patented in the United States), the Bolton and Hartley air compressor (1882), an electric crane gearing (1890), and electrical rock-boring and hammering apparatus (1891). He devised and introduced into the tall office buildings of New York a system of vertical wiring, as well as a system of multiple water supply for fire and house service.

When he came to the United States in 1894 to settle permanently, the character of his work changed. This was the period of the development of the skyscraper, the equipment of which opened up a new field for the engineer. Mr. Bolton became a leading engineer on the design of heating and ventilating methods, electric lighting and power plants, elevator installations, and plumbing and drainage systems. Among the buildings in New York City equipped by him or for which he acted as consultant were the Bowling Green Building, Syndicate Building, Lord's Court, Silk Exchange, Central Bank Building, R. G. Dun Building, La Rochelle Hotel, Grand Central Terminal, Ansonia Hotel, and Ridgwood Pumping Station of the New York Department of Water Supply. The Narragansett Electric Light and Power Company, New York Edison Company, and R. H. Macy and Company were a few of his clients.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 1633.

[3] For memoir, *ibid.*, Vol. LXXXVII (1924), p. 1376.

The active part that Mr. Bolton took in the development of the equipment of the modern skyscraper, without which the high office building could never have attained the success it enjoyed for so long a period, is attested not only by the many installations he designed but, more especially, by his contributions to technical literature and by his activity in the promotion of reasonable regulations, both governmental and otherwise, in relation to safety and good practice. In this connection he made the following contributions: In 1900 at the annual convention in London, England, joining a general discussion on the "Height of Buildings";[4] in 1901 commenting on the article by Charles G. Darrach on the "Mechanical Installation in the Modern Office Building";[5] and in 1904, discussing by letter a comprehensive paper by Thomas E. Brown on "Passenger Elevators"[6] at the International Engineering Congress at St. Louis, Mo. His paper on "The Operation of Passenger Elevators"[7] presented a subject to which he had given much study and involving considerable research. He also wrote several articles for the American Society of Mechanical Engineers on the following topics: "The Equipment of Tall Office Buildings in New York City,"[8] "Test of a Hydraulic Elevator System,"[9] "The Power Plant of Tall Office Buildings,"[10] and "Operating Conditions of Passenger Elevators."[11] Ten papers by him, between 1897 and 1915, dealing generally with operating conditions in steam heating systems, are included in the *Transactions* of the American Society of Heating and Ventilating Engineers.[12]

In his treatment of the subject of the equipment of high buildings Mr. Bolton always stressed the elevator installations as a most important element. In his discussion of the paper by Mr. Darrach he held that "without transportation high buildings would be folly." At the time he came to the United States, although tall buildings (some as high as twelve stories) were not unknown, the development of the real skyscraper, and with it the elevator installation, was just starting. Mr. Bolton took a prominent part in that movement. He was generally present at public discussions and ready to help arrive at safe and reasonable standards, especially when they were under consideration as governmental regulations. His influence was always directed toward public safety. One of the active topics in this connection was the necessity or desirability for door and car interlocks. The relative merits of hydraulic and electric elevators, more particularly from the standpoint of economy of operation, was another open question. The practicability and limitations of the plunger elevator were much discussed. On all these matters he freely expressed his opinions based on a wide experience.

[10] *Ibid.*, Vol. XXV, 1904, p. 1011.

[11] *Ibid.*, Vol. 32, 1910, p. 1295.

[12] "Circulation of Steam for Heating Purposes at or Below the Pressure of the Atmosphere," *Transactions*, Am. Soc. of Heating and Ventilating Engrs., Vol. III, 1897, p. 155; "The Element of Time in Contracts," *ibid.*, Vol. VII, 1901, p. 43; "Depreciation, Maintenance and Interest Charges," *ibid.*, Vol. VIII, 1902, p. 82; "Smoke and Gas-Flue System in the Ansonia Apartment Hotel, New York," *ibid.*, Vol. IX, 1903, p. 144; "Steam-Heating in Connection with Condensing Engines," *ibid.*, Vol. XI, 1905, p. 64; "The Use and Abuse of Fuel," *ibid.*, Vol. XVIII, 1912, p. 57; "Definition of the Unit of Heat," *ibid.*, p. 299; "Hydro-Electric Power Compared with Steam," *ibid.*, Vol. XX, 1914, p. 374; "The Problem of City Dust," *ibid.*, Vol. XXI, 1915, p. 225; and "The Establishment of a Standard for Transmission Losses from Buildings of All Constructions," *ibid.*, p. 552.

His contributions to technical literature were not limited to the papers and discussions appearing in the publications of the several societies of which he was a member. He often addressed organizations, such as the National Council for Industrial Safety, the annual convention of Building Managers and Owners, and others, in the interest of public safety. Some of his more pretentious technical works were on the following subjects: "Motive Powers and Their Practical Selection" (1895); "Elevator Service: Operating Conditions and Proportions, with Diagrams, Formulas and Tables for Passenger Travel" (1908); "Building for Profit: Principles Governing the Economic Improvement of Real Estate" (1911); "An Expensive Experiment: The Hydro-Electric Power Commission of Ontario" (1913); "Power for Profit: Principles Governing the Use of Machinery and Labor in Modern Buildings" (1915); "Results of the Test of the Steam and Electric Plant at the Hall of Records, New York City" (1916); and "A Municipal Experiment: Or the Hall of Records Power Plant" (1917).

Mr. Bolton was most interested in professional activities. In addition to his membership in the Society, he was a charter member of the American Institute of Consulting Engineers, from 1899 a member of the American Society of Mechanical Engineers, from 1902 to 1907 a member of the American Society of Naval Engineers, and from 1918 a member of the New York Electrical Society. In 1897 he joined the American Society of Heating and Ventilating Engineers of which he was president in 1911, was elected to life membership in 1929, and was made an honorary member in 1936 "In recognition of the eminent place occupied as a consulting engineer, author and historian." In these several technical organizations, except the Naval Engineers, he retained his membership up to the time of his death. Before Mr. Bolton came to the United States he had been inducted as associate member in the Institution of Civil Engineers of London, England. In 1902 this organization awarded him the Telford (gold) Medal for his paper on "The High Office Buildings of New York."[13] His connection with the English body lasted slightly over half a century.

Mr. Bolton, a very active man in his own chosen profession, had wider interests than engineering. It was nearly half a century before his death that he made his home in Washington Heights, then a sparsely settled section of Manhattan. Relics of early Indian habitations in which this region abounded aroused his interest. His studies of these remains and research into the life and living of the colonial period of his neighborhood and of the surrounding country was so thorough that he became an authority on the history of New York and Westchester counties. His advice was frequently sought regarding the significance of artifacts or human bones that were from time to time unearthed when excavations were being made for new buildings or public works. Many of his findings have been recorded in pamphlets published by himself or in publications of the Museum of the American Indian (Heye Foundation), the Empire State Society of the Sons of the American Revolution, the Dyckman Institute, and the American Scenic and Historic Preservation Society. Because of his activities in this field, he received an honorary life membership in the New York Historical Society. He also belonged to the City History Club, The American Folk Lore Society, and the American Scenic and Historic Preservation Society (at one time, trustee).

---

[13] *Proceedings*, Institution of Civ. Engrs., Vol. CXLIII, London, 1901, p. 213.

He was a leading spirit in the efforts made to preserve for posterity historic landmarks of New York City. Among these landmarks were the Jumel Mansion on Washington Heights, not far from his home, built in 1758 and serving in the early days of the Revolutionary War as Washington's Headquarters; Poe's Cottage in The Bronx, once the home of the poet; and the Dyckman Museum in Manhattan, built in 1748, the only eighteenth-century farmhouse still existing on Manhattan. In 1931 he was enthusiastically active in the movement to make the New York home of the naturalist, James J. Audubon, a national shrine.

Busy as his professional work and the activities of historic investigation must have kept him, Mr. Bolton found time to take part in civic affairs. His devotion to such matters caused him to be known in his locality as the "Number One Citizen of Washington Heights." He took an active part in the local taxpayers association of which he was secretary for more than twenty years, and, at the time of his death, its honorary president. His membership in the Municipal Art League was another instance of his interest in civic affairs.

Like most of his forebears he was closely identified with the Protestant Episcopal Church. In his latter years he attended the Chapel of the Intercession, a part of Trinity Parish of New York City. He one time boasted of his numerous relations connected with the Church. His father, ordained in England as a priest in 1849, "as a preacher to children was never surpassed." His two grandfathers, two great-grandfathers, two great-great-grandfathers, two brothers, and six uncles were in the priesthood.

Reginald Pelham Bolton was married at London, England, in 1878, to Kate Alice Behenna, youngest daughter of Capt. Henry Behenna, R. A. She died in 1891 before he came to this country to live, leaving him two children—a daughter, Ivy May Bolton, who later entered the Protestant Episcopal Community of St. Mary at Peekskill, N. Y.; and a son, St. George Guy Reginald Bolton, a playwright associated with W. Somerset Maugham in the production of "Theatre." Another son died in infancy in England. He was married for the second time at Pelham, N. Y., in 1892, to Ethelind Huyck, daughter of Leonard Huyck. Mrs. Bolton survives him.

It would seem appropriate that this memoir close with a few lines of a poem "The Worm" from "Vagabond Verse" published in 1937. In this poem Reginald Pelham Bolton is reflecting on the futility of earthly possession when death comes, and he continues:

"But in their graves are never hid
The good and generous things they did
Nor in the quiet earthy bed
Are laid the kindly words they said.

"Above the sods these all remain
And spring to life in Man again
These are sweet things Death never parts
That live and grow in human hearts."

Mr. Bolton was elected a Member of the American Society of Civil Engineers on September 6, 1899.

CHARLES EDWARD BOWRON, M. Am. Soc. C. E.[1]

DIED JUNE 17, 1942

Charles Edward Bowron, son of James and Ada Louisa (Barrett) Bowron, was born in Redcar, Yorkshire, England, on May 25, 1871. His parents came to the United States when he was a child.

He attended public schools in Nashville, Tenn., and Vanderbilt University in Nashville, from which he was graduated with the degree of Bachelor of Engineering in 1891.

His first engineering experience was with the Tennessee Coal, Iron and Railroad Company of Pratt City, Ala., as rodman in coal mines. Following this, he was resident engineer for four years at Tracy City, Tenn.; for one year at ore mines in the Birmingham (Ala.) district; and for one year at the Ensley (Ala.) Steel Plant of Tennessee Coal, Iron and Railroad Company. He then served as purchasing agent and acting chief engineer for Alabama Consolidated Coal and Iron Company (later Sloss, Sheffield Steel and Iron Company) in Birmingham, operating coal and ore mines, coke ovens, and blast furnaces. In 1901 he became general superintendent of Lookout Mountain Iron Company in Battelle, Ala., and supervised the construction of blast furnace, coke ovens, village improvements, water works, and the opening of coal and ore mines. Then, as consulting engineer, he designed various industrial plants in the Birmingham district.

---

[1] Memoir prepared by A. Clinton Decker and Carlton A. Wilmore, Members, Am. Soc. C. E.

In 1906, Mr. Bowron went to California as construction superintendent for the Pacific Fruit Express (Southern Pacific Railroad Company) on refrigerating plants at Colton, Calif., and Roseville, Calif.; an icing plant at Carlin, Nev.; and a reinforced concrete dam at Truckee, Calif. His next tour of duty was with International Vacuum Precooling Company in Chicago, Ill., as engineer and superintendent of construction on railroad precooling plants at San Benito, Tex., and Charleston, S. C. During this same period, he supervised construction of ice plants at Harlingen, Tex., and Bay City, Tex.

In 1915 he became chief engineer for Gulf States Steel Company in Birmingham, remaining in that position through 1937. Work under his direction included blast furnaces, open-hearth furnaces, coke ovens, blooming mill, annealing plant, plate and sheet mills, copperas plant, the electrification of rod mill, power plant, shops, coal and ore mines, quarry, mine haulages, tipples, coal washer, water works, office, stores, construction of and improvements in villages, and general engineering supervision of all operation.

In 1937 Mr. Bowron opened consulting offices in Birmingham. However, in 1940, he was appointed chief engineer on building construction for the State of Alabama, continuing in this capacity until he died.

He served as chairman of Suggestion Committee, U. S. Patent Office, and was author of the book *Dimensions of Bars* for bar dimensions.

The scope of the construction projects on which Mr. Bowron was engaged is indicative of his broad knowledge in engineering and executive fields. He was a man with a keen analytic mind and a great student, industrious and persevering, but withal so modest and retiring, that one had to know his works in order to appreciate his true worth. He possessed a keen dry wit which was known to and appreciated only by his intimates. A great lover of home and family, his home life was as nearly perfect as possible.

Mr. Bowron was, throughout his adult life, a member of the South Highlands Presbyterian Church of which he was a deacon and treasurer for many years. He often referred to this service as his "one real hobby."

He was a Registered Professional Engineer in the State of Alabama. He was active in fraternal work and was a member of Birmingham Temple Lodge 636 A. F. and A. M.; the Alabama Consistory, Scottish Rite; and Zamora Temple Shrine.

His long and meritorious professional service, forthright honesty, loyalty to associates and friends, and his many civic and religious activities are an eloquent tribute to a distinguished engineer, a courteous gentleman, and a fine citizen.

On May 25, 1897, he was married to Adelaide Reilly at South Pittsburg, Tenn. He is survived by his widow; two daughters, Dorothy (Mrs. John B. Collins) and Lillian (Mrs. Fred W. Streit, Jr.); one sister; and eight brothers.

Mr. Bowron was elected a Member of the American Society of Civil Engineers on March 14, 1938.

SYLVESTER QUAYLE CANNON, M. Am. Soc. C. E.[1]

DIED MAY 29, 1943

Sylvester Q. Cannon was born in Salt Lake City, Utah, on June 10, 1877. He was the son of George Q. and Elizabeth (Hoagland) Cannon, both 1847 pioneers of Utah. His father was an editor, a delegate to Congress, a director of the Union Pacific Railroad Company, and a member of the First Presidency of the Church of Jesus Christ of Latter-Day Saints.

After work at the Latter-Day Saints (L.D.S.) College and University of Utah, both located in Salt Lake City, Mr. Cannon attended the Massachusetts Institute of Technology at Boston for four years and was graduated with the degree of Bachelor of Science in Mining Engineering in 1899. Immediately after he was graduated he was called by his church to serve as an unpaid missionary to the Netherlands and Belgium. He became a fluent speaker of Dutch and French and presided over the group of elders in that mission during the latter part of his three-year stay. During this time he made a journey to Palestine.

Soon after his return to the United States he was married to Winnifred Saville. They had four sons, Julian, Winfield, Lawrence, and Donald James; and three daughters, Elinor, Sylvia, and Lucile. The two youngest sons are in the service of the United States.

In 1902 Mr. Cannon began his active practice of engineering, devoting himself to mining, a business in which his family was extensively interested. However, his inclinations, which were conservative, gradually led him to other fields. From 1905 to 1907 he was in charge of hydrographic and irrigation surveys of the Weber River System in Utah, under the direction of the state engineer.

For two years, 1907 to 1909, with his wife and two young children he again went to Europe, being called to serve a second time by his church as president of the Netherlands-Belgium mission. On his return he went into hydraulic and irrigation engineering practice and in 1912 was employed by Salt Lake City to look after its complicated water supply. A year later in April, 1913, he was chosen city engineer, serving until August, 1925. In this capacity, Mr. Cannon was in charge of all engineering and construction, including water supply and water system, sewer construction and maintenance, 60 miles of street pavement, construction of sidewalks, smoke abatement work, and city planning and zoning. Some $11,000,000 was spent under his direction.

During his employment by Salt Lake City, Mr. Cannon arranged many water exchanges with farmers. The farmers, inheriting rights to the mountain streams, which were so well suited to culinary purposes, accepted in exchange water from Utah Lake which was equally suitable for irrigation. The city had acquired the lake water during the days of Brigham Young to provide means of transporting stone through a canal from the mountain quarry for the construction of the Salt Lake Temple. The coming of the railroad made the canal unnecessary, but the water rights acquired were very valuable to the city for exchange purposes.

---

[1] Memoir prepared by a Committee of the Utah Section consisting of Richard R. Lyman, Chairman, R. A. Hart, and R. K. Brown, Members, Am. Soc. C. E.

As city engineer, Mr. Cannon approved the design and supervised the construction of the Mountain Dell Multiple Arch Dam for the reservoir in Parley's Canyon (reinforced concrete, 140 ft high, 610 ft long at the top) and designed and supervised the construction of the Lake Phoebe-Mary Dam (60 ft high and 330 ft long) and the Twin Lakes Dam (72 ft high and 650 ft long)—all for the storage of culinary water for the city.

In 1933 he was one of the three members of the advisory board set up by the federal government through the Public Works Administration to scrutinize and pass upon all state, county, and municipal projects in Utah for inclusion in the $3,300,000,000 federal fund for public works.

Mr. Cannon was a member of the Sons of the American Revolution and of the Timpanogos Club. In 1914–1915 he was president of the Utah Society of Professional Engineers. He had been a member of the Chamber of Commerce and devoted much time to city planning.

From May, 1913, to October, 1925, he was chairman of the Board of Canal Presidents, supervising and directing the Utah Lake Pumping Plant and distributing water to the five main canal companies that supply the irrigation water for Salt Lake Valley. From July to September, 1923, Mr. Cannon acted as consulting engineer for the United States Reclamation Service on public improvements for the new town of American Falls, Idaho.

In June, 1925, an important change occurred in his life when he was chosen by his church to be its Presiding Bishop. (This officer has large responsibilities in the temporal affairs of the institution and is one of its General Authorities.) Mr. Cannon's engineering, as well as his missionary and other spiritual, background was an asset to him in his work. Supervision of buildings, their construction, and other obligations took Mr. Cannon through most of the western United States. Administrative work brought him in close contact with highly varied activities.

Mr. Cannon was president of the board of trustees of the Dr. Groves L.D.S. Hospital at Salt Lake City; the Dee Hospital at Ogden, Utah; and the Idaho Falls Hospital at Idaho Falls, Idaho—all church owned. He was also president of the L.D.S. Business College, Zion's Aid Society, Deseret Gymnasium, McCune School of Music and Art, Radio Service Corporation of Utah (KSL), and Deseret News. He was treasurer of the Uintah Basin Construction Company, supervisor of Salt Lake County Drainage District No. 2, director of Zion's Cooperative Mercantile Institution, Zion's Securities Corporation, Utah Hotel Company, Amalgamated Sugar Company, and U. S. Fuel Company. By appointment of the Governor of Utah, he was chairman of the Special State Flood Commission (September, 1930, to February, 1931) and of the State Advisory Council for Unemployment (August, 1931, to January, 1932).

In April, 1938, Mr. Cannon was chosen assistant to the Council of Twelve Apostles and in October, 1939, one of the members of that council. In discharge of his new duties he traveled almost constantly throughout the United States and also in Hawaii and in Europe.

Mr. Cannon's blameless life, his calmness, and pleasant demeanor gave him a place in the hearts of a great circle of friends. His honesty, tolerance, and thoroughness fitted him for his responsibilities in business, civic, and church positions. He was a tall man in stature and character, and he walked with dignity through life.

Mr. Cannon was elected a Member of the American Society of Civil Engineers on January 15, 1917.

WOOLSEY MOORMAN CAYE, M. Am. Soc. C. E.[1]

Died July 28, 1942

Woolsey Moorman Caye was born at Louisville, Ky., on January 27, 1885, the son of Dr. William Cassius Caye, Sr., and Priscilla (Moorman) Caye.

Mr. Caye was educated in the public schools of Louisville. At du Pont Manual Training High School, which he attended from 1900 to 1904, he is remembered as captain of the famous 1903 football team which defeated the rival team of Louisville Male High School 17–7. While in high school, Mr. Caye gave evidence of his great ability as a designer and draftsman. He produced some freehand drawings of ships and other subjects which were considered by some people to be masterpieces.

Although his father and others urged him to continue his education at college, Mr. Caye was anxious to start active work, and, therefore, secured a job on railroad construction in Mississippi in 1904. He remained in the South for about one year, working on railroad, dock, and harbor construction projects in Mississippi and Alabama. In June, 1905, he returned to Louisville and accepted a position as draftsman with the municipally owned Louisville Water Company in connection with the construction of the Crescent Hill Filtration Plant and additions to the city's water-distribution system.

In December, 1908, he left the Louisville Water Company and entered the employ of the Commissioners of Sewerage of Louisville, a separate nonpartisan municipal corporation established by an act of the Kentucky State Legislature for the purpose of handling the proceeds of a $4,000,000 sewer bond issue of the City of Louisville. Mr. Caye was employed as inspector on construction work and, later, as draftsman in the office. The high quality of the work done by the Commissioners of Sewerage and the training he received (at this time and later) under the chief engineer, J. B. F. Breed, and the designing engineer, J. H. Kimball, M. Am. Soc. C. E., had a permanent influence on Mr. Caye's future career. Mr. Kimball, particularly, took pains to instruct him in design work. In March, 1912, when the Commissioners of

---

[1] Memoir prepared by C. Frank Johnson, M. Am. Soc. C. E.

Sewerage completed this work and dissolved, Mr. Caye went with the Board of Public Works of the City of Louisville, as assistant engineer in a special engineering department on the design and preparation of contract plans and specifications for certain sewerage, drainage, and similar work.

From February, 1915, when he left the Board of Public Works of the City of Louisville, until May, 1916, he was computer with the Miami Conservancy District of Dayton, Ohio, on the design of flood-protection, sewerage, and allied projects for the Miami River Valley—a $35,000,000 undertaking. On this job he again worked under Mr. Kimball, his former supervisor in Louisville.

When the First Kentucky Infantry of the Kentucky National Guard was ordered into active service, in May, 1916, because of the Mexican border trouble, Mr. Caye resigned his position and enlisted in this regiment. After a period of training at Hattiesburg, Miss., he served on the Mexican border, as First Lieutenant of infantry. Later he took artillery instruction at Fort Sill, Oka., and was promoted to Captain in the field artillery. He then went to France, where he served with the 138th Field Artillery in the American Expeditionary Force.

Upon his return to the United States, in May, 1919, he rejoined the organization of the Miami Conservancy District in Dayton as assistant engineer on the design and preparation of contract plans for flood-protection works.

In November, 1920, a second Commissioners of Sewerage of Louisville was established, and Mr. Caye returned to Louisville to serve this organization as designing engineer, in charge of all design. He continued in this position until the death of Mr. Breed, chief engineer, in January, 1928, when he was placed in charge of the entire engineering department, with the title of "consulting technical engineer." In this capacity he performed the duties, and had the responsibility, of a chief engineer, and he continued in this position until his death.

During Mr. Caye's service as designing engineer for the commission (1920–1928), sewerage and drainage work to the value of $7,000,000 was designed, put under contract, and constructed, including a large creek-improvement project with a concrete channel and several tunnel projects, as well as many trunk and main sewers of conventional design. Practically all of this construction required reinforced-concrete sewers of the larger sizes.

During the period (1928–1942) when Mr. Caye was in full charge, sewerage and drainage work costing $11,000,000 was completed by the Commissioners of Sewerage of Louisville. Perhaps the outstanding achievement of this period was the construction of the Southwestern Outfall, a combined sewer serving a large part of the city. This sewer is 4.2 miles long, cost slightly more than $3,855,000, and has an inverted egg-shaped section ranging from 15 ft 8 in. wide by 23 ft 6 in. high, to 18 ft 4 in. wide by 27 ft 6 in. high, interior dimensions. This is probably one of the largest sewerage projects ever completed in the United States. The sewer was constructed through water-bearing material, the ground water varying from 10 ft to 27 ft above the elevation of the inside bottom of the sewer. After completion of this project, the ground-water infiltration into the sewer was measured and found to be practically nil—evidence of first-class construction under difficult conditions.

Besides supervising the design and construction of sewerage and drainage projects, Mr. Caye initiated and directed for the commission many special studies of problems relating to sewerage work. Among these was the study made in 1940 of the sewage-treatment problem of Louisville. Also, in connection with the unprecedented 1937 flood of the Ohio River at Louisville and the resulting proposed flood-protection work, he made several comprehensive investigations and studies of sanitary and hydraulic problems affecting the city sewerage system directly or indirectly.

Mr. Caye took a leading part in the development of Louisville's modern sewerage system. As a result of his insistence and that of his predecessor, Mr. Breed, upon the adoption of high standards, the quality of the engineering and construction work at Louisville probably is exceeded by that of very few cities. The commission's work has always had the reputation of being "the last word" in the field of sanitary and hydraulic engineering. In supervising the design, Mr. Caye utilized the latest and most scientific methods known to him. He was responsible for the introduction of many innovations in Louisville's sewerage system.

Mr. Caye was interested in seeing that the city received a dollar of value for every dollar spent. He insisted on the scrupulous performance by the contractors of their engagements and, to this end, imposed a rigid inspection, which applied impartially to all contractors. Similarly, he insisted that the engineering employees of the commission observe the highest standards in their work. No careless or make-shift work was acceptable. The merit system strictly prevailed, in employing and retaining personnel. No political or other similar considerations ever influenced in any degree the hiring or retention of the employees of the engineering department, and such considerations did not influence any work under Mr. Caye's direction.

Mr. Caye worked energetically and enthusiastically on any project with which he was concerned. One of the members of the sewerage commission by which he was employed stated that Mr. Caye was the "most intense man" he had ever known. This very intenseness may have contributed to his death at the comparatively early age of fifty eight. About a year before his death he had suffered a heart attack from which he appeared to have recovered fully. However, he was under his physician's order to take better care of his heart by not working so hard. This proved to be difficult for him to do. His death came suddenly at lunch one day, during a period when he was working just as hard as, if not harder than, ever.

Mr. Caye took an active part in professional affairs. He was a member of the Engineers and Architects Club of Louisville, and its president in 1931. He was a charter member of the Kentucky Society of Professional Engineers, having served as vice-president in 1935 and 1936, as president in 1939, and as a member of the board of direction in 1934, 1937, 1938, 1940, and 1941. He assisted in promoting the adoption by the State of Kentucky of a registration law for engineers, as well as helping with other work designed to promote the well-being of the engineering profession. He wrote several articles which were published in technical journals.

His hobby was the dual one of shooting and hunting. An expert with gun and pistol, he had won many trophies for his marksmanship at both local and national matches. Like all experts, he made his own cartridges for use in the shooting matches. He had quite an extensive collection of old guns and pistols of all kinds, and belonged to local and national rifle clubs. During the hunting season Mr. Caye spent much time in the field, making good use of his shooting skill. His vacations were usually spent in the woods and wilds of Kentucky, Florida, Canada, or elsewhere, hunting deer and other wild game. He was a member of the Juniper Club—Louisville sportsmen who hunt and fish every year on their own property in Florida.

On April 3, 1918, Mr. Caye was married to Ernestine Wentworth, of Brookhaven, Miss. Besides his widow, he is survived by three daughters, Margaret (Mrs. Paul Campbell), Juanita (Mrs. Cyril Kinsey), and Priscilla; a son, Woolsey M., Jr.; two brothers, L. Chase and William C.; and a sister, Artelia (Mrs. George B. Perry).

Mr. Caye was elected a Member of the American Society of Civil Engineers on December 14, 1925.

EDWARD CARTWRIGHT CONSTANCE, M. Am. Soc. C. E.[1]

DIED APRIL 29, 1943

Edward Cartwright Constance, the son of William Edwin and Josephine (Florence) Constance, was born at High Hill, Mo., on December 27, 1874. His boyhood was spent on his father's farm.

He attended the public schools in High Hill and Jonesburg, Mo., and took more advanced courses in the Central Wesleyan College at Warrenton, Mo., and the State Normal School at Kirksville, Mo. After teaching school for several years, he entered the University of Missouri at Columbia, in 1900, being graduated in 1904 with the degree of Bachelor of Science in Civil Engineering. In 1910 he received the advanced degree of Civil Engineer from the same institution.

In August, 1904, Mr. Constance entered the employ of the United States Government, in the U. S. Engineer Department, St. Louis (Mo.) District, engaged on the improvement of the Mississippi River. Except for a transfer to the Kansas City (Mo.) District, from August, 1916, to December, 1922, he remained in the service of the St. Louis District, without intermission, until his death.

During his long service, his experience embraced a wide range of subjects. He built thousands of feet of pile dikes and bank revetments, and made extended surveys and computations. He supervised the design, construction, and maintenance of large towboats, barges, dredges, and other floating plant.

---

[1] Memoir prepared by James W. Skelly, M. Am. Soc. C. E., in collaboration with Joseph M. Chandlee, Electrical Engr., Webster Groves, Mo.

For several years he was in charge of removal by blasting of an extensive submerged rock which was considered an obstruction to navigation. While engaged in this work, a premature explosion broke both his ankles and impaired his movements throughout the remainder of his life.

He was a man of splendid physique, hale in appearance, and generally enjoyed good health. Early in April, 1943, however, he was stricken with a somewhat rare malady, a deficiency in blood corpuscles, for which there appeared to be no remedy, and on April 29 he died. He was buried in Mount Pleasant Cemetery, in the neighborhood near High Hill, where he had grown up.

Mr. Constance's entire service was characterized by loyalty and devotion to the department which he served so well. He was trained under several engineers and gentlemen of the old school, in the days when government appropriations were granted sparingly, and results were scanned critically.

On December 23, 1905, he was married in Litchfield, Ill., to Ollie Burton, who died on August 31, 1930. Two sons were born to them, Roger Edward and William Burton. On March 31, 1934, Mr. Constance was married in Decatur, Ill., to Mrs. Gladys Mowery Hamman, who survives him.

He was a member of the Masonic fraternity, the Modern Woodmen of America, and was an Elder in the Presbyterian Church.

Mr. Constance was elected a Junior of the American Society of Civil Engineers on December 6, 1904; an Affiliate on February 6, 1907; and a Member on January 20, 1922.

PAUL DARWIN COOK, M. Am. Soc. C. E.[1]

DIED FEBRUARY 26, 1943

Paul Darwin Cook was born on November 13, 1883, at Wysox, Pa., the son of the Rev. Milton Lewis Cook and Mary (Thomas) Cook. He was the third of eight children, five girls and three boys, all of whom were graduated from either Mount Holyoke College at South Hadley, Mass., or Lafayette College at Easton, Pa. His father and two grandfathers were Presbyterian ministers, from whom he inherited a sturdy character and an independent mind.

From the Susquehanna Collegiate Institute at Towanda, Pa., Mr. Cook entered Lafayette College. He was graduated in Mining Engineering in 1905. He began his professional career as draftsman for the Gregg Company, Limited, at Newburgh, N. Y. Later, he went to Chicago, Ill., as resident engineer on construction of yards and railway terminal buildings for the Manufacturers Junction Railway Company, a subsidiary of Western Electric Company. From that time Mr. Cook had the following varied and interesting career:

---

[1] Memoir prepared by a Committee of the Iowa Section consisting of Ross M. Coomer and Almon H. Fuller, Members, Am. Soc. C. E., with the assistance of William L. Steele, member of the firm, Kimball, Steele & Sandham, Omaha, Nebr.

March, 1907, to July, 1909—Chicago, Milwaukee and St. Paul Railway Company, as draftsman and structural engineer, designing bridges and other railway structures on the original system and on the Puget Sound extension.

July, 1909, to September, 1910—Engineer of construction on a $500,000 grade separation viaduct for five interested railroads at Sioux City, Iowa, reporting to the chief engineer of the Chicago, St. Paul, Minneapolis and Omaha Railway Company.

September, 1910, to June, 1912—Engineer for Lewis and Leeder, Municipal Contractors of Sioux City.

June, 1912, to January, 1913—Superintendent of construction for the Davidson Realty Company in charge of construction of a $600,000 fireproof office building in Sioux City.

January, 1913, to May, 1917—Consulting engineer in Sioux City, designing bridges, water works, office buildings, hospitals, churches, schools, warehouses, and viaducts. Among the structures on which he was engaged were the $700,000 Woodbury County Court House and the $180,000 St. Vincent's Hospital.

From the fall of 1916 until the spring of 1919 Mr. Cook was engaged actively in the problems of war. In 1916 the Society suggested to its members that they offer their services to the government. As a result, Mr. Cook, with numerous other members of the Society, was invited by the U. S. War Department to present himself for examinations for a commission:

May, 1917, to September, 1917—First Officers Training Camp at Fort Snelling, Minnesota, and at Fort Leavenworth, Kansas; commissioned Captain of Engineers.

September, 1917, to October, 1918—Captain, commanding Company C, 109th Engineers.

October, 1918, to March, 1919—Major, commanding 1st Detached Battalion, 138th Engineers.

In 1919 Mr. Cook resumed the private practice interrupted in 1917 by the insistent obligations of war:

March, 1919, to June, 1923—Consulting engineer in Sioux City on buildings, bridges, and water works. In this period (winter of 1921–1922) a disability incurred in army service developed which required him to live in a warmer climate. He went to New Orleans, La., where he worked as a draftsman for Favrot and Livaudais, Limited, on structural design.

June, 1923, to February, 1924—District engineer for the U. S. Fidelity and Guaranty Company at Des Moines, Iowa, adjusting surety bonds and completing defaulted contracts in the states of Iowa and Nebraska.

February, 1924, to December, 1934—With Favrot and Livaudais, in responsible charge of structural design and field supervision. He also supervised the New Orleans Municipal Auditorium and New Orleans Public Service Building (each costing about $1,500,000), the Roosevelt Hotel Addition, and Baptist Hospital in New Orleans; and the Botton High School at Alexandria, La.

December, 1934, to April, 1936—Resident engineer inspector for the Public Works Administration (PWA) on an $800,000 high school building at Sioux Falls, S. Dak.

April, 1936, to April, 1938—City engineer of Sioux City.

July, 1938, to September, 1940—Examining engineer for PWA at Regional Headquarters, Omaha and Chicago.

September, 1940, to February, 1941—Airport manager for the municipal airport at Sioux City.

February, 1941, to April, 1942—Consulting engineer on structural design of municipal improvements.

April, 1942, to February, 1943—City engineer of Sioux City.

Paul Cook was a student all his years, and had an extraordinary memory for facts and figures—in fact, an encyclopedic mind. He was well informed not only on engineering topics but also on current events, economics, and things in general. He was interested in reading, but much more so in men. He had a shrewd insight into personal character and hated humbugs and "stuffed shirts." His thought was modestly expressed, without any assumption of authority or superior mental equipment, although he could have laid claim to both. When he spoke, what he said was logical and tempered with common sense. His professional ideals were high, and in his interpretations of professional ethics he was keenly aware of the spirit rather than of the letter. He was modest, unassuming, generous, patient, and always a gentleman. He was a good companion and possessed a keen and sympathetic sense of humor. He was never a "show-off." He did not care who got the credit for a job, if it was done successfully.

A leading citizen of Sioux City, Mr. Cook was active in the Rotary Club from 1913 until he left Sioux City in 1923; he was the executive member of the committee which produced Sioux City's first building code (in fact, he practically wrote most of it); and he was a splendid superintendent of construction, for he not only "knew his stuff," but was a keen and active observer, fair-minded, impartial, and just. Paul Cook inspired confidence and never abused it. As a designer, he studied his problems thoroughly, and his solutions were correct, economical, and often brilliant. He was an ideal consultant on architectural work because any differences of opinion were accompanied by frank arguments and discussions, without any real conflict between architect and engineer. He believed in teamwork and considered it necessary for successful building.

On October 16, 1912, Mr. Cook was married to Hazel E. Miller of Sioux City. He is survived by his widow and two sons, Henry L. and Thomas D.

Mr. Cook was elected an Associate Member of the American Society of Civil Engineers on January 31, 1911, and a Member on June 24, 1916.

WILLIAM OTTO GALBREATH, M. Am. Soc. C. E.[1]

Died March 14, 1943

William Otto Galbreath was born on a farm near Hebron, Ind., on August 24, 1871, the son of Martin Van Buren and Emily (Turner) Galbreath. In 1877 his parents moved to Carrollton, Mo., and, in 1881, to a farm near Utica, Mo.

William Galbreath attended the public schools in Carrollton and Utica and was graduated from the Utica High School in 1891. In 1892 he entered the University of Kansas, at Lawrence, and was graduated with the degree of Bachelor of Science in Civil Engineering in 1898.

In the spring of 1899 he entered the service of the Mexican Central Railroad Company and continued with that company until September, 1906, at which time he joined the engineering staff of the Mexican National Railroad Company (later consolidated with others to form the National Railways of Mexico). He remained with that organization until the spring of 1912. While in Mexico, Mr. Galbreath was promoted from instrumentman on location to division engineer on construction, then to locating engineer, and finally to district engineer in charge of maintenance and construction. In these positions he gained broad experience in all branches of railroad engineering, and, during a part of the time, was in direct charge of the construction of approximately 160 km of railroad including bridges, depots, yards, water stations, etc. However, as a result of the revolution which caused very unsettled conditions and made it unsafe for his family, he left Mexico in the spring of 1912 and returned to the United States. He immediately joined the forces of the Missouri and North Arkansas Railroad Company as engineer of maintenance of way, remaining for four years. During this time, he was in charge of all engineering work including the design and construction of a general shop and yard at Harrison, Ark.

Mr. Galbreath resigned from the Missouri and North Arkansas Railroad Company in the spring of 1916, and was employed at once by the City of Harrison to design and build a water distribution system for the city. After designing the system and letting the contract for its construction, he accepted a position in the office of the chief engineer of the Chicago Great Western Railroad Company in Chicago, Ill., and, after about a year, was made division engineer of the Southern Division with headquarters at Des Moines, Iowa.

In the fall of 1917, he left the employ of the Chicago Great Western Railroad Company to become chief engineer of the Kansas, Oklahoma and Gulf Railway Company at Muskogee, Okla. Thus, he realized the ambition of all railroad engineers. He held this position for three years, until November, 1920.

---

[1] Memoir prepared by Allston T. Cushing, M. Am. Soc. C. E.

After leaving the Kansas, Oklahoma and Gulf Railway Company, Mr. Galbreath was employed by the Kansas City Southern Railway Company and given special assignments including the location of a 0.5% grade line from a point on this company's tracks south of Grandview, Mo., to a connection with the Missouri Pacific Railroad Company, south of Martin City, Mo. He continued with the Kansas City Southern Railway Company until the fall of 1921 when he resigned to become assistant engineer on the plans and construction of the double tracking of the Missouri Pacific Railroad Company west of St. Louis, Mo., remaining for approximately a year.

Early in 1923, Mr. Galbreath moved to Chillicothe, Mo., where he engaged in contracting work on street paving and sewer construction. In August, 1924, he accepted a position with the U. S. Department of Agriculture as valuation engineer, on appraisals of stockyards for use in the establishment of fair rates. He remained in the service of the federal government until his retirement on August 31, 1941—a period of seventeen years, the last five years of which he was in charge of the Kansas City (Mo.) office. At the time of his retirement he held a rating as senior valuation engineer.

Mr. Galbreath's entire career was one of accomplishment. Several of the positions he held carried great responsibility and from them he acquired the ability to grasp a situation quickly, think it through, and then act. The great diversity of the various projects which he designed, built, and appraised shows a large degree of versatility in the use of basic engineering training.

Always of a modest disposition, Mr. Galbreath was calm and quiet under all circumstances. Sincerely enthusiastic about his work, he made such good use of his powers that accomplishment stands out as the main feature of his professional life. He never made a speech or presented a paper before an assembly, but his work spoke for him.

After Mr. Galbreath retired, he lived a quiet life with his family at his home in Kansas City. He made several extended motor trips, visiting his brothers in Michigan and Indiana, and spent his summers in Colorado in the mountains he loved so well. Mr. Galbreath was very active until shortly before his death on March 14, 1943.

William Galbreath was married in Utica, on October 14, 1903, to Blanche Stone, daughter of Ashford and Mary Stone of Utica. He is survived by his widow; two sons, Ashford M. and Thomas S. Galbreath; a daughter, Anita Blanche Galbreath; three grandchildren; five brothers; and one sister. He was a member of the Masonic Lodge.

Mr. Galbreath was elected an Associate Member of the American Society of Civil Engineers on April 6, 1904, and a Member on April 7, 1930. He became a Life Member in 1939.

JOHN PHILIP HALLIHAN, M. Am. Soc. C. E.[1]

DIED JANUARY 1, 1944

John Philip Hallihan, the son of Timothy and Harriet (White) Hallihan, was born on April 27, 1867, in Fond du Lac, Wis. After being graduated from high school at the age of nineteen, he began his engineering career on location and construction work for the Union Pacific and several other western railroad companies. From 1891 to 1897 he served on irrigation, railroad, and mining projects in New Mexico and Colorado. From 1898 to 1901 he was assistant engineer for the El Paso and Northeastern Railroad Company. From 1901 to 1904 he was employed as resident engineer and superintendent of the railways for the Cananea Consolidated Copper Company of Cananea, Mexico. From 1904 to 1907 he was assistant to the president and chief engineer of the Rio Grande, Sierra Madre and Pacific Railroad, locating 150 miles with a 1% grade over the continental divide, and making a reconnaissance of 400 miles for a railroad to the Pacific. He was also in charge of operation on 150 miles of road.

Mr. Hallihan was in South America from 1907 to 1909 as general manager of the South American Construction Company, of which the writer was president. He constructed 125 miles of railroad in Bolivia from Viacha to Oruro, all on a plateau 12,000 ft above sea level. This project was completed within the time limit and at a cost 5% less than that estimated by the chief engineer of the Bolivia Railway Company, for which the work was done.

In 1910 Mr. Hallihan was again associated with the writer, making a reconnaissance of 700 miles for a proposed railroad in Spain, the detailed surveys of which were made by Spanish engineers. On this trip were representatives of the National City Bank of New York and Hallgarten and Company who investigated the financial aspects of the proposed railroad. In Madrid, Spain, the writer and Mr. Hallihan met Señor Canalejas, then Prime Minister, noted for his progressive attitude, who was much interested in having American engineers and contractors develop railroads and other public works in Spain. Unfortunately the prime minister was assassinated the following year, and the project was dropped as far as Americans were concerned.

In succeeding years Mr. Hallihan continued his work in Latin-American countries—railroad surveys in Peru, railroad construction in Haiti, and operation of 3,500 miles of railroad in Brazil.

In 1918 he resigned from his position in Brazil to enter the United States Army, first as commanding officer, Seventieth Engineers, and later as deputy officer in charge of Engineer Supplies Section, American Expeditionary Force. After the armistice he was assigned to the engineering department of the Peace Commission and reported on damages to French railroads. After retiring from the army in 1919, he was associated for several years with the late Frederic A. Molitor,[2] M. Am. Soc. C. E., examining the deferred maintenance situation on various railroads in the United States preparatory to presenting briefs to the Interstate Commerce Commission.

---

[1] Memoir prepared by Philip W. Henry, M. Am. Soc. C. E.

From 1923 to 1935 he was with the late Daniel L. Turner, M. Am. Soc. C. E., on the design of a rapid transit system for Detroit, Mich., and was executive engineer for the Rapid Transit Commission of that city.

In 1935 Major Hallihan was put in charge of the Municipal Section of the Work Projects Administration (then called Works Progress Administration). His broad experience was of great value in working out many of the complications of administration and engineering for WPA. While he was with WPA he was loaned to the Army Specialist Corps where he handled many of their important engineering problems. He remained with WPA until 1943 and had charge of the clearing of the final reports of that organization.

In March, 1943, he was made Chief of Transportation and Engineering Division, Engineering Staff, Railroads, of the Foreign Economic Administration (then known as the Office of Economic Warfare). Here again his wide experience fitted into the many problems that the Foreign Economic Administration had before it.

Major Hallihan, because of his experience in Latin America and his desire always to do his best, spoke Spanish with unusual correctness and fluency. Only a short time before his death he spent several months in Ecuador and Venezuela, investigating certain engineering and construction projects for a well-known contracting firm of New York, N. Y. The author of articles for various engineering publications, his opinions were highly regarded. An active member of the Society, he was President of the Detroit Section in 1926. Major Hallihan also belonged to American Railway Engineering Association, American Transit Association, Detroit Engineering Society, American Institute of Consulting Engineers (member of the Council, 1932–1934), and Tiger Post of the American Legion in New York.

He is survived by his widow, Helen Britt Hallihan, to whom he was married in Leadville, Colo., on June 25, 1897, and by a son, Edward B.

Major Hallihan was elected an Associate Member of the American Society of Civil Engineers on April 4, 1900, and a Member on June 5, 1906.

GEORGE PRINCE HAWLEY, M. Am. Soc. C. E.[1]

DIED NOVEMBER 26, 1941

George Prince Hawley was born at Niagara Falls, N. Y., on August 22, 1872, the son of Royal A. and Helen (Day) Hawley. When Mr. Hawley was six years old, the family moved to Denver, Colo., but three years later they went to Round Grove, Ill., which Mr. Hawley always regarded as his early home. He attended the local grade school, Dixon Business College, and spent two years at Deveaux Military Academy at Niagara Falls, making an outstanding record in debate work.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 1838.

[1] Memoir prepared by James H. Brace, M. Am. Soc. C. E.

In 1893 Mr. Hawley entered the University of Wisconsin at Madison as a special student in civil engineering, continuing in this field for the greater part of his college years until 1896. While at the university, Mr. Hawley was employed during the summer vacations on the construction of the Hennipin Canal near Wyanet, Ill., and on various railroad jobs.

In 1896 Mr. Hawley left the university to become resident engineer on the double-track construction of the Chicago and North Western Railway Company between Madison and Baraboo, Wis. In this work he was associated with the late Walter H. Gahagan,[2] M. Am. Soc. C. E., his lifelong friend.

Next he joined the staff of the late Wallace C. Johnson,[3] M. Am. Soc. C. E., of Niagara Falls on some work at the Cave of the Winds and later at Shawinigan Falls, Quebec, Canada. Although he did not continue long with Mr. Johnson, he first met the fine group of hydraulic and electrical engineers (assembled by Mr. Johnson) who, directed by the late Julian C. Smith,[4] M. Am. Soc. C. E., have supervised the great power developments on the St. Maurice River in Quebec, and assisted in those on the St. Lawrence near Montreal, Canada.

From 1905 until 1911 Mr. Hawley was at De Pere, Wis., first as resident engineer for his college mate and friend, W. G. Kirchoffer, of Madison, on the rebuilding and extension of the city water works and then as city engineer with a private practice.

In 1911 Mr. Hawley again became associated with the St. Maurice-St. Lawrence power developments as resident engineer for the Shawinigan Water and Power Company, the Cedars Rapids Manufacturing and Power Company, and the Montreal Island Power Company. He had a responsible part in the surveys, preparation of plans, and construction of the larger hydroelectric plants and transmission lines of these associated companies which together constitute one of the largest and most economically successful power systems in the world. He played a prominent part in the study and execution of the plans that have met with marked success in minimizing the trouble from frazil ice, that bugbear of the operators of all hydraulic power stations in the north.

Through his integrity, sound engineering knowledge, and good common sense, Mr. Hawley had the confidence of a group of executives and engineers, who have had no peers and who have directed this system through to an outstanding success.

Mr. Hawley was married in 1905 to Nettie Mills of Lodi, Wis. They had no children. A very devoted and congenial couple, they lived much of the time in comparatively small and isolated communities, taking a keen interest in the welfare of the neighborhood and endeavoring to improve educational and religious conditions. They were both much interested in gardening and poultry raising. After Mr. Hawley's retirement at the end of 1937, the Hawleys planned to find some pleasant spot where they could devote themselves to the development of unusual plants, both flowers and vegetables, but, before their plan was realized, they both died, Mrs. Hawley preceding her husband in death by less than three months. In the communities where the Hawleys lived, they were the ones to whom those in trouble could freely appeal—in other words, the best of citizens and friends. Can we say more.

Mr. Hawley was elected an Associate Member of the American Society of Civil Engineers on February 6, 1901, and a Member on June 24, 1914.

JOHN COFFEE HAYS, M. Am. Soc. C. E.[1]

DIED JULY 21, 1942

John Coffee Hays was born on January 5, 1888, in Tulare County, California, of parents whose forebears were prominent in the development of the West. His paternal grandfather, also John Coffee Hays named for Gen. John Coffee, was the famous Captain (later Colonel) Jack Hays, first commander of the Texas Rangers when they were organized in 1840. The exploits of the Rangers under the daring leadership of Jack Hays are among the most thrilling accounts of the early development of the West. Colonel Hays went to California in 1849; became the first sheriff of San Francisco County; and was subsequently appointed Surveyor General for California by Franklin Pierce, the fourteenth president of the United States. (His early training was in surveying, a profession which he also practiced in Texas when not engaged in Ranger service.) Jack Hays' father, Harmon Hays, and grandfather, John Hays, whose residence was the Hermitage, in Tennessee (later the home of Andrew Jackson, seventh president of the United States), served as officers under General Jackson. It was John Hays who built Fort Maysboro in Tennessee. Aside from daring and courage, Col. Jack Hays was known for his extraordinary modesty, as was his grandson although the latter's important accomplishments were principally those of peacetime. However, John Coffee Hays participated in World War I, receiving the title of Major by which he was subsequently known to his many friends.

Susan Calvert of the Alabama family of that name was the paternal grandmother of John Coffee Hays. She made the journey from Alabama with her father by wagon to Seguin, Tex., where she became engaged to Col. Jack Hays and was married to him when he returned from the Mexican War. It was she, with her accounts of the many adventures of her early life, who made a profound impression on her young grandson.

The maternal grandfather of John Coffee Hays was John McMullin, Captain in the Texas Rangers, who came to California with his old friend Colonel

---

[1] Memoir prepared by H. L. Lowe, Stone & Webster Engineering Corp., New York, N. Y.

Hays. He went east to Washington, D. C.; was married to Eliza Morgan; and returned with her to live in the San Joaquin Valley in California where he had purchased land. The two families lived in the closest friendship and his eldest child, Anna, was married to Colonel Hays' eldest son John. Anna and John Hays were the parents of John Coffee Hays.

The childhood and early manhood of John Coffee Hays were spent in California at Fernwood, his grandfather's famous ranch, where were held brilliant parties attended by prominent people from many parts of the United States. He attended private schools in Oakland, Calif., and the Berkeley-Owens Academy, Berkeley, Calif.

At the age of sixteen he entered the employ of the Mount Whitney Power Company and received practical training as lineman, wireman, and station operator, as well as experience in electrical construction. He became chief operator of power house No. 1, a hydroelectric plant of the Mount Whitney Power Company, but left this position to gain further experience on power plant construction with the Henshaw-Bulkley Company of San Francisco, Calif. In order to expand his engineering training he took up experimental engineering at the Pittsfield (Mass.) works of the Stanley Electric and Manufacturing Company (later acquired by the General Electric Company). From 1905 to 1907 he was a member of the engineering staff of the late L. B. Stillwell, M. Am. Soc. C. E., consulting electrical engineer, New York, N. Y., and had charge of all construction work on the New York and Queens County Railway, Long Island Electric Railway, and New York and Long Island Traction Company. He also acted in an advisory capacity on operation and made special investigations and reports of a technological, economic, and business nature.

Upon completion of his work with Mr. Stillwell, Mr. Hays returned to California to make an investigation of the property and business of the Mount Whitney Power Company where he had been employed in the early part of his engineering career. As a result of his studies, he recommended to the board of directors a program for the development of additional hydroelectric power sites and the simultaneous development of market for the power. He clearly foresaw the course which the electric industry would follow in this area and the policy which should be formulated by the company in rendering a service which would be of ultimate maximum benefit to agriculture, the principal industry of this area. In 1907 Mr. Hays became president, general manager, and consulting engineer of the Mount Whitney Power Company—the first company to develop commercially the use of electric power for pumping water for irrigation for which Mr. Hays subsequently was given full credit publicly.

The program of development of the company's property and business recommended in his report was carried out under his direction. The engineering design and construction work was done entirely by the company's forces under his personal supervision. Two new hydroelectric developments, trebling the company's installed hydroelectric generating capacity, were built which embodied modern features of design and construction; and surveys were completed and plans prepared for another development having even greater capacity than the two new ones combined. The capacity of the steam relay plant was trebled and synchronous condenser capacity installed. The transmission and distribution systems of the company were extended greatly and modern substations installed at strategic points. These extensive improvements were undertaken boldly by Mr. Hays in anticipation of a large demand for power which he was confident would result from the existence of an evident ample supply. Thus, the company was in a position to serve a valley agriculturally rich when irrigated as the valley was underlain by a vast subterranean reservoir so near the surface that deep-rooted trees flourished through the long dry season. Mr. Hays contributed to the development of California by the application of his knowledge of engineering and economics to the problem of irrigating a rich valley with subsurface water, at a cost within the reach of the agriculturist. His vision was fulfilled.

Coincident with this work, he was engaged in the formation of several organizations for the development of large hydroelectric projects in California and held the position of president and consulting engineer of the Yosemite Power Company, Mount Shasta Power Company, Tuolumino Power and Light Company, and LaGrange Water and Power Company.

When the United States entered World War I in 1917, he followed the tradition of his family and joined the armed forces, his extensive engineering and construction experience naturally placing him in the Construction Division of the U. S. Army. He served as Construction Quartermaster and Camp Utilities Officer at Camp Lewis in Washington, and Supervising Utilities Officer for Camp Fremont and Camp Kearney in California, with the rank of Major.

When released from the Army in 1919, Major Hays joined the engineering staff of Stone and Webster, Inc. (later Stone and Webster Engineering Corporation) in Boston, Mass. In this capacity, he was consulted on numerous hydroelectric developments and irrigation projects designed and constructed or investigated by that firm. Subsequently, he was placed in charge of engineering reports and, still later, of appraisals made by the organization, in order that his engineering and construction experience, broad understanding of economics, and business acumen could be made fully available to clients. During this period the volume of report and appraisal work done by the corporation greatly increased as did the proportion of work done in the rapidly-growing industrial field. The advice of Major Hays was sought on industrial problems because he was able to apply with accuracy the fundamental principles of engineering and economics which he had learned so thoroughly in the public utility field. During the long years of depression, at its depth in 1932, the corporation advised industries in their attempt to weather the economic storm, and Major Hays' sound business counsel was valued highly. In 1934 the Bridgeport (Conn.) Brass Company, then facing many business and engineering problems, asked him to serve first on the board of directors and then on its executive committee. When the business clouds showed signs of lifting, this company began a program of improvement and expansion of its manufacturing facilities, in which Major Hays played a prominent part. Thus, this company was able to take full advantage of the revival of business activity and was ready to respond to the demand for production of war materials with the beginning of World War II.

In 1929, Major Hays was appointed vice-president of Stone and Webster Engineering Corporation and in 1938 executive vice-president. He was a member of the American Society of Mechanical Engineers, American Institute of Electrical Engineers, Military Order of the World War, Bankers Club of America, Engineers Club of New York, Exchange Club of Boston, and San Francisco Golf and Country Club. He was an enthusiastic yachtsman and was a member of the Columbia Yacht Club of Port Washington, N. Y., and the Dauntless Club of Essex, Conn.

Major Hays is survived by his widow, the former Eva L. Harwood, to whom he was married in New York on December 2, 1908, and by his brother, Harry T. Hays.

Major Hays was elected an Associate Member of the American Society of Civil Engineers on May 4, 1909, and a Member on June 4, 1913.

WILLIAM HERZBERG, M. Am. Soc. C. E.[1]

Died June 4, 1943

William Herzberg was born at Gadsden, Ala., on January 10, 1890, the son of Annie Laurie (Denson) and William Herzberg. When he was nine years old, his family moved to Birmingham, Ala., where he finished grade and high schools. He attended the Sewanee Grammar School (later known as the Sewanee Military Academy) at Sewanee, Tenn., from 1907 to 1910.

After completing his studies at the university, Mr. Herzberg returned to Birmingham in the fall of 1910 and went to work for the Corey Land Company as a rodman on the development of Corey—a model village, later Fairfield, Ala., an industrial suburb of Birmingham. He continued on construction work with this firm and rose to the position of instrumentman. In June, 1911, he became associated with the firm of Meade and Huey, consulting engineers of Birmingham, in the capacity of chief of party on general engineering work in and around Birmingham.

From May, 1912, through June, 1915, Mr. Herzberg was county engineer of Noxubee County, Mississippi, building a county system of gravel highways. He returned to Birmingham in June, 1915, handling a number of Birmingham's earlier subdivisions for the Wheelock Engineering Company. He was connected with this firm through 1917.

Early in 1918, Mr. Herzberg was employed by the Tennessee Coal, Iron and Railroad Company as chief of party and construction engineer on the construction of the Westfield Plant, near Birmingham, on railroad and storm sewer construction. When the Westfield Plant was completed after World War I late in 1919, Mr. Herzberg became party chief on location in heavy country for the Georgia State Highway Department and later office engineer of the Fourth Division at Gainesville, Ga. He remained with the Georgia Highway Department until early in 1921.

---

[1] Memoir prepared by a Committee of the Alabama Section consisting of J. H. Mayer, M. Am. Soc. C. E., Chairman, C. J. Rogers, M. Am. Soc. C. E., and Theo Massey, Assoc. M. Am. Soc. C. E.

On April 1, 1921, he entered the employ of the Second Division of the Alabama Highway Department as resident engineer. He advanced steadily, from assistant division engineer to division engineer, then to associate highway commissioner, and finally to chief state construction engineer. This last position he held from 1939 until his death. About the time Mr. Herzberg was selected as chief construction engineer, the State of Alabama undertook its largest highway expansion program, which consisted of improving existing highways, widening narrow bridges, constructing large bridges over major streams, as well as locating, designing, and constructing four-lane highways as entrances to the larger cities in the state and building a number of access roads to Army camps, air bases, and war plants.

During his twenty-two years of service with the State of Alabama, Mr. Herzberg accomplished much. His sincerity of purpose was appreciated by his colleagues. His work was characterized by thoroughness, keen insight, and tremendous energy.

Mr. Herzberg was married on July 8, 1914, to Katherine Harrington, of Mobile, Ala., and is survived by his widow.

Mr. Herzberg was elected a Member of the American Society of Civil Engineers on December 21, 1942.

ROBERT LESLIE HOLMES, M. Am. Soc. C. E.[1]

Died April 26, 1943

Robert Leslie Holmes was born at Clinton, La., on September 8, 1880, the son of James Alexander and Martha Louise (White) Holmes. He received his elementary education at Clinton Male and Female Academy and studied civil engineering by correspondence.

In March, 1900, Mr. Holmes entered the service of the Texas and Pacific Railway Company as chainman on the construction of a branch line in Louisiana. He advanced through the grades of rodman and instrumentman during the progress of this work, and, on its completion in November, 1903, was transferred to maintenance-of-way duties. In September, 1906, he was promoted to assistant engineer on construction and maintenance of way and in August, 1911, was advanced to the position of division engineer at Marshall, Tex. In August, 1915, he was promoted to assistant chief engineer at Dallas, Tex., and held this position until May, 1916, at which time he was placed in charge of the development and maintenance of water supply for the entire railway, receiving the title of engineer of water supply.

---

[1] Memoir prepared by R. J. Gammie, M. Am. Soc. C. E., and J. G. Roney, Assoc. M. Am. Soc. C. E.

At that time the water supply of the Texas and Pacific Railway Company was inadequate to meet the needs, and the quality was poor. Realizing the great importance of this phase of railroad work, Mr. Holmes began to make a careful study of the problem and zealously devoted himself to the task of developing various sources of supply sufficient to meet the requirements of the railway and choosing the correct methods of treatment to provide water of the proper quality. In this he was successful, for his efforts resulted in producing a system of water facilities second to none, and at the time of his death there was not one water station on the railway that had not been newly constructed or completely rebuilt under his direction.

The largest single project for which Mr. Holmes was responsible was the selection of the site for a large storage reservoir in the Davis Mountains of Texas and, in connection therewith, the design, location, and construction of an earth dam and a 37-mile pipe line to carry the water to points of distribution.

Concurrently with this work, over a period of many years, Mr. Holmes constructed a system of bank protection at several points on the Red River, where it closely parallels the railway. This was done by the installation of a series of jetty boxes, of a type of his own devising, at threatened points of erosion, resulting in the halting of the inroads of the river and obviating the necessity for expensive relocations of the railway. Mr. Holmes was so successful in this type of work that he was frequently consulted by other railways, state highway departments, and foreign countries in connection with similar problems.

In 1920 another project of considerable magnitude was delegated to Mr. Holmes. At this time the railway changed from coal to oil as a locomotive fuel, and Mr. Holmes was charged with the task of designing and constructing facilities for the storage and dispensing of fuel oil, with all the intricacies of unloading devices, heating and pumping equipment, and pipe lines.

In 1916 Mr. Holmes was elected to membership in the American Railway Engineering Association (A.R.E.A.) and for many years served on the Water Service, Fire Protection and Sanitation Committee.

In 1927, at the time of the devastating floods caused by the breaking of the levees of the Mississippi River and some of its tributaries and outlets in Louisiana, Mr. Holmes took an active part in rescue work. His efforts were recognized by the A.R.E.A., which presented him with a scroll bearing the following testimonial:

> "In appreciation of distinguished and meritorious services rendered in rescue and relief work during the Mississippi Valley Flood of 1927, this token of appreciation is awarded to R. L. Holmes on behalf of the American Railway Engineering Association."

On May 26, 1909, Mr. Holmes was married to Minnie Porter, who died on December 16, 1909. On October 16, 1912, he was married to Shirley Wade. Mrs. Holmes, together with two daughters, Shirley (Mrs. K. W. Krueger) and Edith, and a son, Robert Leslie Holmes, Jr., survives him.

Mr. Holmes was by faith a Presbyterian. He was a member of Marshall Lodge No. 22, A. F. and A. M., and Tancred Commandry in Dallas.

Although his entire career was spent in the service of the Texas and Pacific Railway Company, Mr. Holmes enjoyed a wide acquaintance and numbered his friends by the score. He was held in greatest esteem by every one who knew him, from the highest executive on the railway to the lowliest laborer. He earned the respect not only of his superiors, but of those upon whom he relied for assistance as well. The efficient operation of his department was due in a large measure to the kind and considerate treatment he accorded his subordinates.

Mr. Holmes was elected a Junior of the American Society of Civil Engineers on October 1, 1907; an Associate Member on February 6, 1912; and a Member on October 12, 1921.

WINFRED DEAN HUBBARD, M. Am. Soc. C. E.[1]

Died August 13, 1943

Winfred Dean Hubbard was born at Concord, Mass., on January 18, 1877. He was the son of George D. and Elmina (Taylor) Hubbard of Concord whose ancestors were Colonial settlers of that region.

Mr. Hubbard was graduated from the Massachusetts Institute of Technology at Cambridge, Mass., in 1898. From then until October, 1899, he was employed by the late Leonard Metcalf,[2] M. Am. Soc. C. E., consulting engineer, on design and construction of sewers and water supplies for various cities, including Concord. In January, 1900, he was appointed Superintendent of Water Works and Sewers of Concord.

He served in this capacity until March, 1906, when he was appointed an assistant engineer of the Board of Water Supply of the City of New York on reservoir construction work at Brown's Station, N. Y., on various surveys and details. He held this position until August, 1917, when he became principal assistant engineer on the Croton-Catskill Division of the Department of Water Supply, Gas and Electricity for New York, N. Y., which had charge of the distribution of all water delivered to that city. He was appointed division engineer of the latter department in April, 1931, which position he held until his death on August 13, 1943.

His work was varied and consisted of topographical surveys and the relocation of the Ulster and Delaware Railroad, together with new alinements of highways, the location and construction of the Olive Bridge Dam and adjoining dikes, and the construction and operation of the headworks of the Catskill aqueduct, with final inspection and maintenance of all gate-houses and appurtenances included in this extensive system.

---

[1] Memoir prepared by Sidney K. Clapp, M. Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 1110.

His work included the design and maintenance, together with the operation, of many sewage disposal plants throughout the Catskill-Croton developments, and the extension of the Staten Island and Long Island water supplies. The large territory of nearly 1,000 sq miles which Mr. Hubbard supervised included the watersheds of the Schoharie Creek, Esopus Creek, Kensico Reservoir, and Croton River developments, with aqueducts, pipe lines, control gates, and other fixtures north of the city line at Yonkers, N. Y.

During Mr. Hubbard's tenure in office with the Board of Water Supply and the Department of Water Supply he was able to acquire a widely diversified and an intimate knowledge of the details and operations of the water supply of New York City using one billion gallons of water per day—practically the largest water supply system in the world. He was consulted frequently on matters pertaining to storage and distribution of other water supplies, and, due to his wide experience, this advice was of considerable value.

Mr. Hubbard was joint author with the late W. Kiersted, M. Am. Soc. C. E., of a book entitled "Water Works, Management and Maintenance." The book attained a wide circulation among civil engineers and others connected with water works.

For more than thirty-five years Mr. Hubbard was a resident of Kingston, N. Y., where he was widely known. He was a member of the St. Johns Episcopal Church and a member of Masonic Lodge of Concord.

Mr. Hubbard was married on June 4, 1901, to Edna Thatcher, who died in November, 1934. Surviving are a daughter, Mary Thatcher Hubbard; two brothers, Frank S., and Walter; and a sister, Florence Priscilla (Mrs. A. J. Underwood). Both Mr. Hubbard and his wife are buried in the Sleepy Hollow Cemetery at Concord.

Mr. Hubbard was elected an Associate Member of the American Society of Civil Engineers on November 5, 1902, and a Member on April 13, 1936. He became a Life Member in 1937.

CLARENCE WALTER HUDSON, M. Am. Soc. C. E.[1]

Died May 10, 1943

Clarence W. Hudson was born at Manasquan, N. J., on May 20, 1867, the son of James B. and Rachel M. (Longstreet) Hudson. On his mother's side Mr. Hudson's genealogy extended back to the Revolutionary War. He was a member of Pennsylvania Society of the Sons of the Revolution.

Mr. Hudson prepared for college at Freehold Institute, Freehold, N. J.; entered Lehigh University at Bethlehem, Pa., in 1885; and was graduated in 1889 with the degree of Civil Engineer. That he was a good student is evidenced by his election to the Tau Beta Pi fraternity. That he was later an exceptionally able and successful civil engineer is recorded in this memoir and is attested indisputably by the honorary degree of Doctor of Engineering bestowed on him by his alma mater in 1925.

---

[1] Memoir prepared by Emil Diebitsch, M. Am. Soc. C. E.

During the first year after his graduation Mr. Hudson was employed as instrumentman and draftsman on the U. S. Hydrographic surveys for the Third District, Mississippi River, but thereafter he devoted himself to either teaching the basic principles of engineering or applying these principles to the design and construction of bridges and other framed structures. For one year he was with the New Jersey Steel and Iron Works of Trenton, N. J., as draftsman and field engineer on bridge work. The next year he was loaned to Lehigh University, where he was instructor in civil engineering. Then he returned to the New Jersey Steel and Iron Works in charge of a squad of draftsmen on bridge work. Mr. Hudson's reputation as an engineer was growing, and soon the Phoenix Bridge Company of Phoenixville, Pa., secured his services and employed him for fourteen years as designing engineer, in which capacity he designed practically all types of steel bridges.

In 1907, after eighteen years of experience, Mr. Hudson formed a partnership with the late Mansfield Merriman,[2] M. Am. Soc. C. E., of Lehigh University, and they established an office in New York, N. Y., as consulting engineers. Mr. Merriman withdrew from the firm after one year, but Mr. Hudson continued the business until his retirement in 1933.

Mr. Hudson's engineering advice and opinion were in steady demand. He was consultant for the Delaware, Lackawanna and Western Railroad Company on the Tunkhannock Viaduct and the Martins Creek Viaduct. At that time (1908) the Tunkhannock structure was the largest concrete bridge in the world. For the Lehigh and New England Railroad Company, he was consultant on eleven bridges in the anthracite coal region; for the Galveston (Texas) Causeway, Mr. Hudson advised on a concrete bridge one mile long; for the Palisades Interstate Park Commission of New York and New Jersey, he passed on four bridges. He was consultant for private firms on two toll bridges over the Ohio River, one at Steubenville, Ohio, and the other at Pomeroy, Ohio.

Among his most important work was the design and supervision of construction on three outstanding bridges costing, respectively, \$3,000,000, \$3,800,000, and \$3,100,000. The first was the Hill to Hill Bridge at Bethlehem, which welded the three boroughs of Bethlehem, South Bethlehem, and West Bethlehem into the City of Bethlehem. This bridge is of concrete-arch design, with ramps of easy grade feeding the traffic from the low-level streets to the main structure. It stretches in a magnificient roadway over the Lehigh River from the hilltop at the Moravian Seminary in Bethlehem to Fountain Hill in South Bethlehem. The Bethlehem bridge is a masterpiece of engineering design, solving an important municipal problem economically. The bridge was a great asset to a greater Bethlehem. The second bridge, the Washington Bridge at Providence, R. I., also a concrete-arch bridge, faced with granite, was outstanding in its structural stability and architectural beauty. The third structure which Mr. Hudson designed and for which he supervised construction was the Victory Bridge at Perth Amboy, N. J., for the State of New Jersey. This bridge is of steel-girder type.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1658.

From September, 1909, until June, 1927, Mr. Hudson was professor of Civil Engineering and in charge of the Department of Civil Engineering at the Polytechnic Institute of Brooklyn (N. Y.). Despite the duties imposed by so responsible and important a position, Mr. Hudson found time to write and publish three technical books.[3,4,5]

In the business world, Mr. Hudson's acumen and sound conservative judgment were appreciated. He was elected a trustee of Lehigh University in 1924 and held that office until 1932. In 1920–1922 he was a director of the Society. From 1933 to the day of his death he was a member of the United Engineering Trustees, Inc., which holds in trust all the properties and endowments of the four national engineering societies—American Society of Civil Engineers, American Society of Mechanical Engineers, American Institute of Electrical Engineers, and American Institute of Mining and Metallurgical Engineers.

Mr. Hudson was proud of his profession and enjoyed social meetings with his fellow men and fellow engineers. He was a member of the Engineers Club of New York City, Providence Engineering Society, Bethlehem Club, and Upper Montclair (New Jersey) Country Club. His favorite diversions were golf and fishing.

He was married on June 4, 1903, to Elizabeth Morgan at Phoenixville. He is survived by his widow and one son, James Hudson.

Mr. Hudson was elected an Associate Member of the American Society of Civil Engineers on November 7, 1894, and a Member on February 7, 1900.

DAVID EDWARD HUGHES, M. Am. Soc. C. E.[1]

DIED NOVEMBER 19, 1942

David Edward Hughes was born at Palmyra, Ohio, on September 21, 1861, the son of Evan and Ann Johns Hughes. His youth was spent in that locality —attending school, farming for his widowed mother, and working in sandstone quarries. At the age of sixteen, he went to Dunigan in northern California to live with an uncle.

Blessed with mental capability given to few, Mr. Hughes led an intensely active life. He continued his self-education by devoting every spare moment to study, exhausting book after book on both medicine and engineering; teaching in country schools and at Pierce College, College City, Calif.; and, finally, although still in his early twenties, becoming a professor of mathematics.

[4] "Notes on Plate-Girder Design," by Clarence W. Hudson, John Wiley & Sons, Inc., New York, N. Y., 1911.

[5] "Elements of Graphic Statics," by Clarence W. Hudson and Edward J. Squire, McGraw-Hill Book Co., Inc., New York, N. Y., 1923.

[1] Memoir prepared by H. M. McOuat, of San Pedro, Calif.

During this period, the die was cast and for the remainder of his life he followed the profession of civil engineering, gaining eminence. He was to a remarkable degree self-effacing, never striving for gain or credit but always for accomplishment, truth, honesty, and simplicity. Mr. Hughes was, without doubt, one of the finest applied mathematicians of his generation. He evolved, calculated, and published a table on the perfect transition ("Sickle"[3]) curve, or American spiral, which was used on the construction of the Chicago elevated railroad, as well as on other projects. Six-place functions were developed for this spiral at 10-min intervals between 0° and 30° and at 30-min intervals to 90°.

The intense activity of his younger years exhausted Mr. Hughes physically, and he sought opportunity to apply his rare combination of high technical ability and sound common sense in the out of doors. Accordingly, he accepted employment with the U. S. Engineer Department in 1893, remaining with that service until his retirement in 1932.

His first work for the War Department was on the improvement of Humboldt Bay, California, stabilizing the entrance by jetty construction. In 1902 he was transferred to the newly-created Los Angeles (Calif.) Engineer District and, for the following thirty years, was its ranking civilian engineer. He built jetties and fortifications at San Diego, Calif., and breakwaters and fortifications for Los Angeles-Long Beach (Calif.) Harbor. For a year he served as engineer for a board appointed by President Taft to determine the site and the design for San Carlos Dam, later Coolidge Dam, in Arizona. His profound writings on silting, as applied to this project, brought him an offer of a professorship in a state university. His was the guiding hand in the establishment of federal harbor lines along the Southern California coast. These lines determined the development of the harbors.

In his thorough manner, Mr. Hughes investigated tideland law and ownership and became an authority on the subject. Typically, he urged and aided in the litigation which restored the local tidelands to the people and resulted in municipally owned harbors. He experimented and wrote on *surge* and *seiche*. He evolved the idea of substitution of waste dredgings for costly stone in the strengthening of breakwaters, and the vast chain at San Pedro, or Los Angeles, Harbor, built and building from this design is a monument to him.

With all of this vast activity, he remained simple, approachable, and a friend to all. He aided both individuals and communities in time of trouble. He gave unsparingly of his time and substance to help the unfortunate and the ambitious. Many an engineer has had complex and involved problems simplified by Mr. Hughes. Many a young engineer was guided along not only the right technical but also the right ethical and moral road by this kindly, unselfish man.

He hated sham; he hated hypocrisy; he hated pretense. He was unswervingly honest, mentally as well as morally. With his passing a rare individual has gone on—a kindly, unpretentious, disarming soul housing the intellect of a giant.

---

[3] "The Sickle, or Perfect Railway Curve," by David E. Hughes, *Transactions*, Technical Soc. of the Pacific Coast, San Francisco, Calif., April, 1892, pp. 63–81.

Mr. Hughes was married to Lydia Wiklund in 1913 at Florence, Ariz. He is survived by his widow and a brother, Thomas R. Hughes.

Mr. Hughes was elected a Member of the American Society of Civil Engineers on September 6, 1905.

WILLIAM ROBERT KALES, M. Am. Soc. C. E.[1]

Died December 3, 1942

William Robert Kales was born in Chicago, Ill., on August 8, 1870, the son of Francis Henry and Ellen Parker (Davis) Kales. He received his early education in Chicago and was a student at Phillips Exeter Academy at Exeter, N. H., for three years, being graduated with the class of 1889. He then attended Massachusetts Institute of Technology at Boston, for four years, being graduated with the degree of Bachelor of Science in Mechanical Engineering in 1892. He was a member of Sigma Chi fraternity and was president of his class during his senior year, a position he held for life.

After graduation, Mr. Kales was employed in various positions in Worcester, Mass., Chicago, and Milwaukee, Wis., from 1892 to 1895, and then went to Cleveland, Ohio, with the Brown Hoisting and Conveying Machine Company, where he remained until 1899. While in Cleveland, he designed one of the earliest grab buckets, which proved very successful.

On October 1, 1895, he was married to Alice Gray of Detroit, Mich., daughter of John S. Gray. Mr. Gray was a prominent businessman in Detroit and was one of Henry Ford's backers in the founding of the Ford Motor Company and the first president of Mr. Ford's company. Mrs. Kales, four children, and eleven grandchildren survive Mr. Kales.

In 1899 Mr. Kales moved from Cleveland to Detroit and, with James T. Whitehead, founded the Whitehead and Kales Iron Works. The little business prospered and, in 1905, was incorporated as The Whitehead and Kales Company, specializing in the fabrication and erection of structural steel. Mr. Kales served as vice-president and chief engineer during the lifetime of Mr. Whitehead, and, on the latter's death in 1930, he assumed the presidency, which office he held until his death. His company fabricated and erected all the steel for the mammoth Willow Run bomber plant of the Ford Motor Company, for the two great Wright Aeronautical Company plants near Cincinnati, Ohio, as well as for many other large war plants.

Mr. Kales was a brilliant and thorough engineer. He designed many of the early structures fabricated by his company, and much of the erection equipment, adding very considerably to the art of erecting steel. His company once received a contract for prison cell construction, only to find that patents fully covered all known types of acceptable cells. After many busy days and nights, Mr. Kales invented a new type of lock which not only circumvented all the patents, but was a great improvement. Long hours meant nothing to him, and, when there was a big job to do, he begrudged the necessary time to eat and sleep. He was also a tremendous reader and student, and, because of a naturally fine memory, he retained all that he read for years. Study was a pastime, and, while in his middle sixties, he reviewed his college calculus with obvious enjoyment.

---

[1] Memoir prepared by George H. Fenkell, Hon. M. Am. Soc. C. E., and Neil C. McMath, M. Am. Soc. C. E.

He was long a prominent member of the old Detroit Engineering Society, serving as president from April 23, 1909, to April 15, 1910. The year 1924 saw many honors come his way, for it was then that he joined the Society, was made a life member of the Corporation of Massachusetts Institute of Technology, and was appointed by the Mayor of Detroit a member of the City Plan Commission. He had been a member of the Public Lighting Commission of the City of Detroit from 1906 to 1912. He belonged to the American Society of Mechanical Engineers and the new Engineering Society of Detroit.

During the first World War, Mr. Kales had charge of the manufacture and erection of steel hangars for the U. S. Air Corps. He was commissioned a Captain in the Fourth Air Park in the First Pursuit Group of the Air Service and served in France with the Army of Occupation until September, 1919. Following the war, he became a reserve officer with the rank of Lieutenant Colonel in the Corps of Engineers.

He was an Episcopalian and, at the time of his death and for many years before, was a vestryman at St. Paul's Cathedral. In 1936 he received the honorary degree of Doctor of Laws from Wayne University of Detroit.

He was a lover of all kinds of outdoor life and was always fascinated with boats, especially sailing vessels and yachts. He took several trips in his youth on the old lumber schooners operating out of Chicago; in his later years he enjoyed sailboat races both in the Great Lakes and at his summer home on Cape Cod (Massachusetts). He was also an enthusiastic hunter, and, only ten days before his death, he returned from a successful deer hunt in northern Michigan.

During the forty years that Mr. Kales was a resident of Detroit, he became connected intimately with every phase of its financial and commercial life. He played an important part in the development of Detroit's factories, banks and trust companies, homes, and parks and playgrounds, and was an earnest advocate of many civic improvements. He considered the old-fashioned type of education the one best fitted to develop the reasoning powers of man. Greek, Latin, and mathematics to him were essential parts of such an education. He traveled to many lands, becoming acquainted with many different nationalities, which helped him to a better understanding of the people and problems of the world.

No memoir of Mr. Kales could be complete without emphasizing his deep love for his family, his home, and his many friends, and his enduring faith in the Christian religion.

Mr. Kales was elected a Member of the American Society of Civil Engineers on April 7, 1924.

DAVID ANDREW KEEFE, M. Am. Soc. C. E.[1]

DIED MAY 17, 1943

David Andrew Keefe was born in Athens, Pa., on January 28, 1869, the son of Mary (Pyne) and Marcus Keefe, the second generation of sturdy stock from Cork, Ireland. With the exception of seven years, from 1888 to 1895, he spent his entire life in Athens. He was married to Clara Angela Wingerter of Wheeling, W. Va., on September 23, 1913. They had two children, a son and a daughter. A brief outline of Mr. Keefe's career appears in *Who's Who in America,* 1925 edition.

His elementary schooling was in the public schools of Athens, and his high school training in the Athens Academy. His technical and business education was obtained in night schools, the American School of Correspondence, and home study. He was a consistent and ardent student all his days, keeping up to date on the latest developments and applying them.

At the age of sixteen he worked in the shops of Kellog and Maurice (later the Union Bridge Company) in Athens. In 1888 he was employed by the Wisconsin Bridge and Iron Company as shop foreman, later serving as draftsman and designer. After three years with this firm, during which time he took technical courses in night school and under private tutors, he went with R. W. Hildreth and Company and, for four years, was on the 155th Street Viaduct and McCombs Dam Bridge in New York, N. Y.

On the completion of his New York assignment he returned to Athens where he practiced consulting engineering, confining his efforts to the design and construction of bridges, piers, and industrial plants; reports; and structural steel inspection. He was employed by Bradford County, Pennsylvania, as bridge engineer, by Luzerne and Carbon counties (Pennsylvania), and by the State of Pennsylvania in connection with the design and construction of twelve bridges over the Susquehanna River. He was retained by Yucatan, Central America, in connection with the ocean pier at Progresso. He was consultant in connection with bridges for the Lehigh Valley, the Scranton and Binghamton, and the Lehigh and New England railroad companies. The reconstruction of the Steel Pier and the construction of the Garden City Pier at Atlantic City, N. J., are examples of his work as are certain plants of the Union Carbide Company, the Ingersoll-Rand Company, and the Hudson Coal Company colliery at Scranton, Pa. Various towns and commercial interests in the Lehigh and Susquehanna valleys retained him to report on facilities. During his lifetime he was probably the most distinguished engineer of the Susquehanna River Valley.

Early in his life Mr. Keefe became interested in finance. His judgment in financial matters was so uniformly sound that, at the age of twenty seven, he was elected a director of the Athens National Bank and, in 1927, was made president of the Merchants and Mechanics National Bank in Sayre, Pa., resigning from the latter position in order to give more time to civic and personal affairs.

---

[1] **Memoir prepared by F. O. Dufour, M. Am. Soc. C. E.**

His hobbies were golf, travel, motoring, and civic matters. Mr. and Mrs. Keefe made a wedding trip around the world. Also, he took several cruises to the Caribbean and the Mediterranean and went to Ireland to see the old family homestead, still occupied by relatives.

Head of the tire rationing board and active in Red Cross, the Sayre Hospital, the Athens Library, county politics, and town improvements, he took his civic and social duties seriously as well as enthusiastically. He was a member and on the Board of Governors of the Shepards Hill Country Club in Sayre. He belonged to the Rotary Club, the Pennsylvania Society, and the Knights of Columbus. It may well be said of Mr. Keefe that he was an ideal engineer, citizen, and man.

Mr. Keefe was elected a Member of the American Society of Civil Engineers on December 3, 1913.

HARRY RAYMOND LEACH, M. Am. Soc. C. E.[1]

Died June 24, 1941

Harry Raymond Leach was born on July 14, 1891, in Saginaw, Mich., the son of Henry Morris and Kitty (Wilder) Leach. His engineering career began in 1909 when, at the age of eighteen, he went to work as rodman and instrumentman on surveys of the U. S. Indian Irrigation Service in the Pacific Coast states. After three years of field experience he entered the University of Michigan at Ann Arbor, from which he was graduated in 1916 with a degree in civil engineering. He remained in Ann Arbor, assisting H. W. King, M. Am. Soc. C. E., in the preparation of the *Handbook of Hydraulics* until January, 1917, when he was employed by Robert E. Horton, M. Am. Soc. C. E., consulting engineer, of Albany, N. Y.

In 1917, the United States entered the world conflict, and Mr. Leach returned to his home in Saginaw early in 1918 to offer his services to his country. While waiting to join the Army, he worked in the office of the District Highway Engineer. In September, 1918, he entered the Signal Corps of the U. S. Army. In the Meteorological Section of the Signal Corps he was trained in the technique of upper-air sounding and later was placed in charge of Meteorological Detachments at Jefferson Barracks, Missouri, and Camp Bragg, North Carolina.

In the spring of 1919, Mr. Leach returned to civil life and undertook a study of floods in Saginaw County, Michigan. In the summer of the same year he was retained by the Indian Irrigation Service to conduct a study of storage possibilities in the watersheds of the Uinta, White Rock, and Lakefork rivers in Utah—an investigation that required arduous explorations on horseback through the most rugged parts of the Uinta Mountains. When this work was completed, he conducted a four-month investigation of flood flows in the Saginaw River basin. In 1920 he returned to the Indian Irrigation Service, remaining with that organization until August, 1921, when he again became associated with Mr. Horton. The following thirteen years constituted one of the most productive periods of his life. As principal assistant to Mr. Horton, Mr. Leach participated, with distinction, in notable hydraulic and hydrologic investigations and in the design and construction of a number of water supply and hydroelectric projects.

---

[1] Memoir prepared by Howard L. Cook, M. Am. Soc. C. E.

In 1934 he was employed by the State of New Hampshire to supervise the establishment of recreational centers. For a short period, he was associated with an industrial concern. In December, 1935, he became affiliated with the Soil Conservation Service of the U. S. Department of Agriculture and thus was enabled to devote his full time to research in hydrology and hydraulics. In this connection he had hoped to bring into an orderly array the knowledge he had accumulated during the busy years of his professional practice, to fortify this with research, and thus to contribute a number of technical writings to engineering science. He had long contemplated such an undertaking but had hesitated to proceed without that thorough preparation demanded by his exacting personal standards. A long illness and his untimely death on June 24, 1941, prevented attainment of this goal. He was buried in Arlington National Cemetery in Fort Myer, Va.

In December, 1919, he was married to Helen Knudsen in Myton, Utah. His son, Harry King, and his daughter, Helen Karen, were a source of constant refreshment to him. He was deeply grateful to see them reach young manhood and womanhood before his death.

So wholeheartedly did Harry Leach devote himself to his daily tasks that he found little time for technical writing. This, coupled with the exceptionally high standards he set for his work, led him to defer the preparation of papers on many subjects in which he was intensely interested. Fortunately, he did make available to his fellow engineers the very useful procedure for calculating backwater curves that has come to be known as the "Leach Method." During his last illness, under a heavy handicap, he contributed to the volume, "Hydrology," in the Physics of the Earth Series sponsored by the National Research Council. These studies and the few other short papers he managed to prepare during his busiest years do not measure his capacity fairly; but they do indicate the magnitude of the loss suffered by the engineering profession with his death.

During his lifetime Harry Leach worked with many engineers throughout the United States and, to an unusual degree, was afforded opportunities to collaborate with workers in other fields of science. Regardless of the background of his co-workers, he invariably won their respect and affection. They found that he cheerfully carried more than his share of any task and willingly made greater sacrifices than were demanded of him. Moreover, they learned to place a high value on his opinions, not only because of his broad knowledge of engineering principles and methods, but even more because of his sound judgment—for, although engineers of equal erudition are not uncommon, one who possesses so great a store of common sense is not often found. Thus his fellow workers came to depend on him as does a workman on a tried and proved tool, only occasionally appreciating the full magnitude of their reliance.

His professional associates were not alone in cherishing his friendship, for he made true friends in all walks of life. Those who were privileged to know him loved him for his humanity, kindliness, and tolerance; admired his contempt of hypocrisy and superficiality; and sought his companionship because of his congeniality, his gruff yet kindly humor, his constant loyalty, and his quickness to appreciate the good work of others. He numbered among his friends poor men, rich men, laborers, executives, artists, industrialists, and, in fact, people in every circle into which his wide interests brought him. It is notable that so many who knew him have said, "I never knew a man who didn't like Harry Leach."

Mr. Leach was elected a Junior of the American Society of Civil Engineers on August 31, 1915; an Associate Member on May 28, 1923; and a Member on March 10, 1930.

LLOYD TEVIS McAFEE, M. Am. Soc. C. E.[1]

DIED JANUARY 1, 1942

Lloyd Tevis McAfee was born in San Francisco, Calif., on June 27, 1881, the elder son of Clark William and Elizabeth (Cooke) McAfee. His parents came to California from Louisville, Ky. Mr. McAfee attended the public schools of San Francisco and Belmont School (private) in San Mateo County.

At the age of twenty he began his engineering career, following the hard path of a young engineer without the advantage of college training. From 1901 to 1905 he was engaged progressively from rodman to chief of party on railroad surveys in Shasta County and on proposed hydroelectric projects in Kings County; on surveys for Western Pacific Railroad Company in Nevada and California; and on construction of transmission lines, ditches, tunnels, and flumes for the North Mountain Power Company in Trinity County.

He had a wonderful personality, friendly and genial, with vision, humor, and ability finely balanced. On the job he was known fondly as "Mac" by everybody from the laborer to the "Chief." He had the faculty of inspiring confidence in his ability and fairness, earning and holding the respect of his men and the contractors. He had a great love for the out of doors and a faculty for getting things done. All these qualities naturally led him into the construction field.

---

[1] Memoir prepared by N. A. Eckart and L. W. Stocker, Members, Am. Soc. C. E.

In 1905 he took over as construction engineer for the Ocean Shore Railroad Company in Santa Cruz and San Mateo counties. He often referred to the four years on this work until 1909 as happy and busy ones.

After the Ocean Shore Railroad was completed, Mr. McAfee entered the service of the City of San Francisco and spent the next nine years supervising various projects for the city, rebuilding its utilities and facilities after the disastrous fire of 1906. As assistant city engineer of San Francisco, he was engaged in construction of cisterns for the city's auxiliary high-pressure fire-protection system, storm and sanitary sewers, the Fort Mason pumping station, the high-pressure pipe system, and the Stockton Street and Twin Peaks tunnels.

In 1918 Mr. McAfee was appointed construction engineer on the O'Shaughnessy Dam for the Hetch Hetchy Water Supply, with which project he was to be identified intimately and actively for the remaining years of his life. To appreciate the type of work which he directed, a brief outline of this project should be included.

In 1913 Congress approved a grant of lands in the high Sierra to the City of San Francisco to permit development of an adequate water supply. With that authority to use public lands, the city has constructed a great system by which water is impounded and stored in reservoirs in the mountains and carried 137 miles through mountain tunnels and steel pipe to Crystal Springs reservoir on the San Francisco peninsula. The principal units for the impounding and conveyance of this water and for the incidental generation of electric energy are a standard-gage railroad, 68 miles long, to transport construction materials; a construction power plant of 3,300-kva capacity; a storage dam at Lake Eleanor; a larger storage dam at Hetch Hetchy, giving a reservoir capacity of 360,000 acre-ft; the aqueduct system, 137 miles long; a regulatory reservoir with penstocks; and an 80,000-kw power plant at Moccasin Creek; as well as a transmission line, 98 miles long. Expenditures on the Hetch Hetchy Project have amounted to more than $100,000,000. Mr. McAfee, as construction engineer until 1930, had direct charge in the field of several divisions of the project, embracing a wide range of types of construction.

On March 3, 1930, Mr. McAfee was promoted to the position of chief assistant city engineer (under the late M. M. O'Shaughnessy,[2] M. Am. Soc. C. E., then city engineer) with general supervision of all Hetch Hetchy work in the headquarters office and in the field, from the mountains to the sea. In 1932 he became manager and chief engineer of the Hetch Hetchy Water Supply, serving also as chief of the Bureau of Engineering of the newly created Public Utilities Commission. Mr. O'Shaughnessy then was appointed consulting engineer to the commission, which post he held until his death in 1934. In this capacity, the design and construction work of the San Francisco Airport, and later the construction of the $4,300,000 Exposition building program on Treasure Island, came under Mr. McAfee's jurisdiction. Until 1940 the work under his supervision excluded responsibility for operation of the electric power division of the Hetch Hetchy Project, but, in that year, his authority was extended by his appointment as manager and chief engineer of the combined Hetch Hetchy Water Supply, Power and Utilities Engineering Bureau. Thus, he assumed the management of the construction and operation of the Hetch Hetchy Power Project and the supervision of engineering work for the municipal railway.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1710.

Mr. McAfee's engineering career consisted for the most part in planning and building public works which were vital to the welfare of the community which he served.

He was married on July 2, 1907, to Emilie K. Meckel, who, with their three children, Katharine (Mrs. Daniel J. Roche), Harriet (Mrs. Victor Wilson), and Dorothy H. McAfee, survives him.

Mr. McAfee was elected a Member of the American Society of Civil Engineers on July 14, 1930.

CHARLES T. MAIN, M. Am. Soc. C. E.[1]

Died March 6, 1943

Charles T. Main was an engineer by profession. He liked the definition that a professional man is a man trained to service. Men loved him and trusted him. His outlook on life was simple and broad. His standards of conduct and ethics were high and rigidly applied to himself. When judging others, however, his great soul always remembered charity. He lived long and usefully.

Charles Thomas Main was born in Marblehead, Mass., on February 16, 1856, the son of Thomas Main, Jr., and Cordelia Green (Reed) Main. He was descended from Colonial stock. In 1883, he was married to Elizabeth F. Appleton. They had three children, Charles Reed, Alice Appleton, and Theodore.

Mr. Main attended the schools of Marblehead and then was graduated from Massachusetts Institute of Technology in Boston, in 1876. He taught at "Tech" for two years while taking advanced work. He gave his alma mater years of service as president of the Alumni Association, term and life member of the Corporation, and member of the Executive Committee. Also, he helped select several of her presidents.

He followed the principles of his forebears by working hard and long. One could not escape the impression that he worked without apparent effort, which may account for his long and useful life. Mr. Main did much original thinking on technical subjects, especially seeking underlying principles. The study of values relating to industrial subjects interested him, and he brought to this research the trained mind of the engineer and the dearly-bought wisdom of his ancestry.

---

[1] Memoir prepared by F. M. Gunby, M. Am. Soc. C. E.

Starting in 1891, he presented papers before several engineering and technical societies on this subject. These papers—on supply and cost of power, valuation of manufacturing properties, taxation, and other subjects vital to industry—were so clear and simple that they are still basic. In 1924 he presented a paper on power supply for industry before the First World Power Conference in London, England.[2] The method of valuing water power, by comparing costs of methods, which has been in common use for many years, was introduced by Mr. Main.

As a result of this work he received medals from Boston Society of Civil Engineers, National Association of Cotton Manufacturers, and American Society of Mechanical Engineers. Northeastern University in Boston, Mass., conferred on him the honorary degree of Doctor of Engineering. However, the quality of his work was more important to him than the reward.

After leaving Massachusetts Institute of Technology he spent twelve years in the mills at Manchester, N. H., and at Lawrence, Mass. At the age of twenty five, he was employed by the Lower Pacific Mills, designing and constructing mills and water power and steam power plants, the operation of which he later superintended. The effects of this experience were reflected throughout his subsequent work, giving him an unusually broad viewpoint on both engineering and manufacturing. He was adept at learning from books and from life.

After 1893, he specialized in consulting engineering—as a consultant and as a designer and supervisor of construction. He was charitable to other men, seeking their points of view. This contributed to his greatness as a consultant. In 1926, with associates, he incorporated the nationally-known business, bearing his name.

As a result of his own experience, his work and business fortunately covered a wide field. At first the basic interest of the firm was textile mills. By the time this field was slowing up, other work had been developed so that, when the textiles became almost negligible, other lines of industry—steam power, hydroelectric plants, etc.—were available.

Among the more important projects for which he acted as engineer were the Wood Worsted Mills, which, when built, was probably the largest single manufacturing building in the United States; water power and steam power and other plants for many manufacturing establishments; sugar refining, soap manufacturing, rope and jute plants; a system of hydroelectric plants for the Montana Power Company, totaling about a quarter of a million kilowatts; hydroelectric plant in Belgian Congo; manufacturing plants in Canada, India, and the Argentine; the Boston Parcel Post Building; and the foundations for buildings of Massachusetts Institute of Technology. During World War I his firm acted as architect-engineer on work for Camp Edwards, Cape Cod, Massachusetts; the Mississippi Ordnance Plant and Camp McCain in Mississippi; and the Holston Ordnance Works at Kingsport, Tenn. He often acted as consultant, expert witness, or arbitrator.

Mr. Main's philosophy about his business was simple:

---

[2] "Power for Textile Mills," by Charles T. Main, *Transactions*, The First World Power Conference, London, 1924.

> "Get the facts. Give to the client value received and more where possible. Pay employees all you can afford and put it in the pay envelope without frills. Recognize good work on the part of individuals. Develop young men. Give the client your best advice. Then, if he wants something else, help him to get it. If he wants something unsafe, he should go elsewhere. Be fair."

A conservative, he believed in keeping ample reserves from good times to tide over depressions. As a result he lived to send out cards in January, 1943, in commemoration of the fiftieth anniversary of the founding of his business.

Mr. Main felt his responsibilities as a citizen and was active in civic life. While in Lawrence, he and a group of outstanding men where drafted to run for office and clear up a political mess. For three years he was an alderman. In Winchester, Mass., his home, he was a member and chairman of the Water and Sewer Board for years. For the State of Massachusetts, he served on various commissions. He was a director of a savings bank and regularly attended its meetings.

A member of the Congregational Church, he did a great deal of work for the church but would never hold office, believing that he could be more effective in other ways. He performed various duties, among them heading committees to select a pastor and to build a parish house. He was a generous, but always anonymous, giver to charity, both in money and time.

A member of many worth-while social and scientific organizations, he was life member, honorary member, and president of the American Society of Mechanical Engineers; president and honorary member of the Boston Society of Civil Engineers; president and honorary member of the Engineers Club of Boston, which he helped to organize; and president of the American Institute of Consulting Engineers. At the time of his death he was the oldest member of the National Association of Cotton Manufacturers.

Mr. Main always regarded engineering as a profession which must be on a high ethical plane. When president of the Boston Society of Civil Engineers, he drafted the first code of ethics adopted by any engineering society in the United States. He also served on committees for codes of ethics for various engineering societies.

During World War I, he was adviser to the Construction Division of the Army, giving freely of his time. He refused to have his firm considered for engineering work because one of his young associates was in the Construction Division. The Secretary of War appointed him to several boards, principally in connection with construction matters. At the request of the French Government, the American Engineering Delegation, of which he was a member, visited France in 1919 to advise in connection with rehabilitation.

In World War II, his organization has been called on to do a large amount of important work which was a matter of particular satisfaction to Mr. Main. Although he could take no active part, he could look back on the broad problems of the previous war and give priceless advice.

As a man, he had stability of character and calm courage. He was gentle with the gentleness of great strength and poise. He was tactful, patient, and livable. He had imagination and a keen sense of humor and usually had a good story to make a point clear or to relieve a tense situation.

His pastor and friend said at his funeral

> "He was simple and modest, as all great souls are. He had the sunniest, winsomest, sweetest smile of any man I ever knew. Anyone who saw the playful quirk at the corners of his mouth and the kindling of the twinkle in his eye will never forget them. He was a landmark in our lives, like some tall tree on a hill-top. Now he is gone, rich in honors and ripe in years."

Mr. Main was elected a Member of the American Society of Civil Engineers on July 1, 1909.

JOHN WALTER MAY, M. Am. Soc. C. E.[1]

DIED AUGUST 8, 1942

John Walter May was born in Philadelphia, Pa., on August 18, 1884, the son of Frederick May and Mary (Rapp) May. His education was received in the public schools and later through extension courses.

The early years of Mr. May's professional life, 1900 to 1913, were spent with Albertson and Young Company and Lane Construction Company in the vicinity of Atlantic City, N. J., which was then expanding at a rapid rate. This work was highly diversified including, in addition to general building and equipment, the design and construction of water supply and sewage disposal systems, piers, sea walls, and reinforced concrete foundations above and below water. The greater number of these projects were important and gave Mr. May sound experience that proved to be of inestimable value later.

In 1916 he was employed by the George B. Clapp organization of Philadelphia as manager of construction. Here he continued to be interested in reinforced concrete. In this connection his most important work was on the construction of foundations and other structures for a five-and-one-half-mile extension of the Philadelphia Elevated System.

In 1918 Mr. May joined Day and Zimmermann Engineering and Construction Company (later United Engineers and Constructors, Inc.) first as construction supervisor and then as construction manager. The national scope of this company's activities, together with the great variety of work done, presented problems ranging from the normal to the extremely difficult.

In the industrial and general building field, Mr. May directed some thirty projects of different kinds. Among these were textile, cement, cold storage, coal cleaning, paper, and asphalt plants; colleges; hospitals; general service buildings; railroad stations; monumental buildings; and a penitentiary. However, his greatest activities and accomplishments were in the public utility field, supervising the construction of numerous steam power plants, transmission lines, substations, several hydro additions, and the revamping of 300 miles of high-speed electric railway. In all, he was connected with fifty three such projects, several of which are worthy of special note either for their pioneering or for nationally recognized aspects.

---

[1] Memoir prepared by Wallace E. Belcher, M. Am. Soc. C. E., and Rossiter W. Wilbraham, Chief Electrical Engr., United-Engrs. and Constructors, Inc., Philadelphia, Pa.

The 220,000-volt Conowingo transmission line involved an unusual river crossing with difficult cofferdam and foundation conditions. The construction details of the narrow-waisted transmission tower, which was originated for this job, and the methods and provisions for field assembly were greatly influenced by Mr. May. This tower revolutionized heavy transmission line design and construction. It was a definite contribution to the industry and has been used on every major project since then. The original model of this tower has been placed in the Franklin Institute at its request.

Revamping the 300 miles of the Ohio Electric Railway high-speed system presented the problem of changing the power supply from 25 cycles to 60 cycles, and required the building of new substations and the replacement of outmoded equipment in all others. The overhead transmission line and trolley systems had to be modernized and generally reconditioned, and, in the adjacent towns and villages that were supplied with light and power, all customers' meters and utilization devices had to be changed or readapted. Railway schedules and good customer relations had to be maintained under all conditions. The successful completion of this project was a tribute to both the ability for organization and to the good judgment of Mr. May.

The outstanding accomplishment of his professional life was the construction of the Deepwater Submarine Cable Crossing of the Delaware River in the vicinity of Wilmington, Del. Eight 66,000-volt submarine cables were laid in a dredged trench 10 ft deep and 20 ft wide at a maximum depth of 50 ft below mean low water. The length was 3,700 ft and the excavation, approximately 160,000 cu yd. Although it was necessary to maintain constant river traffic, the work was done continuously throughout a severe winter. The cable—the largest single length that could be manufactured—was but slightly greater than the distance across. Thus, the cable had to be laid to a degree of straightness in the trench that never before had been necessary or attempted. To do this, Mr. May developed methods of control for the dredges, maintained the cable-laying barge on a transit line, and laid all eight cables in the trench with one crossing of the river. Equally as important as the cable operation was the development of the first slotted-island-type cable terminal platform which allowed the cables to be terminated offshore. This was a pioneer project in every way and received national recognition. These design and construction methods made possible other similar installations on which Mr. May's construction methods were adopted.

Mr. May was an unusual man in many ways. He was of sterling character with a striking personality and sense of tolerance that won for him many sincere friends. His sound engineering judgment, organizational ability, and leadership commanded the respect of associates and employees as well as of contractors and clients. Mr. May successfully demonstrated the power of accomplishment by strong personal leadership, commencing at a time when "hard driving" was the general practice.

He was a member of the Engineers Club of Philadelphia and the Aronomink Country Club. He was always an active Roman Catholic.

In 1906 Mr. May was married to Mary T. Lane. He is survived by his widow; one son, John; and two daughters, Florence Claire (Mrs. Arthur Bender) and Mary Lane (Mrs. Hugh Clark).

Mr. May was elected a Member of the American Society of Civil Engineers on August 17, 1931.

JAMES LAFAYETTE PARKER, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 10, 1942

James Lafayette Parker was born in Fayetteville, N. C., on April 6, 1881, the son of James F. and Elizabeth (Cromartie) Parker. He attended the North Carolina State College at Raleigh, and was graduated in 1902 with the degree of Bachelor in Engineering.

After graduation Mr. Parker was employed, for about four years, by various steel companies, obtaining valuable experience in structural detailing and designing. From 1906 to 1916, he was associated with Herbert C. Keith, M. Am. Soc. C. E., in New York, N. Y., as principal assistant engineer in charge of the design and preparation of plans for various kinds of bridges, including movable spans. After this he spent two years with the New York Central Railroad Company on preliminary designs for a high level bridge over the Hudson River near Albany, N. Y., to cost about $5,000,000. Also, he prepared design plans for a four-track lift span.

From August, 1918, to December, 1918, he served as Captain in the U. S. Corps of Engineers. After the war for a year and a half, Mr. Parker was with the Bureau of Public Roads (later Public Roads Administration) as bridge engineer for the Eighth District, with headquarters in Montgomery, Ala. Following this, he served as bridge engineer for the South Carolina State Highway Department in charge of the design and construction of bridges, costing several million dollars. He was the designer of the $550,000 Ashley River Bridge and directed construction on the $850,000 Santee River Bridge.

From 1924 to 1935, Mr. Parker was in private practice as consulting engineer at Charleston, S. C., specializing in the design and construction of road and bridge projects. In March, 1936, he was reinstated in the Public Roads Administration at Washington, D. C., as highway bridge engineer. Later he was promoted to senior highway bridge engineer, continuing in this capacity until his death.

Mr. Parker designed a proposed highway bridge across Chesapeake Bay near Baltimore, Md., and spent considerable time attempting to develop the project. Immediately before the outbreak of the second World War, there was renewed interest in this project from various sources.

---

[1] Memoir prepared by Nathan Wilson Morgan, M. Am. Soc. C. E.

An engineer of outstanding ability, Mr. Parker was thoroughly competent in the design of all types of bridge superstructures and foundations. He was an accurate analyst and possessed keen ability in sensing the most logical solution to bridge engineering problems. His thoroughness and insight often led him to discover defects in designs, particularly the failure to consider the action of certain natural forces acting upon the structure. Thus, his work was always thorough and never lacked the principle of conservatism. His associates found him a man of retiring disposition, forceful in his opinions, yet friendly and congenial.

Mr. Parker never was married. He was devoted to his family and made his home with his brother in Hyattsville, Md. He is survived by this brother, James F. Parker, and by a sister, Eunice (Mrs. Eunice Parker Chesnutt). He was a member of the Antioch Methodist Church of Parkersburg, N. C., which town was named for Mr. Parker's grandfather.

Mr. Parker was elected a Junior of the American Society of Civil Engineers on April 2, 1907; an Associate Member on May 3, 1910; and a Member on November 21, 1921.

HARRY TINKER POE, JR., M. Am. Soc. C. E.[1]

Died November 21, 1942

Harry Tinker Poe, Jr., the son of Hal T. and Dora (Sloan) Poe was born in Greenville, S. C., on November 15, 1882. He was educated at Clemson College, at Clemson, S. C., where he received in 1902 a Bachelor of Science degree in Electrical and Mechanical Engineering, and in 1903 a degree in Civil and Textile Engineering.

Although most of his life was spent in and around Greenville, prior to 1917 he was in responsible charge of projects in Texas, Pennsylvania, Georgia, Alabama, Tennessee, and Maryland. For a time he was a marketing specialist in Washington, D. C. From 1921 through 1933, he was president of Poe Construction Company of Greenville, a firm engaged in construction of water and sewer systems, roads, streets, etc., as well as in engineering, design, and construction of industrial work.

From 1934 through 1937 he was state traveling engineer; inspector for South Carolina; project engineer for Meeting Street Housing Project, Charleston, S. C.; and senior engineer, Power Division, Public Works Administration, Washington, D. C. From 1938 through 1940, Mr. Poe was principal engineer on the Santee-Cooper Power and Navigation Project in Charleston. At the time of his death he was employed by J. E. Sirrine and Company, Engineers, of Greenville, and was serving as resident engineer on a Greenville housing project.

During World War I, Mr. Poe was commissioned Major, Construction Department, Quartermaster Corps.

---

[1] Memoir prepared by J. E. Sirrine and William S. Lindsay, Members, Am. Soc. C. E.

In 1913, Mr. Poe was married to Julia May Swift. Five children were born to them—Hal T., Frank Swift, William Nelson, Ann, and Nell.

Both in his work and in his personal life, Mr. Poe's efficiency and cheerful disposition won him many friends and admirers.

Mr. Poe was elected an Associate Member of the American Society of Civil Engineers on February 5, 1908, and a Member on November 13, 1939.

WALTER PERCIVAL RICE, M. Am. Soc. C. E.[1]

Died August 21, 1941

Walter Pervical Rice was born on September 2, 1855, in Cleveland, Ohio, the son of Percy W. and Mary T. (Cutter) Rice and a grandson of the Hon. Harvey Rice, of Conway, Mass., who was a descendent of Edmund Rice of Burkhamstead, England. On September 2, 1903, he was married to Margaret Anderson Barteau.

Mr. Rice attended Lehigh University in Bethlehem, Pa., being graduated in 1876 with the degree of Civil Engineer. His practical experience, which began soon after his graduation, was so varied in character that it was distinctly instrumental in developing a very able engineer. In addition to his educational training, diversified experience on important projects did much to further his career.

Mr. Rice's professional work began and was continued during the period before civil engineering had reached the specialized stage which it later attained. A successful engineer in this period consequently was required to do much original study and was forced to draw upon his own ability and knowledge when developing design and construction methods for any important work, since descriptions of similar work were often not available. This situation was characteristic of the period and probably explains the ability of the successful pioneer engineers of the United States in overcoming obstacles and proving themselves capable men. Mr. Rice was definitely a pioneer. Through associations he both gave and received the benefits of valuable experience. He developed a quality of leadership greatly valued and appreciated by his associates and assistants, who all looked upon him as a master in his profession. Illustrative of the engineering work which received Mr. Rice's attention and direction was that on rivers and harbors prior to 1887 as an assistant to Col. John M. Wilson, federal officer in charge of waterway improvements along Lake Erie from Dunkirk, N. Y., to Detroit, Mich.

He was City Engineer of Cleveland from 1887 to 1890, and again from 1893 to 1895. From 1899 to 1901, he was Director of Public Works of Cleveland. During this time he directed many important surveys, road construction, bridges, sewers, river and harbor work, and other similar projects naturally accompanying engineering progress in a large growing city. Every important project under his direction was given his personal attention, and he took a special delight in working out both the general plans and many of the important details. He was assistant engineer on the Superior Street Viaduct in Cleveland—one of the large and important bridges of its time, completed in 1879 under the general direction of the late B. F. Morse,[3] M. Am. Soc. C. E., then City Engineer. (The viaduct, about 3,500 ft long, was replaced by a more modern structure in 1916.) It was a swing bridge over the Cuyahoga River with a westerly approach of stone arches and an easterly approach of steel and iron construction. During Mr. Rice's second term as City Engineer he sponsored and, in 1895, built the Columbus Road Bridge, a double-span swing bridge with approaches extending over a bend in the Cuyahoga River. This bridge, said to be the only one of its kind in the United States, was built to widen the channel and to facilitate both roadway and river traffic. In 1940, a major river improvement necessitated the removal of this bridge to permit the erection of a modern lift bridge of larger span and roadway width.

---

[1] Memoir prepared by Robert Hoffmann, Hon. M. Am. Soc. C. E.

At various times when not holding public office, Mr. Rice was in private practice under the firm name of Walter P. Rice Engineering Company. Among the projects on which Mr. Rice was engaged were a three-hinged concrete arch at Greenville, Ohio; a large masonry arch at Wheeling, W. Va.; a sea wall on Lake Erie (in which he introduced the use of submerged groins); and, in collaboration with the late F. C. Osborn,[4] M. Am. Soc. C. E., the steel arch bridge between Brooklyn and Brighton in the suburbs of Cleveland. The steel bridge has been replaced as part of a general improvement. He also served on special commissions and gave expert testimony in many courts.

Although busy with engineering work, Mr. Rice found time to participate in societies and organizations devoted to promoting professional affairs. He was a man of many activities and a student of many subjects. His interests and studies developed not only an engineer of high standing but a many-sided professional man who reflected credit upon the profession. He was a charter member of the Cleveland Civil Engineers' Club and an honorary member of the Cleveland Engineering Society (successor to the Civil Engineers' Club). In addition he belonged to the Permanent International Association of Navigation Congresses and to the Lehigh Club of Northern Ohio.

Always interested in "Cleveland's" early history and growth, at the time of his death he was president of Cleveland's "Early Settlers Association of the Western Reserve." For recreation, he enjoyed hunting, fishing, and yachting. He was an Episcopalian. In politics, he was a Democrat.

Mr. Rice was elected a Member of the American Society of Civil Engineers on March 6, 1889.

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 1884.

JAMES WALTER RICKEY, M. Am. Soc. C. E.[1]

Died April 19, 1943

In the last decade of the nineteenth century when James Walter Rickey was beginning his professional career, a tremendous development began in the science and application of hydroelectric power which history will record as a prominent feature of human progress in the twentieth century. His activities coincided with so many of the forward steps taken during that time that, without hesitation, he can be awarded a foremost place among the leaders of that movement. His keen interest in every possible further improvement rewarded those whom he served handsomely, and was a source of inspiration to those under him. He became a leader in the profession at an early age, and his activities took him to many foreign lands, where he met the foremost men of his profession.

James W. Rickey, the son of James and Rosaltha (Jones) Rickey, was born at Dayton, Ohio, on November 10, 1871. He received his early education at Minneapolis, Minn., advancing from its high schools to Rensselaer Polytechnic Institute in Troy, N. Y. He was graduated with the degree of Civil Engineer in 1894. His first engineering work was a brief assignment in the office of the eminent consulting hydraulic engineer, the late John T. Fanning, M. Am. Soc. C. E., of Minneapolis. Then he served in the office of a division superintendent of the Northern Pacific Railway Company from September, 1894, to July, 1896. In the fall of 1896, he became principal assistant hydraulic engineer with the Lake Superior Power Corporation, working on a 10,000-hp hydroelectric plant in Sault Sainte Marie, Ont., Canada, and a 40,000-hp plant in Sault Sainte Marie, Mich. (one of the giant plants of its day). In 1897 he became principal assistant engineer with the St. Anthony Falls Water Power Company at Minneapolis, under the late William de la Barre, M. Am. Soc. C. E. This association lasted ten years, during which time he designed the 3,500-hp Hennepin Island and several other hydroelectric plants. In these early years of his career he applied himself intensively to his chosen field of work and by arrangement with his company undertook privately the design of several other projects in the West and Middle West. This additional work occupied his eager mind into late hours of the night for months at a time.

During this period he developed a number of important inventions and improvements in the design of hydroelectric plants, including such widely adopted features as semicircular steel bulkheads for turbine flumes and a novel type of bear-trap dam.

During these early years while Mr. Rickey was getting his practical training, a new industrial giant was developing. The aluminum industry, which had been an important factor in the development of electro-chemical industries using Niagara River power, found the possibilities of further development at Niagara rather limited, and had taken over the old St. Lawrence River Power Company's hydro plant on the St. Lawrence River at Massena, N. Y., in the belief that its requirements had been met for some years to come. However, the industry was growing so rapidly that, since the necessity for greater additional power sources was becoming apparent, a consistent policy of heavy expansion of power facilities had to be adopted. In June, 1907, Mr. Rickey came to Massena as chief hydraulic engineer of the Aluminum Company of America (the old Pittsburgh Reduction Company). He immediately embarked on construction operations with the object of increasing the capacity of the original Massena plant through enlargement of the canal and installation of additional generating units.

---

[1] Memoir prepared by a committee of the Pittsburgh Section consisting of James P. Growdon, Chairman, and R. F. Ewald, Members, Am. Soc. C. E., and D. J. Bleifuss, Assoc. M. Am. Soc. C. E.

At the same time, looking to the future, plans were prepared for the development of the Long Sault Rapids on the St. Lawrence River, and initial steps were taken toward the organization of a company for the purpose of making that project a reality. This called for active participation in many involved negotiations with state, federal, Canadian, and international authorities and engineers. The Long Sault project is one of the world's great water power possibilities, and as such it was certain to challenge the creative imagination and vision of an engineer such as Mr. Rickey. This was one of his fondest dreams, and he may properly be credited with the economic foresight that led to the eventual adoption by the U. S. Army Engineers of the single-stage high-head development now generally favored. Mr. Rickey maintained his interest in this project long after it had passed from the Aluminum Company, and it may be taken as a tribute to his skill that his plans for this great project have been approved by many prominent engineers connected with it at one time or other.

When it became evident that immediate development of the Long Sault would be barred by political considerations, the Aluminum Company turned to other localities for much needed power, and the acquisition and development of those sites constituted Mr. Rickey's major activities for the next thirty years. In 1910 and 1911 Mr. Rickey made a thorough search for, and surveys of, power resources east of the Mississippi, much of this work antedating any government interest in hydro power and requiring original survey work and collection of field data. More than thirty undeveloped sites were investigated personally.

In 1911 the Aluminum Company, under his direction, began the purchase of property in the Little Tennessee River basin in Tennessee and North Carolina, with the object of creating therein a completely integrated hydroelectric development. As the plans grew, many new and interesting engineering problems were solved. Some of these solutions constitute real "firsts" in hydroelectric engineering. Mr. Rickey's proposal for the construction of overfall dams 185 ft and more in height, allowing for floods of more than 250,000 cu ft per sec, was a very bold project for 1914, but, since it was based on thorough investigations of models which disclosed for the first time the importance of the hydraulic jump in the control of erosion, the soundness of the project was proved.

The Little Tennessee projects will always have an interesting place in the history of hydroelectric development in America. A brief description of each follows:

Project	Location	Completed	Capacity (kw)	Head (ft)
Cheoah	At Tapoco, N. C.	1919	80,000	185
Santeetlah	Near Robbinsville, N. C.	1927	45,000	663
Calderwood	At Calderwood, Tenn.	1930	121,500	215
Glenville	Near Glenville, N. C.	1941	21,600	1,215
Nantahala	At Nantahala, N. C.	1942	43,200	1,005

The turbines for Cheoah were duplicates of those installed at the Narrows plant on the Yadkin River in North Carolina and constituted a step forward in size and power when they were ordered in 1916. The use of vibrators in placing concrete was begun in the final stages of construction of Santeetlah Dam in 1927, probably marking the first use of such equipment on dams. Glenville and Nantahala, with the highest heads east of the Rocky Mountains, were constructed after the termination of Mr. Rickey's active services, but the general plans for them were prepared during his active years.

Fontana (N. C.), under construction during 1942–1944 by the Tennessee Valley Authority, was originally a part of the company's Little Tennessee System. This great project, with its 477-ft dam and 202,500-kw power house, is being built substantially according to plans made during Mr. Rickey's active direction of the preliminary studies for this project.

In 1915 a partly completed development at the Narrows on the Yadkin River, begun by a French company in 1913, was taken over by the Aluminum Company of America, when the former company found itself unable to proceed as a result of the outbreak of World War I. Mr. Rickey made drastic revisions in the plans, nearly tripling the spillway capacity and simplifying the generating units along lines that are now practically standard but that constituted a marked step forward in contrast to the then standard equipment proposed by the French company. In addition, two other developments were built under Mr. Rickey's direction on the Yadkin. The complete schedule for this project follows:

Project	Location	Completed	Capacity (kw)	Head (ft)
Narrows	Near Badin, N. C.	1917	81,200	179
Falls	Near Badin, N. C.	1919	20,300	52
High Rock	At High Rock, N. C.	1927	33,000	59

During the early 1920's, Mr. Rickey made several extended foreign tours which gave him excellent opportunities to familiarize himself with the best practice in hydraulic engineering in all parts of the world and to add to his already wide list of acquaintances.

In 1925, the aluminum industry took an active interest in the development of the Saguenay River in Quebec, Canada, and, as chief engineer of Alcoa Power Company Limited, Mr. Rickey was active in the design and construction of Chute à Caron power house and dam, and preliminary design of the Shipshaw Project. In connection with this work, he was responsible for one of the most spectacular feats of engineering history—the construction "on end" of a massive 92-ft-long concrete dam, which was tipped into place for the purpose of diverting the Saguenay River into a new channel during the closure of the main dam. This "precast dam" which became generally known as the "Chute à Caron Obelisk" was hailed far and wide as one of the boldest engineering ventures ever undertaken. Chute à Caron Dam and its 260,000-hp power house, completed in 1931, were the first steps in a power development which was completed in 1943 with a capacity of 1,200,000 hp at the one site.[3]

The foregoing brief synopsis covers only the major projects with which Mr. Rickey was associated during his busy career. He acted as consultant on numerous smaller projects in Canada, northern New York, and North Carolina, and on the investigation of hydro power projects all over the world.

Throughout his career, he applied himself intensively to his professional work and allowed himself little in the form of diversion or hobbies. His standard reply to inquiries regarding his favorite hobby was "anything pertaining to hydraulic power development." His mind was highly inventive and he was constantly seeking unconventional and new ideas which offered opportunities for important savings for his clients. He had the courage of his convictions, and, once he was satisfied that the engineering fundamentals were sound, he did not hesitate to stake his name and reputation on the adopted plan, no matter how bold.

He took particular delight when members of his staff developed valuable new ideas and insisted that they receive all the credit whenever such ideas proved successful. He was a "man builder" in the real sense and his demands for performance were high. Engineers by the scores who were members of his staff at one time or another may be found in many parts of the United States. Invariably they recall their good fortune in having been associated with Mr. Rickey, their chief, counselor, and good friend who inspired them to better engineering and better citizenship.

A strong and active member of the Society, he valued his membership and urged his associates and employees to participate actively in developing professional solidarity. In his desire to see his company's engineers advance in professional standing, he encouraged them to write papers for the Society's publications under their own names, at the same time thus making the developments carried out under his direction known to the profession at large. His sociability, histrionic abilities, and widespread charities will always be remembered.

Practically his only nonprofessional activity in Pittsburgh's civic affairs was his service as director of the Pennsylvania Association for the Blind and of Pittsburgh's Workshop for the Blind. He derived much satisfaction in being of assistance to those who could not see.

On January 1, 1938, Mr. Rickey retired from active service as chief hydraulic engineer of the Aluminum Company of America, but continued as a consultant. With characteristic energy he took up hobbies which he had foregone during his more active days and achieved considerable fame as an amateur photographer in the few short years remaining to him. As would be expected, he started an active career in photographic research, which no doubt would have led to many improvements had he been permitted to continue.

---

[3] "Blasting a Precast Dam into Place," by C. P. Dunn, *Civil Engineering*, December, 1930, p. 159; also "Models Predict Behavior of Falling Dam," by Adolph J. Ackerman, *ibid.*, July, 1932, p. 415.

On January 24, 1899, Mr. Rickey was married to Lucy A. Mitchell at Minneapolis. In 1940 he and Mrs. Rickey, who survives him, moved from Pittsburgh, Pa., to Washington, D. C. In his well-deserved freedom from the heavy professional responsibilities of earlier years, he found keen enjoyment, devoting much of his time to his wide circle of friends and to his newfound hobby. It was therefore all the more distressing to see this happiness suddenly interrupted overnight by the loss of his sight. However, the courage and optimism which had been the foundation of his great career carried him forward, and, during the eighteen months preceding his death, he maintained a cheerful spirit which was an inspiration to all who visited him. Strangely enough, the type of helpful encouragement, which he at one time had given to blind friends in Pittsburgh, served him well to the end.

He was a member of Sigma Xi and Theta Nu Epsilon fraternities, the American Technical Committee of the International Committee on High Dams, Engineers Society of Western Pennsylvania, and Rensselaer Society of Engineers.

Mr. Rickey was elected an Associate Member of the American Society of Civil Engineers on September 3, 1902, and a Member on April 4, 1905.

JOHN WESLEY RIPLEY, M. Am. Soc. C. E.[1]

DIED NOVEMBER 10, 1943

John Wesley Ripley was born in Sag Harbor, L. I., N. Y., on February 5, 1870, the son of John W. and Julia (Douglas) Ripley. One of his forebears, Capt. Joseph Ripley of the brig *Hope* was a skipper of the Sag Harbor whaling fleet which, prior to 1800, carried a greater tonnage of foreign commerce in square rigged ships than the City of New York (N. Y.).

From his seafaring ancestors, Mr. Ripley inherited a great love for the sea and for sailing. During his boyhood in Sag Harbor he worked before and after school during the winter making and setting out fish nets and clamming. He also was employed in the local shipyard and, as first mate on a small craft, carrying freight and sailing parties. Later he skippered his own boat, advertised as follows:

"Poquatuck
Sailing or Picnic Parties
will find the
Yacht Poquatuck
Both comfortable and safe
with prices moderate
John W. Ripley
Orders may be left with G. A. Halsey"

---

[1] Memoir prepared by R. T. Betts, M. Am. Soc. C. E., with the assistance of F. Douglas Ripley, Rate Engr., Long Island Lighting Co. Mineola, N. Y.

Mr. Ripley was a life member and for two years a Commodore of the Bayside, L. I., N. Y., Yacht Club, and his schooner-rig *Kumalong* was always listed in the club's annual Block Island race. After his boat came in second or third several times, he determined to win. A scale model of the boat was made, and the writer witnessed the trial of different sizes, shapes, and sets of sails with the aid of an electric fan. That year Mr. Ripley won the race.

He was graduated in 1893 from Cornell University at Ithaca, N. Y., with the degree of Civil Engineer. During the next five years he was a draftsman for the Groton (N. Y.) Bridge Company, Milliken Brothers, and Jackson Architectural Iron Works.

From January, 1898, to February, 1901, he was principal assistant engineer on the 125th Street viaduct in New York for the extension of Riverside Drive, being in full charge for several months of this rather unique and spectacular crossing of the valley on that part of Manhattan Island. From February, 1901, until 1909, Mr. Ripley was chief engineer, structural department, of John Monks and Sons of New York, in full charge of design and construction of the superstructures of many piers in New York City, particularly those on the East River between Fulton Street and Coenties Slip. During this same period he acted as consulting structural engineer for Copeland and Dole, Architects of New York, on the design and construction of several tall buildings in New York City. While with John Monks and Sons, The Monks-Ripley Pile Company was formed to promote the use of the "Ripley Combination Pile," a 3-in. reinforced concrete covering for wooden piles to be used in waters infested with wood borers. Mr. Ripley was granted a patent for this invention which has long since expired. The Ripley Combination Pile was used about 1908 in the construction of a pier in Port au Prince, Haiti—the first use of a protection of this kind for wooden piles.

In October, 1909, Mr. Ripley and Allan A. Robbins, M. Am. Soc. C. E., organized The Robbins-Ripley Company, engineers and contractors, for the design and construction of all types of waterfront improvements. The firm participated in the design and reconstruction of the bulkhead and pier structures for the entire Brooklyn (N. Y.) waterfront of the New York Dock Company and in the construction of similar structures for the Eastern Steamship Lines, Inc.; New York Central Railroad Company; Cunard White Star, Ltd.; Furness, Withy and Company, Ltd.; Delaware, Lackawanna and Western Railroad Company; Hoboken Dock Company; Submarine Base, New London, Conn.; Montauk Development Company; Larchmont Yacht Club; Beard's Erie Basin, Inc.; The Port of Embarkation, Brooklyn Army Base; Merchant Marine Academy, King's Point, L. I., N. Y.; and others. Also, this firm acted as engineers for the Eastern Steamship Lines, Inc., on the design and construction of a new terminal on the North River and for Cunard White Star, Ltd., on the restoration and rehabilitation of Pier 54, North River, after the disastrous fire of May, 1932. Mr. Ripley was vice-president and treasurer of the company from its inception until his death.

A man of short and sturdy stature, he had a fine, gentle, and friendly disposition. He was a welcome guest and a delightful host.

A friend of more than fifty years paid tribute to him in the following words: "If I were to be left on a desert island with one other person only, I should choose John Ripley."

He was active in the affairs of the First Methodist Church and the Young Men's Christian Association of Flushing, L. I., N. Y. At the time of his death, he was a director of the Long Island Bankers and the Seaboard Commercial Corporation, and a trustee of the Queens County Savings Bank.

On August 27, 1896, Mr. Ripley was married to Eleanor Orr in Stamford, N. Y. He is survived by his son, F. Douglas; a daughter, Eleanor (Ripley) Crosby; and a granddaughter, Eleanor Crosby.

Mr. Ripley was elected a Member of the American Society of Civil Engineers on May 1, 1907.

LOUIS CHARLES ROCKETT, M. Am. Soc. C. E.[1]

DIED APRIL 13, 1943

Louis Charles Rockett was born on February 10, 1889, at Chicago, Ill., the son of Henry George Rockett and Elizabeth Mary (Rowe) Rockett.

He received his early education in the grade and high schools of Chicago. He entered the University of Wisconsin at Madison, in 1911, and was graduated with the degree of Bachelor of Science in Civil Engineering in June, 1915.

From June, 1915, to November, 1917, Mr. Rockett was employed in the division office of the Chicago and North Western Railway Company in Chicago. From November, 1917, to June, 1918, he worked for the Wisconsin Highway Commission. From July, 1918, to January, 1919, he was with the U. S. Army on location and construction of railroads. From February, 1919, to July, 1922, he was again employed by the Wisconsin Highway Commission. From July, 1922, to the time of his death, he was in the Santa Fe (N. Mex.) branch office of the U. S. Public Roads Administration.

Mr. Rockett was active in civic affairs, a veteran of World War I, and a member of the vestry of the Episcopal Church. Prominent in the Masonic Lodge, he served as Worshipful Master of Montezuma Lodge No. 1 and as Worthy Patron of the Order of Eastern Star, Chapter No. 19. In addition, he was Past Grand Master of the Grand Lodge of New Mexico, Past Grand High Priest of the New Mexico Grand Chapter, R. A. M., Past Grand Commander of the New Mexico Grand Lodge, Knights Templar, and Inspector General, Honorary 33 Degrees of the Scottish Rite bodies.

Mr. Rockett was married on June 30, 1927, in Portland, Ore., to Lillian Sundberg. He is survived by his widow; two sons, John and Louis Charles; his mother, Mrs. E. M. Rockett; three sisters, Mrs. Mary Richardson, Mrs.

---

[1] Memoir prepared by a Committee of the New Mexico Section consisting of Berkeley Johnson, M. Am. Soc. C. E., Rufus H. Carter, Jr., Assoc. M. Am. Soc. C. E., and John O. Joerns, Jun. Am. Soc. C. E.

Lilly Kenney, and Mrs. T. R. Marchant; and a brother, William R. Rockett. Funeral services and burial were conducted in Santa Fe on April 15, 1943.

Mr. Rockett was elected an Associate Member of the American Society of Civil Engineers on June 16, 1924, and a Member on October 26, 1931.

EDWARD HENRY ROCKWELL, M. Am. Soc. C. E.[1]

Died May 26, 1943

The death of Edward Henry Rockwell brought to a close a long and diversified career, well balanced between service as a teacher in Tufts College (Medford, Mass.), Lafayette College (Easton, Pa.), and Rutgers University (New Brunswick, N. J.), and a wide activity in the practical field of his profession. Although retired, he gladly returned to carry a share of the teaching burden, abnormally increased by war conditions, in the Department of Civil Engineering at Lafayette College, where he had spent fifteen years in administration and teaching. For forty years he gave valuable instruction to students in civil and structural engineering. He died suddenly from heart failure at his home in Easton.

Mr. Rockwell was born in Worcester, Mass., on April 20, 1869, the son of Edward Munson and Martha Josephine (Smith) Rockwell. He was educated at Worcester Polytechnic Institute in Worcester, being graduated in 1890 with the degree of Bachelor of Science. His alma mater also awarded him the professional degree of Civil Engineer in 1920 and, in 1933, the honorary degree of Doctor of Engineering.

After a brief experience in drafting and shop inspection of bridges in Chicago, Ill., with the late G. S. Morison,[2] Past-President, Am. Soc. C. E., he returned home to engage in business with his father. For two years he was Sub-master in the Leominster (Mass.) High School. Following a half-dozen years of work with several Massachusetts firms as draftsman and superintendent of bridge construction, he resumed his teaching, first as an instructor of civil engineering in Tufts College from 1902 to 1903. His advancement was rapid. He became assistant professor the next year and full professor of civil and structural engineering three years later, continuing from 1918 to 1922.

While teaching at Tufts College at Medford, a suburb of Boston, Mass., he was often engaged as a consultant and director on many engineering projects in that vicinity. He helped to design the Haymarket Station of the Boston subway, the $1,000,000 Suffolk County Court House Extension, and a number of important bridges in the Boston district. He examined and reported upon two proposed designs for the Galveston (Tex.) Causeway Reconstruction, and was consulting engineer in 1917 on designs for reinforced-concrete ships, and also for new United States arsenals. In 1921 he was in charge of plans and construction for the $300,000 chemical laboratory for Tufts College. Before that building was completed, Professor Rockwell was called to Rutgers University to become Dean of the Engineering School and Professor of Civil Engineering, a position that he held with distinction until 1928. From 1928 until his retirement in May, 1942, he was Simon Cameron Long Professor of Civil Engineering at Lafayette College and director of the division of civil engineering.

---

[1] Memoir prepared by Albert H. Gilmer, Prof., Speech and Dramatic Art, Lafayette College, Easton, Pa.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LIV (1905), p. 513.

Professor Rockwell was widely recognized as a leading authority in the field of blasting effects of explosives, and his services were often in demand by owners and operators of quarries and mines, who employed him as an expert witness in court cases. Such professional service often took him afar—to midwestern states and even to the mines of Montana. Out of experience and knowledge in this field he wrote his authoritative volume, "Vibrations Caused by Blasting and Their Effect on Structures."[3]

He also contributed the section, "Reinforced Concrete Arch Highway Bridges,"[4] in the *American Highway Engineers' Handbook,* and wrote occasional bulletins for the Society for the Promotion of Engineering Education.

Professor Rockwell was a member of Phi Beta Kappa, Sigma Xi, Tau Beta Pi, and Lambda Chi Alpha fraternities, in the academic field; and, in the professional field, of the Society for the Promotion of Engineering Education, the American Association of University Professors, and the New Jersey Society of Professional Engineers (ex-president, 1928). He was a member of the Lehigh Valley Section of the Society (President in 1932). At one time he was Lieutenant-Commander, Civil Engineer Corps, U.S.N.R.

Professor Rockwell attributed his usual good health to his love of the out of doors, where he engaged actively in his favorite recreational sports—fly-fishing for bass and trout in the streams of New England, and golf until the week of his death. He was a member of the Country Club of Northampton County, upon whose golf links he was often to be found thoroughly enjoying the game which he played so well with his colleagues.

Both a theoretical and practical scientist of solid character and of many notable achievements, Professor Rockwell had a high pride in his profession and enjoyed teaching its principles and standards to the prospective engineers in the classroom and laboratory.

He was gentle, yet sturdy, and, in his personal relationships, friendly and tolerant, with a desire to understand the viewpoints of others and thus to be fair. He had the high regard, confidence, and hearty cooperation of his fellow workers. His career as a teacher, as a creative engineer, and as a wise counselor in affairs pertinent to his profession is a testimonial to the value of one engineer's share in the mass contribution of civil engineers to the times and places in which they live and labor as cooperative citizens in civilized communities.

Professor Rockwell was married twice. On October 29, 1891, at Worcester, he was married to Lena Hortense Warfield. The five children of that union, all of whom are living, are Grace Margaret (Mrs. Stanley R. Kingman), Dorothy (Mrs. Mark A. Burns), Doris, Lt.-Comdr. Donald Edward, and Rosamond Warfield (Mrs. William W. Cheney). Mrs. Rockwell died in February, 1933. In June, 1941, Professor Rockwell was married to Mrs. Nellie May Williamson Owens of Easton. Besides the children of his first marriage, ten grandchildren, and two great-grandchildren, some of whom are in the military service of their country, he is survived by a brother, Alfred C. Rockwell, and a sister, Ruth Rockwell.

---

[3] "Vibrations Caused by Blasting and Their Effect on Structures," by Edward Henry Rockwell, Hercules Powder Co., Wilmington, Del., 1934.

[4] "Reinforced Concrete Arch Highway Bridges," by Edward Henry Rockwell, *American Highway Engineers' Handbook,* Arthur H. Blanchard, Editor-in-Chief, 1st Ed., John Wiley & Sons, Inc., New York, 1919, p. 1437.

Professor Rockwell was elected an Associate Member of the American Society of Civil Engineers on June 1, 1909, and a Member on May 28, 1912.

WALTER ALEXANDER ROGERS, M. Am. Soc. C. E.[1]

Died January 3, 1944

Walter Alexander Rogers was born in Milwaukee, Wis., on January 19, 1868, the son of Martha (Ross) Rogers and Alexander Hamilton Rogers. He was the second of five children, all of whom were boys.

In 1882 the family moved to a farm in Wauwatosa, Wis., not far from Milwaukee, where in early boyhood Mr. Rogers learned the value of hard work in the daily tasks on the farm.

When he finished high school in Milwaukee in 1884, he entered the University of Wisconsin at Madison. After being graduated in 1888 with the degree of Civil Engineer, he was awarded the John Johnston Fellowship and remained at the university for a year to teach mathematics and to do research work in the comparatively new subject of concrete. At this time he organized the first cement and concrete testing laboratory at the university—one of the first of its kind in the United States.

After a short period with the Wisconsin Central Railway Company, in the spring of 1891 he was employed by the Northern Pacific Railway Company as division engineer at Livingston, Mont.

Mr. Rogers then returned to Milwaukee and was employed by the Chicago, Milwaukee and St. Paul Railroad Company as assistant engineer in the Bridge and Building Department in charge of the double tracking of twenty miles of line, with headquarters at Gurnee, Ill. In 1898 the railroad undertook its first track elevation in Chicago, Ill., and Mr. Rogers was made engineer of subways to handle the bridge construction on this work. In 1899 he was appointed engineer of permanent structures on the Milwaukee Road System. All masonry at that time was built by company forces, and he directed the operation of these forces. While he held this position, the use of concrete in place of stone masonry became a practice on the railroad through Mr. Rogers' continued research and efforts.

---

[1] Memoir prepared by Lester C. Rogers, M. Am. Soc. C. E.

On April 26, 1901, he resigned his position with the Chicago, Milwaukee and St. Paul Railroad Company, and, with the late Onward Bates,[2] Hon. M. and Past-President, Am. Soc. C. E., organized the Bates and Rogers Construction Company. From 1909 until 1937 he was president and active head of the company.

In the early days the firm built such structures as the Tennessee River Bridge for the Illinois Central Railroad Company; one of the early irrigation dams for the United States Reclamation Service at Minidoka, Idaho; and the bridges and tunnel lining for the Chicago, Milwaukee, St. Paul and Pacific Railroad through the Bitterroot Mountains in Montana. When the Grand Trunk Pacific Railway extended its main line from Edmonton, Alta., Canada, to Prince Rupert, B. C., Canada, in 1913, this company constructed all the bridges and lined a number of the tunnels on this pioneer project, in spite of severe weather and transportation problems. The firm constructed two locks and dams on the Ohio River for the War Department, and did a large amount of work for the railroads of the United States until 1917.

During World War I the Bates and Rogers Construction Company was chosen to build the army cantonment at Camp Grant, Rockford, Ill.; the railroad yards at the Hog Island (Pa.) Shipyard; the large government warehouses at Cumberland, Pa.; the shipyard and wooden ships at Millville, Fla.; and the large air nitrates plant at Toledo, Ohio.

During the twenty-five years between World War I and World War II, the company built power stations and dams for a number of the large power companies, and constructed such unusual projects as the Ontario Street Subway for the Cleveland (Ohio) Union Terminals. The firm specialized also in tunnels, placing the lining in the famous five-mile Connaught Tunnel of the Canadian Pacific Railway, constructing and lining the Musconetcong Tunnel for the Lehigh Valley Railroad Company, together with the construction, enlargement, and revision of a large number of tunnels for various railroads throughout the West. In 1937 Mr. Rogers was made chairman of the board of Bates and Rogers Construction Corporation. The firm continued its tunnel work, building Blue and Kittatinny Mountain tunnels for the Pennsylvania Turnpike.

When World War II began, Mr. Rogers again placed the organization and facilities of his firm at the disposal of the government, and, under his chairmanship, war projects worth more than $100,000,000—including the huge Kingsbury and Oak Ordnance plants and permanent bridges on the Alaskan Military Highway—were creditably completed. The company also had the major interest in a joint venture known as Quincy Barge Builders, which built large numbers of tank landing craft and floating dry docks for the Navy.

Mr. Rogers was greatly interested in the construction industry as a whole, and was one of the original group that organized the Associated General Contractors of America, and helped to put meaning into the slogan of that organization—"skill, integrity, and responsibility." He was the second president of this organization, and continued to take a major interest in the growth and standards of the industry throughout his life.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 1484.

On July 1, 1891, he was married to Julia Margaret Cushing, of Wauwatosa, who had attended high school and the University of Wisconsin with him. They made their home in Livingston until the spring of 1892. In 1941 Mr. and Mrs. Rogers celebrated their Golden Wedding Anniversary in company with their family and many friends. Mr. and Mrs. Rogers were the parents of five sons and a daughter—the writer, Margaret G., Ross W. (deceased), Carl R., Walter C., and John W. Mr. Rogers is survived by his widow and five children.

Mr. Rogers resided on his beautiful farm near Glen Ellyn, Ill., with his wife and daughter. He took a great interest in community life, and was an active supporter of the Glen Ellyn Congregational Church, the Young Men's Christian Association, and kindred activities. For many years he was chairman of the board of George Williams College in Chicago, an institution specializing in the training of young men and women for Christian group work in community life.

In his business and home life he insisted on the highest standards of honesty and integrity. Walter Alexander Rogers will be best remembered for his kindly, tolerant spirit, his quiet perseverance in what he believed was right, and his willingness to lend a helping hand.

Mr. Rogers was elected a Junior of the American Society of Civil Engineers on September 10, 1891; an Associate Member on November 3, 1897; and a Member on April 4, 1900.

HARRY ROBINSON SAFFORD, M. Am. Soc. C. E.[1]

DIED APRIL 10, 1943

Harry Robinson Safford was born in Madison, Ind., on February 7, 1875, the son of James Broderick and Josephine (Branham) Safford. He was educated at Purdue University in Lafayette, Ind., from which he received the degrees of Bachelor of Civil Engineering in 1895, Civil Engineer in 1918, and Doctor of Engineering in 1920.

In 1895, immediately after graduation, Mr. Safford began his career in railroad engineering in the engineering department of the Illinois Central Railroad Company as roadmaster from 1900 to 1903; principal assistant engineer from 1903 to 1905; assistant chief engineer from 1905 to 1907; and chief engineer, maintenance of way, from 1909 to 1910. From 1910 to 1911 he was employed as assistant to the president of Edgar Allen Manganese Steel Company of Chicago, Ill. He was chief engineer of the Grand Trunk Railway Company from 1911 to 1918. In the latter year he was asked by the government to serve as assistant regional director of the U. S. Railroad Administration, which position he held until 1920. From 1920 to 1925 he worked for the Chicago, Burlington and Quincy Railroad Company, first as assistant to the president and then as vice-president. During part of this period (1921–1925), he also served as assistant to the president of the Colorado and Southern Lines, Fort Worth and Denver City Railway Company. In 1925 he was appointed vice-president of the Missouri Pacific Railroad Company, and executive vice-president of Gulf Coast Lines and International–Great Northern Railroad Company and subsidiaries, continuing in this capacity until his death.

---

[1] Memoir prepared by Robert J. Cummins, M. Am. Soc. C. E.

As evidence of his tremendous responsibilities, a list of the twenty-two railroad companies and railroad properties for which he was a director is given here: Asherton and Gulf Railway Company; Asphalt Belt Railway; Austin Dam and Suburban Railway Company; Beaumont, Sour Lake and Western Railway Company; Brownsville and Matamoros Bridge Company; Galveston, Houston and Henderson Railroad Company; Houston and Brazos Valley Railway Company; Houston Belt and Terminal Railway Company; Houston North Shore Railway; Iberia, St. Mary and Eastern Railway Company; International–Great Northern Railway Company; New Iberia and Northern Railroad Company; New Orleans and Lower Coast Railroad Company; New Orleans, Texas and Mexico Railway Company; Orange and Northwestern Railroad Company; Rio Grande City Railway Company; St. Louis, Brownsville and Mexico Railway Company; San Antonio Southern Railway Company; San Antonio, Uvalde and Gulf Railroad Company; San Benito and Rio Grande Valley Railway Company; Sugar Land Railway Company; and Western Townsite Company.

In 1920–1921 he served as president of the American Railway Engineering Association. At one time he was a member of the Western Society of Engineers, a director of Engineering Institute of Canada, and a member of the Advisory Council of the U. S. Department of Commerce.

For two successive terms in 1931 and 1932, he served as president of the Chamber of Commerce of Houston, Tex., bringing to that high office the splendid executive ability that had rightly earned for him such high honors in railroad circles. These years tried men's souls, and it is an index of the man that, during Mr. Safford's administration as president, the following meritorious projects were inaugurated by the Chamber of Commerce: (1) A survey of the city's water supply with special reference to additional available sources of supply; (2) the opening-up of foreign trade with a number of South American republics and the establishment of new consulates in Houston; (3) "Foreign Trade Week," an annual event in Houston, was first sponsored; and (4) the highway department took active part in state and federal highway activities, and many miles of new highways were planned.

As an Elder in the First Presbyterian Church of Houston, Mr. Safford gave public expression to the deeply religious convictions that actuated him in all his business relationships and sought to carry into practice the teachings of his Saviour.

His associates on the official board of that Church speak with loving tenderness of his loyalty and devotion as a ruling Elder and his zealousness for the cause he held so dear, never stopping to count the cost in weariness of body or spirit that he might serve worthily as a soldier of the Cross.

Busy man though he was with the countless calls on his time both at home and on the road, Mr. Safford nevertheless found time to serve for four years as president of the Sam Houston Area Council, Boy Scouts of America. From 1938 until his death he was a member of the National Executive Board of the Boy Scouts of America.

His dignified bearing coupled with his abounding love for boys enabled him to wield a powerful influence over the members of the 409 Scout Troops in the Houston area. Hundreds of Houston boys serving with the armed forces were challenged in their younger days to a nobler way of life by Mr. Safford's inspired leadership and his heart warming talks to the Scouts at the numerous jamborees during his term of office. Those who were present on such occasions will long remember the lasting impression made on participants and audience alike as this man of kingly bearing bestowed the honors conferred on the members of the various troops for tasks faithfully performed.

The fact that he found time to devote to such altruistic movements was a source of wonderment to his friends and business associates, but find time he did, and never in half-hearted fashion, but with all his heart and soul and mind.

His influence for good will reach on through the years, and his closest personal friends will long remember him, not so much as one of the outstanding railroad executives of his generation, but rather as a Christian business man whose life exemplified the "Golden Rule" in principle and practice, and who literally inspired hundreds of boys to the nobler way of life.

Mr. Safford was a Thirty-Second Degree Mason and Shriner. He belonged to Sigma Alpha Epsilon fraternity.

On December 12, 1900, he was married to Nell Gertrude Whittemore of Little Rock, Ark., who, with his son, Capt. Harry Robinson Safford, Jr., of the Ordnance Department, U. S. Army, survives him.

Mr. Safford was elected a Member of the American Society of Civil Engineers on July 1, 1908. He became a Life Member in January, 1943.

WILL JOSEPH SANDO, M. Am. Soc. C. E.[1]

DIED FEBRUARY 23, 1943

Will Joseph Sando was born at Scranton, Pa., on April 9, 1864, the son of Joseph William Sando and Mary (Grogan) Sando. His early life was spent in Scranton, where he attended the public schools. At the age of fifteen he began a five-year apprenticeship in the machinist trade, followed by two years as a mechanical draftsman with the Dickson Manufacturing Company of Scranton. From 1886 to 1889 he served as draftsman and shop inspector on power plant machinery and pumping engines for E. D. Leavitt of Cambridgeport, Mass.

---

[1] Memoir prepared by James L. Ferebee and Langdon Pearse, Members, Am. Soc. C. E.

In 1889 Mr. Sando became draftsman in charge of the drafting office of the U. S. Engineers at the William Cramp and Sons Shipyards at Philadelphia, Pa. The following year he returned to the employ of Mr. Leavitt with whom he remained until 1897. From then until 1900 he served as superintendent of pumping stations for the Metropolitan Water Board (Boston, Mass.). From 1900 through 1901, he was chief engineer and manager of the pumping engine department for the International Steam Pump Company (New York, N. Y.). In 1903 he was appointed engineer, pumping department, of the Burr-Hering-Freeman Commission on Additional Water Supply for the City of New York. From 1904 to 1910, he was employed by the Allis Chalmers Company of Milwaukee, Wis., as chief engineer and manager of the pumping engine department, and, from 1907 to 1910, also managed its hydraulic turbine department and studied installations abroad.

From 1910 until his death, Mr. Sando was engaged in practice as a consulting engineer on plans, specifications, inspection, tests, and valuation reports for water works pumping plants; high-pressure fire systems; steam, electric, and hydraulic power plants; cracking still plants for the production of gasoline; and mechanical equipment in sewage treatment plants. For the City of Boston, he prepared plans and specifications for the underground automatic electric sewage pumping station in Summer Street, the high-pressure fire service, the Albany Street aboveground automatic electric sewage pumping station, and the remodeling of equipment at the Calf Pasture Pumping Station. He served the Milwaukee Sewerage Commission as consulting mechanical engineer during the construction and early operating stages of the Jones Island plant, and, from time to time, advised The Sanitary District of Chicago (Ill.) on sewage pumping equipment.

At various times he was engaged as an expert by the following: The City of Cincinnati (Ohio) on litigation in connection with its water works pumping plant; the Chicago and North Western Railway Company on personal injury litigation; Summit (N. J.) and the Indianapolis (Ind.) Water Company on water rate litigation; and the Passaic Valley (New Jersey) Water Commission on the acquisition of property of the Passaic Consolidated Water Company. His advice was sought on pumping engines by Lowell, Mass.; the Alberfoyle Manufacturing Company at Chester, Pa.; and the Pittsburgh Plate Glass Company at Crystal City, Mo.

During World War I he was president of the Milwaukee Boiler Company and of the Monarch Boiler Arch Company. He was a member of a Milwaukee draft board.

Among his other activities, he was an advisory engineer for the Reconstruction Finance Corporation, Chicago Loan Agency, analyzing various loans under consideration.

As an engineer, Mr. Sando was a recognized expert on pumping machinery of various types and on steam practice. His judgment, based on broad experience in the manufacturing and designing field, was valued by his associates.

Mr. Sando was a member of the American Society of Mechanical Engineers, the American Institute of Consulting Engineers (1925–1937), and the Boston Society of Civil Engineers. In addition to his professional work, he was interested in social clubs, serving for twelve years as a director of the Milwaukee Club. He enjoyed bowling and golf and formerly was a member of the Milwaukee Country Club and Tripoli Country Club (Milwaukee). At one time he also belonged to the Engineers Club in New York City and the Engineers Club in Boston.

In 1889 he was married in Boston to Clara Smith Collins, who died in 1906. In 1928 he was married in Chicago to Eleanor Burke Williams, who, with a stepdaughter, Eleanor Burke Williams, survives him.

Mr. Sando was elected a Member of the American Society of Civil Engineers on August 31, 1909.

MARSHALL NEY SHOEMAKER, M. Am. Soc. C. E.[1]

DIED FEBRUARY 9, 1943

Marshall Ney Shoemaker was born in Manayunk, Philadelphia, Pa., on October 6, 1873, the son of Marshall Ney and Anna Anderson (Simpson) Shoemaker. His Quaker ancestors came from Kriegsheim, Bavaria (later Germany), in the seventeenth century and settled Shoemakertown (later Elkins Park, Pa.) and Germantown, Pa.

He attended the public schools in Manayunk and was graduated from the Grammar School. Shortly thereafter he secured a position with A. and P. Roberts Company at Pencoyd, Pa., as apprentice surveyor. After about two years of surveying, during which he received individual instruction in engineering from the late C. C. Schneider,[2] Past-President, Am. Soc. C. E., and the late Paul L. Wolfel,[3] M. Am. Soc. C. E., he was transferred to the drafting room to trace stress sheets and figure estimates. In 1895 he had advanced so far in his studies and had gained sufficient experience to be given the responsibility of making estimates and structural designs for bridges and buildings. When the American Bridge Company was formed in May, 1900, Mr. Shoemaker was made secretary to the vice-president, Engineering Department. In 1901 he acted as assistant to the chief engineer at Pencoyd, and, from then until 1903, he was engineer of the Eastern Division Drawing Room, stationed in New York, N. Y.

From 1903 to 1910 he was vice-president of the American Concrete Steel Company with offices in Newark, N. J. During that time he designed and supervised the construction of a number of schools and industrial buildings of reinforced concrete construction.

In 1910 Marshall Shoemaker opened an office in Newark as a consulting engineer and architect and practiced until he retired in 1930. His work was concerned largely with industrial buildings. He was also active in many civic matters and wrote a new building code for the City of Newark, which was in effect at the time of his death. He was a prominent appraiser of real estate values and was called on continually to testify in this connection.

---

[1] Memoir prepared by G. E. J. Pistor, M. Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 1665.

[3] For memoir, *ibid.*, Vol. LXXXIV (1921), p. 940.

The possessor of a most kindly disposition, Mr. Shoemaker always was ready to assist his fellow men, if they were worthy. He extended a cheerful welcome to all. To those who were fortunate enough to know him well he was a staunch friend.

Although Mr. Shoemaker obtained his education the hard way—through study at night and experience by day—he was very appreciative of the opportunities offered by the institutions of higher learning. He was always ready and willing to help the young man who, without help, could not attend college. In fact, he took a sincere interest in any young person capable and anxious to advance.

On November 14, 1907, at St. Judes Church in Philadelphia, Pa., Mr. Shoemaker was married to Mary Bernard, who survives him.

He was a charter member of the Kiwanis Club of Newark; a life member of Mosque Temple; and a member of Kane Lodge No. 55 F. and A. M., Royal Order of Jesters, and Odd Fellows of Roxborough (Pa.). Among the scientific societies to which he belonged were the American Society for Testing Materials and the American Institute of Architects.

Mr. Shoemaker was elected an Associate Member of the American Society of Civil Engineers on April 1, 1903, and a Member on January 3, 1911. He became a Life Member in 1938.

ARTHUR GREGG SINGER, M. Am. Soc. C. E.[1]

Died November 9, 1942

Arthur Gregg Singer was born in Philadelphia, Pa., on December 10, 1872, the son of Charles Arthur and Elizabeth (Gregg) Singer. He received his preparatory education in the public schools of Philadelphia and was graduated from the University of Pennsylvania at Philadelphia, in 1892, with the degree of Bachelor of Science in Civil Engineering. He received the degree of Civil Engineer from the same University in 1893.

Mr. Singer's boyhood was spent in an atmosphere filled with educational interests. His father, Charles, and an Uncle Edgar (Singer) lived in adjoining homes and both possessed wide reputations as educators in the public schools of Philadelphia. For many years, Charles was the principal of the Marshall Boys Grammar School of Frankford, and Edgar was an assistant superintendent of the public school system in Philadelphia. Although Edgar's oldest son also became an educator, Charles' only son, Arthur, turned to the engineering profession for his lifework.

---

[1] Memoir prepared by Thomas Buckley, M. Am. Soc. C. E.

The community in which Mr. Singer was born and raised has been noted for three quarters of a century for the number of its young men who have sought technical careers in municipal service. He was attracted early to this field of activity and, after graduating from the University, entered the Bureau of Surveys, Department of Public Works of Philadelphia, on September 27, 1893. His engineering career began when he was appointed second assistant in the Second Survey District of the Bureau of Surveys and a member of a field corps in charge of surveys for sewers, paving, conveyances, park improvements, and the establishment of the city plan. He held this position until promoted to first assistant on June 15, 1901. From 1901 to 1907, as first assistant in the Second Survey District, he was in responsible charge of surveys, plans, and designs required in connection with sewer, park, and boulevard construction, and city planning.

In 1906 the City of Philadelphia began a comprehensive program of grade crossing eliminations that continued for many years. A number of trunk-line railroads and numerous grade separations were involved, and it became necessary to expand the engineering forces of the Bureau of Surveys by the creation of a unit designated as the Grade Crossing Division. Because of his excellent service record Mr. Singer was transferred in July, 1907, to the newly organized Grade Crossing Division as assistant engineer, remaining until July, 1920.

During this time he was in responsible charge of construction work on the abolition of numerous grade crossings on various lines of the Philadelphia and Reading Railway Company, the Pennsylvania Railroad Company, and the Baltimore and Ohio Railroad Company in the City of Philadelphia. One of the most notable of these projects was the elimination of grade crossings on the Port Richmond branch of the Philadelphia and Reading Railway Company and the opening and underpassing of several important highways blocked by this railway. The work included grade separations at two important arterial highway intersections, the construction of five new underpasses, and the reconstruction of an existing underpass. The majority of the bridge structures carry a 24-track system. There was, in addition, a great volume of construction work on the approaches to these underpasses, including extensive grading, sewer construction, underpinning, and repaving.

Mr. Singer's services in the Grade Crossing Division included the design and supervision of railroad structures and track layouts, the design and construction of sewer systems, street improvements, underpinning, railroad yards, structures, abutments, and the preparation of specifications and plans. During the same period he was also in responsible charge of construction work on the widening and improvement of Delaware Avenue, which runs alongside the Delaware River, and constitutes Philadelphia's most important commercial and industrial highway.

In 1920 the program of grade crossing abolitions was completed, and, on July 1 of that year, Mr. Singer was appointed surveyor and regulator in the Bureau of Surveys, Department of Public Works, and assigned to the Second Survey District. It is of interest to record that this district which he directed was the same one in which he began his engineering career twenty-seven years earlier. As surveyor and regulator he had charge of city planning, plans and projects for parks, boulevards, and other municipal improvements, and the making of surveys for all classes of improvements for both public and private interests within the Second Survey District. On March 17, 1925, he was placed in charge of the Tenth Survey District, which division of the Bureau of Surveys was doing the largest volume of construction work ever performed by any survey district.

Grade crossing elimination activities were resumed in Philadelphia in 1926, and Mr. Singer resigned his position as district surveyor and regulator to accept the appointment of assistant division engineer in the Grade Crossing Division of the Department of Public Works. Upon his return to the work of eliminating grade crossings, Mr. Singer directed construction for abolishing grade crossings on the lines of both the Philadelphia, Germantown and Norristown Railroad Company and the Philadelphia, Germantown and Chestnut Hill branches of the Philadelphia and Reading Railway Company. A number of important highway underpasses were constructed under this project in the Manayunk, Germantown, and Chestnut Hill sections of the City of Philadelphia.

Mr. Singer resigned from municipal employment on December 15, 1932, retiring after a period of nearly forty years of continuous efficient and honorable service in the Department of Public Works of the City of Philadelphia. His record in the Bureau of Surveys and the Grade Crossing Division affords an excellent example of a career man in public service. In addition to his engineering attainments, Mr. Singer was endowed with a pleasing personality and maintained at all times an attitude of helpfulness and consideration in his relationships with others. His judgment in public affairs was firm and sound and, in all contractual relations, tempered by a sense of fairness that won universal respect. He was unswervingly loyal to the best interests of the city and a trustworthy servant of both the city and the public.

For a long period of his life Mr. Singer was an enthusiastic and highly competent cricket player. He was a member of the old Oxford Cricket Club and the Frankford Cricket Club, and participated in many important games in this field of sport. He was a member of the Engineering Alumni of the University of Pennsylvania, the Engineers Club of Philadelphia, and the Frankford Historical Society.

Being of an exceedingly industrious nature, Mr. Singer's greatest enjoyment was found in constructive labor. He succeeded his father, Charles Arthur Singer, as the secretary of the Decauter Building and Loan Association, and was interested in the development of sound building association activities. At the time of Mr. Singer's death the Decauter Association was about one hundred years old and the oldest organization of its kind in the United States.

On January 21, 1909, he was married to Edith Elizabeth Good in Olney (Philadelphia). He is survived by his widow; two sons, Charles Gregg and Arthur Gregg, Jr.; and his mother, a woman of remarkable qualities who had reached the notable age of 102 years at the time of her son's death.

Mr. Singer was elected a Member of the American Society of Civil Engineers on August 28, 1922.

CHARLES SLEEPER STERLING, M. Am. Soc. C. E.[1]

Died September 6, 1943

Charles Sleeper Sterling was born on August 29, 1878, at Watkins Glen, N. Y., the son of Daniel and Sara (Sleeper) Sterling. He was graduated in 1902 from Colgate University, at Hamilton, N. Y., with the degree of Bachelor of Philosophy. He was a member of Phi Beta Kappa and Phi Kappa Psi fraternities. He was registered in New York State as a Professional Engineer and Land Surveyor. Although his formal education did not lead to an engineering degree, it was not strange that he entered the engineering field as his father had long been identified with railroad construction and maintenance.

For the greater part of the period between 1902 and 1915 he was employed in railroad engineering work by the Pennsylvania and the Lehigh Valley railroad companies, and on the construction of an electric railway in New Jersey and railroad surveys in Cuba. The remainder of this period was spent as a teacher of mathematics at the Mercersburg (Pa.) Academy and the Morristown (N. J.) School for Boys, as engineer for the New York State Barge Canal Terminal Commission, and in private practice. From 1915 to early in 1918 he was engaged on highway work for the State of New York. In 1918 he was commissioned a Captain in the Engineer Reserve Corps, U. S. Army. On receiving his honorable discharge from the armed forces he resumed his work with the State of New York and in various engineering capacities was engaged on Barge Canal construction until the end of 1924.

In 1925 Mr. Sterling again entered private practice, and from then until his death he was associated with the late Frank M. Williams,[2] M. Am. Soc. C. E., and the writers in general consulting practice at Albany, N. Y.

Charles Sterling was a man of deep convictions. Once he had decided on a course of action charted as the result of his characteristic critical analysis of the facts, there was no deviation. Any thought of appeasement or compromise involving principles never entered his mind. He was a good engineer and displayed a keen interest in upholding the standards of his profession. He gave generously of his time and effort to many worthy causes. His unfailing interest in civil affairs, in the activities of his church, and, particularly, in the welfare of the less fortunate was most pronounced. Not only to his close friends but to a wide circle of acquaintances his strength of character and his unswerving determination to do what he felt was right made a deep and lasting impression.

Mr. Sterling was married in 1921 to Eugenie M. Spoor of Rochester, N. Y., who survives him.

Mr. Sterling was elected a Member of the American Society of Civil Engineers on July 11, 1927.

---

[1] Memoir prepared by Roy G. Finch and Edward H. Sargent, Members, Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 1626.

GEORGE HENRY TINKER, M. Am. Soc. C. E.[1]

DIED OCTOBER 1, 1942

George Henry Tinker was born in Lawrence, Mass., on January 18, 1868, the son of William H. and Emma (Beale) Tinker. He was married to Ida A. Leek of Cleveland, Ohio, in 1906. Mrs. Tinker and her two daughters by a former marriage are dead.

Mr. Tinker was educated at the University of Nebraska, in Lincoln, being graduated with the degree of Bachelor of Civil Engineering in 1890. In 1897 he received the degree of Civil Engineer.

From 1890 to 1899, he was engaged in miscellaneous engineering work for city and county organizations in western sections of the United States. From 1899 to 1903 he was employed in engineering positions on western railroads. From 1903 to January, 1904, Mr. Tinker was with the Minnequa Water Company, in charge of location of a canal and of designing wood-stave pipe siphons.

From April, 1904, until he retired in 1939, he was in the employ of the New York, Chicago and St. Louis Railway Company. At first, he functioned as inspector and assistant engineer on important work for the railroad company. In 1907 he was promoted to bridge engineer. In his position of bridge engineer he redesigned and rebuilt many structures requiring strengthening and reconstruction, as well as new bridges in connection with grade-crossing eliminations and other locations.

Although Mr. Tinker's principal employment considered from the viewpoint of years of service, and possibly from the degree of importance, was as a bridge engineer, he acquired a varied experience in other important engineering lines—especially on work in the West during his early years as civil engineer.

He was outstandingly careful and conscientious in his work, which caused him to be held in great respect and esteem by his associates and other engineering representatives who admired his ability.

An insight into his character and activities is afforded by the following:[2]

> "Mr. Tinker was actively interested in engineering and scientific societies. He was a life member of the American Society of Civil Engineers and of the Cleveland Engineering Society, and had served on committees of both organizations for many years. Before his retirement he had also been an active member of the American Society for Testing Materials and served on several joint committees.
>
> "Mr. Tinker joined the American Railway Engineering Association in 1907, and from that date until his retirement, he took an active interest in all its work, seldom missing an annual meeting. He was a member of Committee 15 for many years, retaining his committee membership after his

---

[1] Memoir prepared by a Committee of the Cleveland Section consisting of Robert Hoffmann, Hon. M. Am. Soc. C. E., and Wendell P. Brown and B. R. Leffler, Members, Am. Soc. C. E.

[2] *Bulletin*, A. R. E. A., January, 1943.

retirement. His advice and counsel were always welcome and were of great benefit to the Association. He was a real student in matters pertaining to his profession."

For many years Mr. Tinker was secretary-treasurer of the Cleveland Section of the Society. He also gave much of his time and effort to promoting the welfare of other engineering organizations.

For recreation Mr. Tinker was interested in nature studies and incidental to them he developed the hobby of mountain climbing and hiking. He was a member of the Appalachian and of the Rocky Mountain climbers clubs and of the Cleveland Hiking Club.

Although not active in politics, he was interested in the Republican Party. His church affiliations were Protestant Episcopalian.

Mr. Tinker was elected a Member of the American Society of Civil Engineers on August 31, 1909.

ENRIQUE AUGUSTO TOUCEDA, M. Am. Soc. C. E.[1]

DIED OCTOBER 20, 1943

Enrique Augusto Touceda, the son of Gabriel Touceda and Maria Augustina Solis Touceda, was born on April 15, 1862, in Matanzas, Cuba. He received his early education in Cuba; later attended Georgetown University at Washington, D. C.; and was graduated from Rensselaer Polytechnic Institute at Troy, N. Y., in 1887 with the degree of Civil Engineer.

During his student days he was employed as a chemist and from 1887 to 1893 he was metallurgist and mechanical engineer for the Troy Steel and Iron Company. From 1893 to 1895 he was employed as a metallurgist and mechanical engineer by the Walter A. Wood Company of Hoosick Falls, N. Y., manufacturers of harvesting machinery. From 1895 to 1898 Mr. Touceda was chief metallurgist of the Troy Steel Products Company, a reorganization of the old Troy Steel and Iron Company. In 1899 he opened an office and laboratory as a consulting metallurgical engineer which he maintained actively until his death.

In 1906 Mr. Touceda was appointed professor of metallurgy by Rensselaer Polytechnic Institute, remaining for thirty years as an active professor. In 1937 he was appointed Emeritus Professor of Metallurgy and consultant to the department of metallurgy, which position he held at the time of his death. While engaged in teaching, Mr. Touceda was constantly employed as a consulting engineer and in his laboratory in an endeavor to improve metal products. As a result of his investigations, in 1912 he was appointed consulting engineer by the American Malleable Castings Association, later the Malleable Founders' Society. He continued in this capacity until his death.

---

[1] Memoir prepared by Ernest D. Hendricks, M. Am. Soc. C. E., in collaboration with Helen Callan, former Secretary to the deceased, and Charles P. Wagoner, Albany, N. Y.

Professor Touceda was the first recipient of the John A. Penton Gold Medal awarded by the American Foundrymen's Association (A.F.A.) for conspicuous service to the foundry industry. From June 21 to 23, 1922, he delivered an exchange address for the A.F.A. before the Institute of British Foundrymen at Birmingham, England. The subject of this paper was American methods of manufacture of malleable castings, and some data in connection with the finished products were also presented. Following the presentation of this paper he was awarded a gold medal by the Institute for outstanding contributions to the science of metallurgy. In addition, Professor Touceda contributed to the technical press and to the *Transactions* of the American Society of Mechanical Engineers, American Institute of Mining and Metallurgical Engineers, Society of Automotive Engineers, and A.F.A.

For many years Professor Touceda acted as a consultant for the Draper Corporation of Hopedale, Mass., and the York Manufacturing Company of York, Pa. Many other companies also called on him for advice and assistance in solving their problems. He considered the improvement in the metallurgical and mechanical properties of malleable cast iron as his greatest accomplishment.

For forty years Professor Touceda was a member of the American Society for Testing Materials. He also belonged to the Society of Automotive Engineers, American Institute of Mining and Metallurgical Engineers, American Chemical Society, Albany (N. Y.) Society of Engineers, Society of Engineers of Eastern New York, A. F. A., Army Ordnance Association, the Institute of British Foundrymen (honorary member), British Iron and Steel Institute, Technical Association of the Paper and Pulp Industry, Sigma Xi, University Club of Albany (charter member), Albany Country Club, the Union League Club of Chicago, and Chi Phi fraternity. Professor Touceda was a licensed professional engineer in New York State.

Although Professor Touceda devoted most of his time to metallurgy, he also investigated mining properties in Cuba, Mexico, Alaska, and Cobalt, Canada, for clients who recognized his honesty and ability.

He was a scientist who was constantly endeavoring to improve the materials used by the engineering profession. In collaboration with his son he discovered an alloy which is extensively used in war work. Although Mr. Touceda was not actively engaged in the practice of civil engineering, the products of his knowledge and laboratory experiments are constantly being used by civil engineers. His laboratory in Albany was utilized not only for the analysis of chemical and mineral substances but also for the purpose of instructing students in metallurgy and kindred subjects. He gained his outstanding success as a teacher in his alma mater.

Professor Touceda came from a Cuban family of patriots who were driven from Cuba during the revolutions preceding the Spanish-American War. After his graduation from Rensselaer Polytechnic Institute and prior to the liberation of the Cuban people from Spanish tyranny, Professor Touceda contributed to the fullest extent of his financial ability to the cause of the Cuban patriots. Following the Spanish-American War his philanthropy did not cease but was devoted to the needy whenever his help was solicited. However, he always observed the principle of anonymity—no one but himself and the recipient was aware of his gifts.

A charter member of the University Club of Albany, he was usually present every Saturday night to preside over the whisky-poker game. It was an educational privilege to hear his terse and wise remarks on the topics of the day and his descriptions of contemporaneous public characters whom he knew. Of a most unassuming and modest disposition himself, his gentle satire would deftly prick the bubble of publicity-seeking braggarts. His memory will long remain fresh in the minds of his friends, and his character has left an enduring impression that will never be erased.

On February 27, 1892, he was married to Mary Augusta Ritschell, of Troy. He is survived by his widow; two sons, Enrique G. Touceda, Lieutenant Commander, U. S. Navy, and Arturo A. Touceda; three grandchildren; and a sister, Mrs. Arturo Padro.

Professor Touceda was elected a Member of the American Society of Civil Engineers on January 3, 1900. He became a Life Member in January, 1933.

THOMAS THOMSON TOWLES, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 27, 1943

Thomas Thomson Towles, son of the late Dr. William Beverley Towles of "Lynnwood," Cumberland Court House, Va., and Mary Ellen Thomson of Fort Motte, S. C., was born on March 2, 1886, in Charlottesville, Va., where his childhood and early manhood were passed. His father was for many years a distinguished member of the faculties of the University of Virginia at Charlottesville and the University of Vermont at Burlington. Mr. Towles' grandfather, Dr. William B. Towles I, built "Lynnwood."

On both sides of his family, he was descended from early Colonial ancestry. About 1650 the Towles family emigrated from Yorkshire, England, to the Colony of Virginia, settling on the banks of the Rappahannock River at "Towles Point." (A part of the original homestead is standing, still owned by the family.) Mr. Towles' great-great-grandfather, Col. Oliver Towles, Fifth Regiment of the Line, Continental Army, was the first secretary of the Society of the Cincinnati in Virginia and one of the founders. Oliver Towles, Jr., his great-grandfather, was a Major in the War of 1812. His father, Dr. William Towles, left home at the age of sixteen to enlist in the Confederate Army and served with the Army of Northern Virginia for two years before the surrender of Gen. Robert E. Lee at Appomattox. After he was graduated in medicine at the University of Virginia, he became distinguished as professor of anatomy at that institution and at the University of Vermont. Mr. Towles' great-great-great-grandfather on the maternal side, Col. William Thomson of South Carolina, was cited for bravery and formally thanked by the Continental Congress in Philadelphia, Pa., on July 20, 1776, for his defense of Sullivan's Island with his regiment of Rangers (the Third Regiment in South Carolina) on June 28, 1776.

---

[1] Memoir prepared by Mrs. Thomas T. Towles with the considerable assistance of Miss Eleanor Towles, John L. Newcomb, M. Am. Soc. C. E., Douglas Freeman, Editor of *Richmond News,* Richmond, Va., and through the courtesy of H. E. Bralley, Asst. to the President, Stone & Webster Eng. Corp., New York, N. Y.

Mr. Towles' early education was obtained in Charlottesville at the preparatory school of Maj. Horace W. Jones, who had served on the staff of General Lee in the War Between the States.. He entered the University of Virginia at a very early age and completed three subjects—Latin, Greek, and Mathematics—of the four required for the degree of Master of Arts in the Classics by the time he was eighteen years old. Active in athletics at the University of Virginia, he was awarded two letters for two years of varsity football, and he also played tennis and baseball. He was a member of Delta Tau Delta fraternity. Between the time spent in the College of Arts at the University of Virginia and his study of engineering, for two years he was a teacher in the McGuire Preparatory School in Richmond, Va., and at the same time the coach of the football teams.

Following a year with the Bridge Department of the Virginia State Highway Commission as a draftsman on steel highway bridges, he was employed in Panama from 1912 through 1914 by the Isthmian Canal Commission as chief of party and designing draftsman on the machinery for the Miraflores Locks and on the general design of bridges, sewers, and water supply systems.

In September, 1914, he entered the University of Texas at Austin to complete his engineering work started at the University of Virginia. In June, 1915, he received from the University of Texas the degree of Bachelor of Arts; also, from the School of Engineering at that University, degrees in Civil Engineering and the degree of Bachelor of Science in Mathematics.

Upon the completion of this work, he was engaged for two years on maintenance and general construction for the Gulf, Colorado, and Santa Fe Railway Company, a branch of the Atchison, Topeka and Santa Fe Railway Company at Galveston, Tex. When the United States entered World War I, he took an active part in the design and construction of the Naval Aeronautic Station at Pensacola, Fla.

In December, 1918, Mr. Towles entered the employ of the Dupont Engineering Company, serving as construction engineer, division engineer in charge of civil engineering design, and estimator at the Wilmington (Del.) office. In 1921 he became associated with the Department of Public Works of the City of Richmond. For the next five years he was, successively, Chief of the Bureau of Design, Assistant Director of Public Works, Engineer in Charge of City Planning, Chief Engineer of the Zoning Commission, and Acting Director of Public Works.

In 1926 Mr. Towles joined Stone and Webster Engineering Corporation. During the following sixteen years he was engaged almost continuously on major engineering and construction projects and on important engineering investigations and reports, in many parts of the United States, until his retirement because of ill health in May, 1942. He then returned to his home in Charlottesville.

Mr. Towles was an able and cultured engineer of broad experience in a variety of fields of activity. He was also a diligent student of world conditions, historically, politically, and economically. To this study he brought a mind wise, tolerant, and kind.

He is survived by his wife, Alice Otis Bird Towles, to whom he was married on June 11, 1918, at Trinity Church in Galveston; a sister, Eleanor; and a brother, Oliver.

Mr. Towles was elected a Member of the American Society of Civil Engineers on June 19, 1922.

PAUL ANTHONY TROST, M. Am. Soc. C. E.[1]

DIED APRIL 13, 1937

Paul Anthony Trost, long associated with George F. Hardy, M. Am. Soc. C. E., in work for the paper and pulp industry, died on April 13, 1937. He was born on March 9, 1877, at Jersey City, N. J., the third child of Paul and Margaret Trost. After graduation from high school, he attended the U. S. Naval Academy at Annapolis, Md., for a time and was tutored privately in architecture and engineering until 1897. From then until late in 1898 he secured some practical experience and training under several architects and engineers in New York, N. Y., and vicinity.

In November, 1898, Mr. Trost obtained a position in the Engineering Department of the International Paper Company, whose offices were in New York City. He was assigned as assistant to one of that company's division engineers, W. R. Farnsworth, whose headquarters were in Turners Falls, Mass., and who had supervision over new construction and maintenance of the company's mills in Massachusetts, Vermont, and New Hampshire. Mr. Trost held this position until November, 1901, and then conducted a mapping business for several months.

Mr. Hardy was chief engineer of the International Paper Company from 1898 to late 1901, when he opened an office in New York City for general consulting and designing work in the pulp and paper industry. In March, 1902, Mr. Trost joined him as one of his principal assistants, remaining as such until his death. In the year 1918, while Mr. Hardy was New York district manager of Supply Emergency Fleet Corporation, Mr. Trost was also his principal assistant, returning with him to the pulp and paper industry when the war was over. In this association he was prominently identified with many plants in the United States and Canada and was highly esteemed in the industry and by his associates.

Mr. Trost was a licensed professional engineer, and a member of the American Society of Mechanical Engineers and the Engineering Institute of

---

[1] Memoir prepared from records on file at the headquarters of the Society and of the American Society of Mechanical Engineers.

Canada. He was a Thirty-Second Degree Mason and a Knight Templar, and belonged to the fraternal orders of the Elks and Odd Fellows.

His widow, Mildred C. (Smith) Trost, to whom he was married in 1918, survived him but has since died. A stepdaughter, Mildred E. Brush, several brothers, and a sister survive him.

Mr. Trost was elected a Member of the American Society of Civil Engineers on June 11, 1917.

HENRY ALDIS VARNEY, M. Am. Soc. C. E.[1]

Died April 10, 1941

Henry Aldis Varney was born in Gilmanton, N. H., on June 7, 1870, the eldest son of Edwin and Julia (Brett) Varney. His paternal ancestors were Quakers, having moved from Vermont to Gilmanton. His maternal ancestors were settlers in Massachusetts. His father was a surveyor in Newport, R. I.

In 1888 Mr. Varney entered the employ of the late Alexis H. French,[2] M. Am. Soc. C. E., a civil engineer engaged in private practice. This office performed the engineering services required by Brookline, Mass., and, from 1890 to 1894, Mr. Varney supervised the construction of the town's sewers and masonry bridges.

The Town of Brookline established an Engineering Department in 1894, appointing Mr. French, Town Engineer, and Mr. Varney became a member of the engineering staff as an assistant engineer engaged in general municipal engineering work. In 1901 he was appointed first assistant engineer, in charge of the office staff, as well as of park construction and part of the new sewer, surface water drain, and street construction. He served in this capacity until September, 1914, when he was appointed Acting Town Engineer.

For many years Mr. Varney served as consulting engineer for Brett and Hall, of Boston, Mass., and Montreal, Quebec, Canada. This firm specialized in city planning. As a city planner, Mr. Varney's thinking was always four-dimensional: physical, cultural, social, and esthetic, and in his designs the factors of space, color, and massiveness always were incorporated.

In 1915 he was appointed Town Engineer of Brookline.

Unlike most other municipalities, Brookline had a by-law, which established the Engineering Department and required that all engineering work for the various municipal departments, whether design, estimate, construction, study, or report, be under the supervision of the Town Engineer. Such demands required an engineer possessing qualifications of diversified knowledge and experience. Mr. Varney was an ardent student of modern engineering and possessed a keen perception of future development. Although his Yankee background had taught him thrift, he believed that the best engineering and construction methods and practices were the most economical. The result was that the Town of Brookline developed and was making use of the latest engineering practices long before municipalities much greater in size adopted them. He built up the personnel of the department so that its capabilities, integrity, devotion to duty, and achievements are, and might well be, the envy of other municipal engineering departments.

---

[1] Memoir prepared by Walter A. Devine, M. Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 2148.

He was an indefatigable worker, fair, earnest, and honest in his policies and determinations. The two motivating thoughts which were always foremost in his mind were his chosen profession and the rendering to his town of the greatest possible achievement. His personal and professional uprightness was always an inspiration to the members of his staff.

Although Brookline always has been a strictly residential area, the town grew from a sparsely settled town to a large metropolitan residential community during the time that Mr. Varney served as Town Engineer. At times, the growth in many sections was exceedingly rapid, entailing extensive hydraulic, highway, park, sanitary, and structural design and construction and also landscaping. Among the projects designed and constructed under Mr. Varney's direction were a water works filtration system and high service storage reservoir, sanitary sewer and surface water drain systems in various sections of the town; all the bridge superstructures; highways; landscaping for parks, playground, and land about public buildings and several town service buildings; and the construction of one of the first municipal incinerators in New England. Brookline was one of the pioneers in the development and adoption of municipal zoning laws, and the Engineering Department, under Mr. Varney's guidance, made all the necessary studies and final plans. Mr. Varney had his department so well organized and balanced that these great demands upon it were not only met, but accomplished, with the exactitude and proficiency demanded of the best engineering offices.

From 1926 to 1940, as engineer and secretary of the Brookline Planning Board, Mr. Varney spent many hours beyond the demands made upon his time as Town Engineer in planning for the future needs of Brookline. His foresight and consequent able planning saved the town much valuable time and expense. He never deviated from any plan or course of action which he considered right, no matter what pressure was brought upon him. He possessed the courage of his convictions and yielded only in deference to better ones.

On July 1, 1940, after forty-six years of continuous service in the Brookline Engineering Department, Mr. Varney resigned from the department. He returned to Gilmanton, where he always had maintained a summer home. After a brief illness, he passed away on April 10, 1941.

Mr. Varney was married in 1899 to Lucia C. Pillsbury, daughter of Dr. S. B. Pillsbury, of Middletown, N. Y. She died at Brookline on February 20, 1940, after a long illness. Mr. Varney's great devotion to her, especially during her later years, was often the subject of comment among his many friends.

In 1897 Mr. Varney became a member, and in 1927 a senior member, of the American Society for Municipal Improvements. In 1940, in recognition of his forty-six years of service to the Town of Brookline, that society presented him with its veteran's award. He was also a member of the Boston Society of Civil Engineers, as well as Past Master of Brookline Lodge, A. F. and A. M.

Mr. Varney was elected a Member of the American Society of Civil Engineers on April 17, 1917.

WILLIAM WESLEY VARNEY, M. Am. Soc. C. E.[1]

Died July 30, 1943

William Wesley Varney died at the home of his son in Washington, N. J., on July 30, 1943. He was born in Boston, Mass., on September 17, 1864, the son of William Henry and Mary E. (Hoffman) Varney. He studied mechanical engineering for three years at Massachusetts Institute of Technology, at Boston, being a member of the Class of 1886. He was graduated from the University of Maryland Law School, at Baltimore, in 1893 and was admitted to practice in federal and state courts the same year.

His engineering career began as a draftsman for Cramp's Shipyard, Philadelphia, Pa. In 1889 he moved to Baltimore as draftsman in charge and superintendent of construction for the Columbian Iron Works, where he remained until 1892. From 1893 to 1899 he practiced as a consulting engineer. He served as city commissioner (city engineer) and president of the Board of Public Works of Baltimore from 1899 to 1900, and was a member of the Water Board from 1900 to 1903. He again engaged in the practice of consulting engineering from 1903 to 1917. He was Harbor Engineer from 1917 to 1918.

In his later years he testified as expert in patent cases and practiced patent law until shortly before his death. He filed patent applications on Television and Television in Natural Colors, in U. S. Patent Office, January 9, 1892, Serial No. 418,209, "System and Means of Transmitting Optical Impressions in Colors"; January 8, 1892, Serial No. 417,404, "System and Means for Transmitting Optical Impressions" (which covered the transmission of moving pictures in natural colors, from life as well as from films); and January 22, 1892, Serial No. 418,898, "Method and Means of Transmitting Optical Impressions Electrically and Reproducing the Same in Record Form."

He was a member of the American Society of Mechanical Engineers (member of the nominating committee in 1921, chairman in 1922, and ex-officio member in 1923); a Member of the Society of Naval Architects and Marine Engineers; and he served on the American Engineering Council for four years (including a year and a half as treasurer, and two years on the executive board). He was Past Grand Master of the Independent Order of Odd Fellows of Maryland.

---

[1] Memoir prepared by W. Watters Pagon, M. Am. Soc. C. E.

Mr. Varney was a reticent, silent man. He was extremely fond of boating, sailing what is known in the Chesapeake Bay as a "bugeye." He was a member of the Maryland Yacht Club (vice-commodore for two years), and the Corinthian Yacht Club (past-commodore for three years). He served on the Board of Trustees of the First Christian Church of which he was a loyal member. He was a member of the Engineers Club of Baltimore and was an active participant in club activities for many years.

He was married in 1899 to Edith McDonald, who died before him. Surviving are two sons, Dr. William H. Varney and John H. Varney.

Mr. Varney was elected a Member of the American Society of Civil Engineers on April 16, 1918.

ROBERT SPURR WESTON, M. Am. Soc. C. E.[1]

DIED JULY 29, 1943

Robert Spurr Weston was born of early New England Colonial ancestry on August 1, 1869, in Concord, N. H., the son of Lon and Martha Burtch (Greenman) Weston.

At the age of four or five, his parents established a home in Mystic, Conn., and two years later moved to Brockton, Mass., remaining until 1909. Mr. Weston's grandfather on his mother's side was the builder of ships in Mystic and founded the Village of Greenmanville (Connecticut). His father was the owner of the Tuck Manufacturing Company, the makers of fine tools, in Brockton. Following his marriage in 1909, Robert Weston made his home in Brookline, Mass.

In 1891 Mr. Weston was graduated from Amherst College at Amherst, Mass., with the degree of Bachelor of Science, and received the degree of Master of Arts in 1894. During the period from 1894 to 1896 he was a graduate student in chemistry, biology, and sanitary engineering at the Massachusetts Institute of Technology in Boston, and studied in Germany at the University of Berlin during the winter of 1896–1897. From 1913 to 1916 he was assistant professor of public health engineering at the Massachusetts Institute of Technology.

Mr. Weston's professional career began as a chemist. Chemistry was always a subject that he greatly enjoyed, and a field in which he won distinction. One of his earliest engagements was as assistant chemist in the important water filtration experiments and studies at Louisville, Ky., in 1895–1896. His fellow workers included J. W. Ellms, the late George W. Fuller,[2] and the late George A. Johnson,[3] Members, Am. Soc. C. E., whose names have since made sanitary engineering history.

In 1898–1899 he was associated with Mr. Fuller, then a consulting engineer in New York, N. Y.; and during 1899 he joined with the late William Wheeler, M. Am. Soc. C. E., of Boston, in private practice, as a consulting sanitary engineer. During the succeeding years his services were widely sought on many sanitary engineering problems.

---

[1] Memoir prepared by George A. Sampson, M. Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1653.

[3] For memoir, *ibid.*, p. 1678.

On January 1, 1916, he entered a consulting engineering partnership with the writer, his principal assistant engineer, under the firm name of Weston and Sampson, with offices and laboratory in Boston. This association was terminated only by his death. Few engineering partnerships have continued for more than twenty-seven years without any change in the principals and with complete harmony. Mr. Weston was truly an ideal partner.

Mr. Weston served several states and many cities, towns, corporations, institutions, and individuals, in connection with water supply, water purification, sewerage, sewage treatment and disposal, industrial waste treatment, stream and harbor pollution, and other public health problems. During World War I, he was consulting engineer for the United States Shipping Board and the United States Housing Corporation. He was engaged as a sanitary expert in many important litigations, including those on the Chicago Drainage Canal, Delaware River (New Jersey versus New York), and the Connecticut River (resulting from the taking of the Ware and Swift rivers for the Boston metropolitan water supply).

Mr. Weston was coauthor of "Waterworks Handbook,"[4] published in 1916 with new editions in 1918 and 1927, and author of many technical papers dealing with public health subjects. He was always seeking new and better methods of solving perplexing problems, and was recognized by his associates as well abreast of the times. An eminent sanitary chemist has remarked that many of Mr. Weston's theories, although considered radical by some, were in fact ten years in the future. He was an early advocate of the filtration of water supplies to improve public health and their chemical treatment to prevent corrosion of the distribution systems. He was the first to establish the value of prechlorination of colored surface sources as an aid in coagulation and filtration. For his studies on lead poisoning and its prevention, in 1920 he was awarded the Dexter Brackett Memorial Medal by the New England Water Works Association. He also received the Desmond Fitzgerald Medal from the Boston Society of Civil Engineers.

Mr. Weston faithfully attended engineering, chemical, public health, water works, sewage works, and other meetings of associations to which he belonged, and contributed freely to discussion. An indefatigable reader of technical literature, he readily retained the important facts. In addition to his professional career, he greatly enjoyed social contacts, faithfully attended church, and was fond of music. He was kind, understanding, generous to a fault, and especially helpful to young chemists and engineers in whom he took a fatherly interest. One of his outstanding traits was fairness, and his constant purpose was to maintain high ethical standards in his profession. Mr. Weston was a man of large stature and commanding presence.

---

[4] "Waterworks Handbook of Design, Construction and Operation," compiled by A. D. Flinn, R. S. Weston, and C. L. Bogert, McGraw-Hill Book Co., Inc., New York, N. Y., 1916, 1918, and 1927.

In addition to the Society, Mr. Weston had long belonged to the American Institute of Consulting Engineers, American Institute of Chemical Engineers, American Chemical Society, American Public Health Association, American Public Works Association, American Academy of Arts and Sciences, American Water Works Association (honorary life member), New England Water Works Association (honorary member), New England Sewage Works Association, Boston Society of Civil Engineers, Boston Rotary Club, Boston City Club, and the Society of Mayflower Descendants. He was a former president of the New England Water Works Association, Boston Society of Civil Engineers, and Boston Rotary Club; vice-president of the American Institute of Consulting Engineers and the Howard Benevolent Society of Boston; chairman of the Sanitary Engineering Division of the Society; and director of the American Water Works Association. He served on many technical committees and gave freely of his time and energy.

On December 29, 1909, he was married to Josephine Fitz-Randolph, of Plainfield, N. J., who, together with a son, Joseph Fitz-Randolph, and a brother, Lawrence G. Weston, survives him. A daughter, Elizabeth, died on September 28, 1932.

Mr. Weston was elected an Associate Member of the American Society of Civil Engineers on February 5, 1902, and a Member on October 31, 1911.

DANIEL MERRICK WHEELER, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 29, 1943

This is the life story of a man who practiced his profession actively as a civil engineer for more than seventy-five years.

Daniel Merrick Wheeler was born on July 3, 1846, in Rutland, Mass., on Wheeler Farm (acquired by an ancestor in 1756 and now owned by one of the fifth generation in succession).

Mr. Wheeler attended school at Worcester Academy in Worcester, Mass., and in 1867 and 1868 he was a special student at Massachusetts Institute of Technology at Boston. He was a member of the first class to be graduated from that institution. Early in 1943 he received the congratulations of the Alumni Association on the seventy-fifth anniversary of his graduation.

His first work was in Massachusetts where for ten years, 1869 to 1879, he was a member of the firm of Buttrick and Wheeler, Civil Engineers, of Worcester. In this capacity, he was, from 1869 to 1870, engineer in charge of surveys for the Lancaster Railroad Company; from October, 1870, to February, 1872, locating engineer for the Massachusetts Central Railroad Company; from 1872 to 1873, chief engineer for the Worcester and Shrewsbury Railroad Company; from 1873 to 1876, chief engineer for the Commonwealth of Massachusetts in connection with the building of a very large state hospital at

---

[1] Memoir prepared by Edmund R. Kinsey, M. Am. Soc. C. E.

Bloomingdale, Mass.; and, from 1876 to 1878, engineer on various railroad surveys and miscellaneous construction work around Worcester.

At the age of thirty two, Mr. Wheeler was appointed chief engineer of the Magdalena Railroad in the United States of Colombia, South America, where, from November, 1878, to December, 1880, he located and built a railroad with one half of its mileage either on trestles or in tunnels.

He then returned to the United States and within a month was made assistant engineer of the St. Louis-San Francisco Railway Company. In that position, from January, 1881, to January, 1884, he had charge of the construction of part of the main line of that railway through the Ozark Mountains in northwestern Arkansas, including the Boston Mountain tunnel and much heavy mountain work. He also located and built feeder lines in southwestern Missouri.

This was a period of almost feverish railroad building in the Middle West, and Mr. Wheeler moved from job to job, sometimes even overlapping, as fast as work was completed. His services were in great demand, and, in rapid succession, he held the following positions:

January, 1884, to March, 1885—assistant chief engineer of the Burlington, Cedar Rapids and Northern Railway Company (later a part of the Chicago, Rock Island and Pacific Railway Company), building railroads in Iowa, Minnesota, and Dakota Territory.

March, 1885, to April, 1886—assistant chief engineer of the St. Paul and Northern Pacific Railway Company, constructing a double-track railroad from St. Paul, Minn., to Minneapolis, Minn., with several branch lines (the work including the Westminster Tunnel in St. Paul, a double-track bridge across the Mississippi River at Minneapolis, and the Northern Pacific shops at Como, Minn.).

In 1886—chief engineer of the Duluth, Watertown and Pacific Railway Company (later part of the Great Northern Railway Company) with headquarters at Watertown, S. Dak. (then Dakota Territory); in the same year, chief engineer of the Wisconsin, Minnesota, and Pacific Railroad Company, building for the latter company a road from Eagle Lake, Minn., to Mankato, Minn.

January 1, 1887, to April, 1888—division engineer and later acting chief engineer of the Minneapolis, St. Paul and Sault Sainte Marie Railway Company, in charge of work from Minneapolis across Minnesota, Wisconsin, and Michigan to Sault Sainte Marie, Mich., and also from Minneapolis into North Dakota.

April, 1888, to February, 1892—chief engineer and superintendent of the Winona and Southwestern Railway Company with headquarters at Winona, Minn., building a railroad from Winona to Osage, Iowa, and in charge of operation; at the same time, chief engineer of the Winona Bridge Railway Company in charge of construction on the lower drawbridge over the Mississippi River at Winona (the draw span of which was 444 ft long, at that time the longest on the Mississippi River), and building a line from Marshland, Wis., to the Winona Bridge.

February, 1892, to September, 1893—in charge of construction of an extension of the Missouri, Kansas and Texas Railway Company from Boonville, Mo., to St. Louis, Mo.

The railroad building boom was nearly completed. Mr. Wheeler, who had worked on more than one thousand miles of railways, returned to Massachusetts and in 1894 was appointed state inspector of railroads by the Railroad Commission of Massachusetts. He remained in this capacity until July 3, 1916, when, because he was seventy years old, he was retired by provision of law. As a matter of fact, however, he was only seventy years young.

In April, 1917, Mr. Wheeler was appointed consulting engineer of the Berkshire Street Railway Company, operating street railways in Pittsfield, Mass., and other towns, and interurban lines reaching south into Connecticut, north into Vermont, and into the State of New York. In February, 1921, he became chief engineer of the Berkshire System, holding that position until his death on September 29, 1943. He worked actively until after his ninety-seventh birthday. Thus, although he was retired because of age when seventy, he continued for twenty-seven years longer in the practice of his profession.

During such a busy life there were naturally many interesting experiences. About two years after his graduation, Mr. Wheeler became dissatisfied with the engineer's chain then in common use, and he searched for some kind of improvement. A Worcester firm, making the women's hoop skirts of the period, used long, narrow steel bands in the process. Mr. Wheeler obtained some of this material, experimented in methods of using it, and finally adopted a method of putting spots of solder on the bands. On these spots the foot marks were accurately placed. Thus the steel tape in common use today was discovered.

When the Massachusetts Institute of Technology moved from Boston, Mr. Wheeler was accorded the honor of turning the key in the old building in which he had pursued his studies, and then joining the ceremonial procession to Cambridge.

It was natural for Mr. Wheeler to be deeply interested in the history of the New England states where his forebears participated actively in early settlements, in repelling attacks by Indians, in the French and Indian War, and in the Revolutionary War. Acting for the Massachusetts Historical Society, he rebuilt Fort Massachusetts on the ruins of the old fort on the Hoosac River near Williamstown, Mass. This fort figured prominently in the early Indian wars and in the Revolutionary War, and has been under four flags—Colonial, French, British, and United States.

Mr. Wheeler had a practice which is commended to all engineers—he kept diaries, and he kept them faithfully. He began this practice on January 1, 1867. Among other records, he wrote down the mileage traveled each day, at the end of each diary he noted the mileage traveled in the year, and from year to year he computed the total. There are seventy-seven diaries in this series; the last entry, made on August 31, 1943, indicated a grand total of 1,834,511 miles (approximate average of once around the earth for each of seventy-six years) of travel during his long and busy life.

In his professional practice and in his personal life Mr. Wheeler had one compelling motive—he sought to learn the right thing to do. Once satisfied on that point, nothing swerved him from the indicated course. However, the stern application to duty which he required of himself and those under him and the driving force of his executive capacity were in no way inconsistent with his kindly personality toward people, nor with his great love of beauty in nature and in art.

As a hobby he collected pictures of covered wooden bridges and had a surprisingly large collection. He also was an admirer of architectural beauty, particularly as expressed in old New England churches, of which he had a very fine collection of pictures.

Mr. Wheeler had a keen sense of humor, and as long as he lived he exchanged clippings of funny stories with correspondents. He was vigorous all his life and at ninety drove his own car and could outwalk many men forty years younger. The writer knows about that. He was a Christian gentleman who lived his religion seven days in each week and all his life.

Mr. Wheeler came from early New England stock, and his American genealogical record is virtually complete. Of sixty-four ancestors in the seventh generation back, he had records of fifty six, all of whom were born in England and came to America in the early part of the seventeenth century. His records of the succeeding generations which converged in him are complete. His American descent from the Wheeler line traces from Richard Wheeler, born in England in 1611, who was killed by Indians in 1675 at Lancaster, Mass., during King Philip's War. Fourteen other relatives also were massacred in this war.

Other lines of his forebears show many names familiar in New England history. Lest someone might think that dominant characteristics are always conveyed through male lines of descent, it may be noted that an explanation of Mr. Wheeler's long life may be drawn from the fact that his mother, Susan Halladay, lived to be ninety two; her mother, Susanna Adams, ninety two; her mother, Susanna Underwood, ninety eight; and her mother, Hannah Richardson, ninety five.

Mr. Wheeler was married to Arvilla Jane Putnam on November 19, 1868. As might be inferred from her name, Mrs. Wheeler too was from old New England stock, and her ancestral background contains many names familiar in early American history. She died on October 9, 1918.

Mr. Wheeler is survived by a son, Milton Merrick, and by three daughters, Inez Viola (Mrs. Edmund R. Kinsey), Clara Susan (Mrs. Charles F. Harris), and Grace Leota.

Thus ends the story of an all-American gentleman who used his excellent technical training to contribute much to the development of the United States during a long and useful life.

Mr. Wheeler was elected a Member of the American Society of Civil Engineers on March 6, 1901. He became a Life Member in January, 1926.

JAMES GILBERT WHITE, M. Am. Soc. C. E.[1]

DIED JUNE 2, 1942

James Gilbert White was born at Milroy, Pa., on August 29, 1861, the son of the Rev. J. W. White and Mary (Beaver) White. He was graduated from the Pennsylvania State College, at State College, in 1882 with the degree of Bachelor of Arts, and in 1884 received the degree of Master of Arts from the college. At the time of Mr. White's graduation, instruction at the Pennsylvania State College was largely in mathematics and physics. Since he desired to supplement his education, on receiving a fellowship in electrical engineering, he entered Cornell University, at Ithaca, N. Y., being granted the degree of Doctor of Philosophy in 1885. Leaving Cornell, Mr. White became an instructor in physics at the University of Nebraska, in Lincoln, where he taught from 1885 to 1887.

Mr. White was married in Lincoln on December 15, 1886, to Maud Mullon, who survives him, as do one son, J. Dugald White; a sister, Mary B. White; and a brother, John Beaver White.

In the spring of 1887, Mr. White organized the Western Engineering Company with Dugald C. Jackson, M. Am. Soc. C. E., and the late Harris J. Ryan, as associates. For the Western Engineering Company, Mr. White solved some electrical engineering problems in the development of steam and hydroelectric generating stations and electric railways. He also supervised a number of small but important installations. However, the Western Engineering Company was dissolved when his principal associates desired to return to the field of teaching. In 1890 he established the firm of J. G. White and Company, Inc., in New York, N. Y.

During the decade from 1890 to 1900, Mr. White directed many pioneer installations, including steam and hydraulic electric power plants, high tension transmission lines, and one of the first high-speed interurban electric roads—the Buffalo-Niagara Falls Electric Railway. Mr. White's work during this period brought him national and international distinction. English capitalists sought his advice and skill on the construction of a large amount of engineering work in Australia. In 1900 these connections led to the establishment of an English branch of the firm, J. G. White and Company, Ltd. Through that company, Mr. White supervised a large amount of power plant and electric railway and other electrical construction work, including an extensive underground conduit street railway system for the London County Council in London, England. During the next twenty years, Mr. White's English and American companies operated extensively in five continents. In addition to the more strictly electrical work, Mr. White was instrumental in forming the Waring White Building Company, Ltd., of London, which built such notable structures as the Ritz and Waldorf hotels in London, the Liverpool Cotton Exchange in Liverpool, England, the great Selfridge Store in

---

[1] Memoir prepared by Gano Dunn, M. Am. Soc. C. E.

London, and many important office and apartment buildings. Mr. White also established a Canadian subsidiary, the Canadian White Company, Ltd., which built important steam and hydroelectric plants and important office buildings in Canada.

In 1913 Mr. White formed The J. G. White Engineering Corporation to assume the functions previously exercised by the engineering and construction departments of the parent company, which since that date has restricted its activities to the investment banking field. The work of Mr. White's American companies is too extensive and too well known to be listed in this memoir, but the range of their activities covers practically all branches of the engineering and construction fields. Mr. White retired from active business in 1928.

Mr. White was distinctly a pioneer and a leader, a useful and inspiring citizen, as well as an eminent engineer. He was a warm friend and commanded the respect and affection of his associates. Throughout his life he maintained an active interest in his alma mater, the Pennsylvania State College, and for many years he was a trustee of that institution, at which he established loan funds for students, and contributed generously to an emergency building fund of the college. His technical affiliations were many, including membership in the American Institute of Electrical Engineers. During his long business career, he was a member of many clubs and organizations in New York and London.

Mr. White was elected a Member of the American Society of Civil Engineers on March 2, 1904.

HARRY JAMES WIGHT, M. Am. Soc. C. E.[1]

Died July 30, 1943

Harry James Wight, the son of Ambrose Elerson Wight and Mary (Casler) Wight, was born on January 31, 1881, in Ilion, N. Y. His early boyhood was spent in Ilion. In 1887 his family moved to Youngstown, Ohio, and, in 1889, to Chattanooga, Tenn. Mr. Wight lived in Chattanooga until 1891, and then went to Harriman, Tenn. In 1897 he moved to Knoxville, Tenn., where he resided at the time of his death. He was educated in the grammar and high schools of Youngstown, Chattanooga, and Harriman. His technical education was obtained through private instruction.

In the spring of 1902, he entered the employ of the Louisville and Nashville Railroad Company in the Engineering Department, advancing from rodman to instrumentman and finally to construction engineer. In 1908 he left the railroad to become engineer on construction of railroads and highways in Cuba for the William J. Oliver Company, a railroad contracting organization. Upon completion of this work, in eighteen months, Mr. Wight returned to the United States as engineer on railroad construction in North Carolina until 1915, when he accepted a position with the Chicago, Burlington, and Quincy Railroad Company as a valuation engineer. In 1918 he went to Washington, D. C., to do similar work for the Interstate Commerce Commission.

---

[1] Memoir prepared by Leonard C. Bailey, Assoc. M. Am. Soc. C. E.

Because it was urgent for Mr. Wight to be with his family in Knoxville, he resigned from the employ of the Interstate Commerce Commission in March, 1923, and became office engineer in the Department of Public Service of the City of Knoxville. In December, 1927, he was appointed city engineer of Knoxville, remaining in this position until he was promoted to Director of Public Service in August, 1933. During his tenure of office, Mr. Wight was in charge of one of the largest engineering and construction programs ever undertaken by the city. Many miles of streets, bridges, and sanitary and storm sewers were built. Consultation with many governmental agencies regarding expansion of their programs greatly augmented the activities of the department. Mr. Wight was efficient, accurate, and painstaking in every job undertaken; his men followed his leadership willingly and eagerly.

In January, 1938, he resigned as Director of Public Service and accepted employment as engineer of surveys for the Knoxville Housing Authority on the planning and construction of three large low-rent public housing projects.

In June, 1941, on completion of the housing projects, he was employed by the Tennessee Valley Authority as a cost engineer in the Construction and Maintenance Division. In this capacity, he handled construction costs on highways, bridges, sewers, and other types of work in connection with building Watts Bar Reservoir on the Tennessee River. At this time, Mr. Wight's health declined greatly, and he resigned about January, 1942, in order to recuperate. Although he regained some of his strength, he never fully recovered. Because of the man-power shortage, he returned to the city engineer's office in Knoxville as office engineer to assist on the type of work he knew so well, remaining until his death on July 30, 1943.

He is survived by his widow, Carrie Hoefer Wight, to whom he was married on November 23, 1927, and by his daughter, Harriet Jane Wight.

A tireless and energetic worker, his character, honesty, and consideration for his fellow men created loyalty in, and left an indelible impression on, all those who had the privilege of working with him.

He was a member of the First Methodist Church of Knoxville. He was a registered Professional Engineer of the State of Tennessee.

Mr. Wight was elected a Member of the American Society of Civil Engineers on October 17, 1938.

EDGAR KENNARD WILSON, M. Am. Soc. C. E.[1]

Died March 31, 1943

Edgar Kennard Wilson was born in Southington, Conn., on November 14, 1878, the son of the Rev. Joseph K. and Lucy Stone (Taylor) Wilson.

Mr. Wilson was educated at Worcester Academy at Worcester, Mass., and University of Maine at Orono. He belonged to Sigma Chi fraternity.

From 1898 to 1905 Mr. Wilson was engaged in surveying and construction, advancing through the usual grades, from chainman to chief of party. In 1905 he was assistant engineer in charge of construction for the Philadelphia and Western Railroad. From 1906 to 1909 Mr. Wilson worked with the engineering force of the Panama Canal, as transitman in charge of estimates on the Culebra Division and later as assistant in the office of the resident engineer on layouts and design of railroad yards, trestles, and a suspension bridge. After 1909 Mr. Wilson spent some time in private practice in Illinois, and as assistant engineer of the Water District in Portland, Me.

He joined The Pitometer Company, Engineers, in 1912 and continued to serve this firm with great skill and fidelity for thirty-one years until his death, except for five months during World War I. At this time he volunteered for service in the U. S. Army, and, after training at Camp Humphreys, Virginia, was commissioned Captain of Engineers.

In 1918 Mr. Wilson returned to The Pitometer Company, later becoming chief engineer and treasurer. He was engaged actively on hydraulic experiments for the development of the pitometer and on the design of extensions for water distribution systems in many cities throughout the United States.

His work also included the analysis of flow for the betterment of trunk-main conditions in city water works—a service to which he contributed much in conception of methods as well as organizing skill. Mr. Wilson was widely known among water works men in all parts of the United States for his knowledge of distribution problems. He was the author of a number of valuable papers[2] on water works subjects, which added greatly to his reputation. During his association with The Pitometer Company he won the esteem of his associates for his sterling character and professional skill. He also was vice-president and director of the Pitometer Log Corporation.

Mr. Wilson belonged to American Water Works Association, serving as chairman of the New York section; New England Water Works Association;

---

[1] **Memoir prepared by Edward S. Cole, M. Am. Soc. C. E.**

[2] For example, see the following papers by Mr. Wilson: "Keeping Water Works Maps and Field Records Up to Date," *Water Works Engineering,* Vol. 83, No. 16, July 30, 1930, pp. 1143–1144 and 1177–1178; "Maps and Field Records," *Journal,* Am. Water Works Assn., Vol. 23, No. 6, June, 1931, p. 809; "Trunk Main Surveys," *Journal,* Am. Water Works Assn., Vol. 24, No. 5, May, 1932, p. 669; "Why Valves?" *Journal,* Am. Montclair Society of Engineers; and Railroad Machinery Club. For several years he was on the New Jersey Mosquito Extermination Commission.

He was a devoted member of Union Congregational Church, Upper Montclair, N. J., which he served as trustee and custodian of property.

In 1909, he was married to Ida H. Pinkham of Portland. Mr. Wilson is survived by his widow and by his daughter, Elizabeth (Mrs. Dura S. Bradford), and two grandchildren. Of old New England stock on both sides of his family, he lived up to the best traditions of his patriot ancestors.

Mr. Wilson was elected an Associate Member of the American Society of Civil Engineers on May 28, 1923, and a Member on October 1, 1926.

SAMUEL LAMSON WONSON, M. Am. Soc. C. E.[1]

Died September 30, 1943

Samuel Lamson Wonson, son of Gardner Kidder Wonson and Harriet Augusta (Chase) Wonson was born at Gloucester, Mass., on July 1, 1877. The first of the Wonson family settled in Gloucester in 1720, having come from Scotland where the Wonson clan, of Scandinavian origin, had lived for several centuries.

Mr. Wonson's boyhood was spent in Gloucester where he attended the public schools. An episode characteristic of the young Sam is the following: On the opening day he was taken to school dressed according to the then current style for boys living on "the right side of the tracks." Upon returning home he announced in no uncertain terms that his clothes, of what a few years later would have been best described as a "Little Lord Fauntleroy outfit," were definitely out and that, before he would return to school, he must have trousers with patches on them like the other boys. This striving to be a good fellow among men remained with Sam throughout his life.

Sam's father died when the boy was only eight, but this did not prevent the completion of his schooling. At Harvard College, he was an outstanding student, being graduated in 1899, Magna Cum Laude, with the degree of Bachelor of Arts. Further evidence of his scholarship was his election to membership in Phi Beta Kappa—although modesty prevented his key from ever being displayed. After leaving Harvard, Mr. Wonson spent two years at the Massachusetts Institute of Technology, being graduated with the degree of Bachelor of Science in Civil Engineering in 1901. The following year was spent at M.I.T. as Assistant in the Department of Civil Engineering, teaching surveying. He then entered the service of the American Bridge Company where, between June, 1902, and April, 1904, he was a draftsman in the erecting department, and, from 1904 to 1907, Assistant Engineer. During this period he was in charge on the ground of the erection of a railroad bridge over Rio d'Agua in Colombia, South America.

---

[1] Memoir prepared by W. J. Burton and C. E. Smith, Members, Am. Soc. C. E.

This engagement was followed by one which took Mr. Wonson to Mexico City as Assistant Bridge Engineer of the Mexican Railway Company. The three years ending in July, 1910, were spent in the design and reconstruction of both substructures and superstructures for many of the bridges on that railroad.

In August, 1910, desiring to return to the United States, Mr. Wonson accepted an offer from C. E. Smith, M. Am. Soc. C. E., then Bridge Engineer of the Missouri Pacific, to become the latter's assistant in the very large program of bridge work being undertaken. In this work Mr. Wonson's training, supplemented by those traits usually associated with the combination of Scotch and New England ancestry, made him a very valuable man. Because much of its mileage was in the lower Mississippi Valley, the Missouri Pacific had a greater mileage of bridges and trestles than any other large railroad. Among these were some thirty draw spans over navigable (or theoretically navigable) streams. There were more than ten thousand bridge openings and some 150 miles of untreated timber trestles, all of which had been designed for light locomotives. The originally plentiful local timber supply had resulted in the use of untreated timber to such an extent that, when increasing timber prices compelled the change to more permanent construction, there was a near crisis, and great skill was required to make the best of the very limited funds then available.

Mr. Wonson became Bridge Engineer of the Missouri Pacific in 1913 and ten years later was promoted to Assistant Chief Engineer, under the late E. A. Hadley,[3] M. Am. Soc. C. E. About this time the work of bringing the railroad to a higher standard for efficient transportation was greatly accelerated, and Mr. Wonson's promotion brought with it the responsibility for all parts of the construction program. Each year this called for the study and design of a very considerable number of projects. Although many of these were relatively small and followed standardized practice and plans, a not inconsiderable number involved choices between possible alternates and thus much detailed study. No job was too small or too large for Mr. Wonson's personal careful study. He never avoided onerous details by merely passing these on to subordinates. Every conceivable contingency was considered and appropriately provided for. He naturally dealt with a great many contractors and among these, which included some of the best known in the United States, he was regarded as eminently fair, never taking advantage of mere technicalities but at the same time always looking out for the rights of his employer. He recognized that a reputation for fair dealing, when unforeseen contingencies arise, pays in the long run through lower contract prices.

An idea of the extent of planning and supervision under Mr. Wonson's direction is had from the fact that during his twenty years as Assistant Chief Engineer some sixty thousand separate improvement projects were completed at a total cost of about $150,000,000.

Mr. Wonson never was married. Shortly after moving to St. Louis, Mo., he brought his mother to live with him, and he was devoted to her. Even after her death in 1930, he maintained the home alone, as nearly unchanged as possible. His only avocation was his collection of United States postage stamps, with which he spent many long evenings.

---

[3] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 1547.

He was an active member of the American Railway Engineering Association, taking part in the work of two committees—those on Economies of Railway Location and Operation, and Waterways and Harbors. He was also a member of the St. Louis Engineers' Club, The Circle Club, and Delta Upsilon fraternity. He was a Baptist, being a member, and at one time a deacon, of the Second Baptist Church in St. Louis. His funeral in St. Louis was followed by burial in the Wonson family lot in Mt. Pleasant cemetery at Gloucester. His nearest surviving relatives are cousins and an aunt in Massachusetts.

Mr. Wonson was elected an Associate Member of the American Society of Civil Engineers on October 5, 1909, and a Member on October 11, 1920.

EDWARD LOWREY WOODRUFF, M. Am. Soc. C. E.[1]

Died April 1, 1943

Edward Lowrey Woodruff was born on October 8, 1851, in Buffalo, N. Y., the son of Gen. Israel Carle Woodruff, Corps of Engineers, U. S. Army, and Caroline A. (Mayhew) Woodruff.

With two brothers and three sisters his early years were spent in Washington, D. C. There he was educated at the Emerson Institute and the George Washington University (then known as Columbian College). At nineteen years of age he left the latter school to attend the Columbia University School of Mines, New York, N. Y., during the years 1870 and 1871.

During the crucial years of the Civil War his father was second in command to Gen. J. G. Barnard of the City of Washington, and some of Mr. Woodruff's most vivid recollections were of that period. His boyhood services then were much the same as those of Boy Scouts of the present day, filling canteens and performing other similar tasks for the soldiers constantly passing through Washington. His pleasantest memories included meeting Abraham Lincoln and playing games with the president's sons, Tad and Willie. Still a boy at the close of the war, he was introduced to Gen. Ulysses S. Grant and Gen. Robert E. Lee.

During an unbroken professional career of fifty-two years Mr. Woodruff's engineering and architectural talents were devoted to the public service of his country. This doubtless was a natural heritage, for his family history is replete with distinguished public service. His mother was a direct descendant of Thomas Mayhew, 1593–1682, "Patriarch to the Indians, the Worshipful Governor & Chief Magistrate of the Island of Martha's Vineyard, Proprietary of Martha's Vineyard, Nantucket & the Elizabeth Isles, and Lord of the Manor of Lisburg in North America" (see "Thomas Mayhew," by Lloyd C. M. Hare). His father's family home was in Trenton, N. J., and his forebear, Aaron Dickinson Woodruff, was that state's attorney for twenty-four years. Mr. Woodruff's father and two brothers pursued distinguished careers in the U. S. Army.

---

[1] Memoir prepared by R. R. Tinkham, M. Am. Soc. C. E.

Immediately on leaving school, in 1872, Edward L. Woodruff launched a career in the civil service of the federal government as noteworthy as the military service of his brothers. He was employed as assistant superintendent of construction by the U. S. Lighthouse Service, and in that capacity, and successively as superintendent of construction and assistant civil engineer, served in the 3d Lighthouse District, New York, for eighteen years. Early manifestation of those talents that were to earn for him eminence as a lighthouse engineer was rewarded by a call to Washington during the successive summer periods of 1875, 1876, and 1877 as special assistant to Joseph Henry, the great physicist, who was Director of the Smithsonian Institution from its foundation in 1852 until his death in 1878, and who at that time was also chairman of the Lighthouse Board, the administrative agency of the Lighthouse Service. It was Mr. Woodruff's privilege to assist Joseph Henry in experimental research on lighthouse illuminants and sound fog signals that was to revolutionize lighthouse practice and equipment.

During the period of his service in New York he designed, constructed, and equipped eight major light stations in the waters of Connecticut, New York, and New Jersey. Notable among these were Race Rock, Stratford Shoals, and Stepping Stones, all of which stand today, with every evidence of permanence, as monuments to his professional integrity. Concurrently many engineering tasks of less import commanded his equally meticulous attention, including sea-wall construction and minor lights and other aids to navigation. An interesting item not long before his departure from New York was his design and construction of a power house and electric plant on Bedloe's Island for lighting the Statue of Liberty.

With the seemingly inexhaustible energy that remained an outstanding characteristic to the end of his life, Mr. Woodruff occupied his own time outside his official duties to meet a discriminating clientele for his architectural talents, and between the years 1876 and 1890 in New York he designed and prepared the plans for many public and private buildings, including two hotels, a boat club, an amusement park, schoolhouses, the chapel of St. John's Church, and some thirty-six residences and seaside homes, from New Jersey to Massachusetts.

In the spring of 1890 Mr. Woodruff accepted the opportunity for greater responsibilities in his chosen career by transferring to Detroit, Mich., which then was headquarters for the Lighthouse Service on the Great Lakes. There, as the principal assistant engineer, he was closely associated with some of the outstanding officers of the Corps of Engineers, including the late Gen. O. M. Poe and the late Gen. William Ludlow,[2] Members, Am. Soc. C. E., and under their direction was responsible for all design and construction of lighthouses and other aids to navigation on Lake Michigan, Lake Superior, Lake Huron, Lake St. Clair, and connecting waters. During the next nine years he designed and directed the construction of eighteen major light stations in those waters, together with appurtenances and minor aids to navigation, constituting a majority of such structures then extant on the Lakes.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1700.

In February, 1899, the growing magnitude of the work on the Great Lakes having made a division necessary, Mr. Woodruff transferred to the newly created 9th District with headquarters at Milwaukee, Wis. It was there, between 1899 and 1908, that he performed some of his most outstanding accomplishments as a lighthouse engineer. Notable among his lighthouses of this period were Racine Reef and White Shoals, both distinctive and monumental in architecture, and both exceptional engineering structures on subaqueous foundations—Racine Reef in 30 ft and White Shoals in 20 ft, subject to the unique forces of winter ice packs and storm seas of Lake Michigan. These, too, may be added to his many monuments that will stand far into the future.

In 1910 the Congress enacted statutory reorganization of the Lighthouse Service by creating the Bureau of Lighthouses in the Department of Commerce, superseding the Lighthouse Board, which since 1852 had functioned with notable credit to the Army, Navy, and civil officers who had directed its activities.. This threefold responsibility under transitory officials had become outmoded, and the new organization was designed to eliminate much duplication and overlapping. Quoting from the Army and Navy Register for March 4, 1939, regarding this transition: "The end sought justified the means—the United States system of lighthouses, lightships, buoys and ranges is now unsurpassed in all the maritime world." To this record Mr. Woodruff was an important contributor.

Between 1908 and 1910 Mr. Woodruff indulged in a well-earned recess from the exacting demands of his career, the first real vacation of his life. During that period he visited Europe, the first of many such visits to England and the Continent since an early voyage to England with his father when they were entertained by the Master (Duke of Edinburgh) and Brethren of Trinity House, the governing agency of the British Lighthouse Service, a visit that indubitably influenced his subsequent career. Afterward he sojourned in Los Angeles, Calif., where he renewed the private practice of architecture he had undertaken in spare time during those earlier years in New York. However, this was but an interlude.

In the reorganization of the Lighthouse Service in 1910, Mr. Woodruff was selected for one of the principal executive posts in the Service—that of Lighthouse Inspector (later Superintendent of Lighthouses) in charge of the 11th District. Pending the transition from residuary officers of the Lighthouse Board administration to the completed personnel reorganization of the Bureau of Lighthouses, Mr. Woodruff served as Superintendent (chief engineering officer) of the 18th District in San Francisco, Calif. In harness once more, he devoted his talents with renewed energy and enthusiasm to the problems of lighthouse engineering on the California coast. It was at this time he designed the lighthouse which may be said, perhaps, to have become the most notable of his career, the Los Angeles Harbor Light Station, constructed at the seaward extremity of San Pedro west breakwater. It is a bas-relief replica of this lighthouse which adorns the façade of the monumental Department of Commerce building in Washington, D. C., as symbolic of the Lighthouse Service. Years later, for his design of this lighthouse, Mr. Woodruff received the Phebe Hobson Fowler Architectural Award (3d prize) from the American Society of Civil Engineers, in 1929—a belated but fitting tribute to the completion of his active professional career.

In 1912 Mr. Woodruff assumed his post as Lighthouse Inspector in charge of the 11th District with headquarters in Detroit, having under his jurisdiction all aids to navigation and their operating appurtenances in the United States waters of Lake Superior, Lake Huron, Lake St. Clair, and their connecting and tributary waterways to the mouth of the Detroit River. Thus he returned to fields essayed two decades earlier replete with products of his own genius; but now he was the "boss," and drawing upon his wealth of knowledge and experience and progressive thought he devoted himself during the next twelve years to perfecting and reimplementing this ancient service to mariners and to directing the activities and developing the talents of the younger engineers of his staff whose feet were on the lower rungs of the ladder he had surmounted. This was a period of accelerated progress in lighthouse engineering, which witnessed the introduction of automatic flashing lights and modern fog signals to multiply the aids to the navigator, and culminated in the radiobeacon which first became a world reality in the United States in 1921. In all of this Mr. Woodruff had an active part, and in the closing years of his career he was instrumental in extending the system of aids to navigation on the Great Lakes to meet the needs of that vast inland commerce which had attained a tonnage greater than that of any other waterway of the world.

In 1924 Mr. Woodruff retired from active service at the age of 72, twice having received executive extensions of service beyond the statutory retirement age of 70 in order that he might complete important undertakings he had initiated. His career as a lighthouse engineer has no parallel in the United States. It is more nearly comparable with those of successive generations of the Stevenson family in Scotland whose services as lighthouse engineers for the Commissioners of Northern Lights in Great Britain have been made famous by the chronicles of Robert Louis Stevenson.

Remarkable as was his professional career, Mr. Woodruff was equally devoted to his family, for whom he had a deep though unobtrusive pride. On August 25, 1875, he was married to Mariana Bateman in Portland, Me. They had three children, Grace L. (the Lady Ashfield, wife of Lord Ashfield, London, England), Josephine H. (the late Mrs. C. Austin Whitehouse, New York), and Leslie B. (Public Service Corporation, New Jersey). He leaves seven grandchildren—two daughters of Lord and Lady Ashfield, three daughters of Mr. and Mrs. Whitehouse, and a son and daughter of Mr. and Mrs. L. B. Woodruff. There are thirteen great-grandchildren. Mrs. Woodruff died in 1937 shortly after they had celebrated their sixty-first wedding anniversary, terminating a remarkably long and close companionship. In 1925 they had returned to the scenes of their early days together to make their home in Flushing, New York City, where they resided during the many years remaining to them.

Mr. Woodruff was catholic in his tastes and interests. Of wiry physique and possessed of limitless nervous energy, he remained physically active until the day of his death, keenly interested in all that transpired about him. He was fond of books and was widely read, often emphasizing a point by classic quotation. He was a member of the Protestant Episcopal Church in which he was an active layman for many years. In Detroit he was an active member of the Detroit Yacht Club and an Honorary Commodore. A deep interest in the early history of his country led him to affiliate with a number of patriotic societies, to membership in which his lineage entitled him. These included Society of Colonial Wars, Colonial Lords of the Manor in America, National Society of Puritan Descendants, and the Military Order of the Loyal Legion. He was a member of the National Geographic Society, and a charter member of the Society of American Military Engineers. During World War I he served by Executive Order under the Navy and was awarded the Victory Medal.

To those of us who had the good fortune of personal association with Mr. Woodruff he was a man of charming personality, a thorough gentleman of innate dignity, kindly and tolerant, possessed of a fine sense of humor, but one who, on occasion, could be roused to righteous wrath by any who sought unscrupulous advantage or unethical and devious influence; for he was imbued with high ethical standards, and with an unswerving integrity to his profession and loyalty to his trust. The beneficence of his personal influence on his subordinate associates was immeasurable. He was at once a mentor and a director, of rare ability and success. He maintained his interest in these men and his friendship for them to the end of his life. When the Lighthouse Service was merged with the U. S. Coast Guard in 1939 by Executive Order, a considerable number of the lighthouse engineers who then were commissioned as officers in the Coast Guard were of Mr. Woodruff's tutelage, and all occupy positions of trust and responsibility. In his later years Mr. Woodruff could contemplate with much satisfaction the part he had taken in the training of these men, and on their part he was regarded with highest esteem and affection.

Mr. Woodruff was elected a Member of the American Society of Civil Engineers on October 3, 1900. He became a Life Member in 1925.

EDWARD RUSSELL ALLEN, Assoc. M. Am. Soc. C. E.[1]

DIED JANUARY 26, 1941

Edward Russell Allen was born in Towson, Md., on November 22, 1905, the youngest of five children of the late State Senator Newton D. R. Allen and Rose (Heathcote) Allen.

---

[1] Memoir prepared by Carlton M. Soule and Joseph K. Knoerle, Members, Am. Soc. C. E.

Following graduation from the Towson High School in 1922, Mr. Allen entered the Engineering College of the University of Maryland at College Park. He was graduated with the degree of Bachelor of Science in Civil Engineering in June, 1926. While at the university, he was particularly interested in military training activities and in his senior year was Captain of the Reserve Officers Training Corps Company which received the award for being the best drilled. He was an excellent lacrosse player and was named to a defense position on the all-American team.

After graduation from the University of Maryland, Mr. Allen entered the employ of the J. E. Greiner Company, Consulting Engineers, of Baltimore, Md., and remained with that firm until his untimely death. His first assignment was as assistant resident engineer on the construction of the General U. S. Grant Highway Bridge across the Ohio River at Portsmouth, Ohio. This bridge was a wire cable suspension bridge with a main span of 700 ft and side spans of 350 ft.

This project was completed in February, 1927, and Mr. Allen returned to the firm's Baltimore office where, as designer and draftsman, he worked on different types of fixed and movable bridges, piers, bulkheads, and buildings. By January, 1930, he had demonstrated his ability to such an extent that he was appointed assistant chief draftsman and placed in charge of design and preparation of plans for many of the projects on which the firm was engaged. These included the Howard Street Bridge in Baltimore, which later was awarded honorable mention in the annual bridge competition conducted by the American Institute of Steel Construction (A.I.S.C.).

In October, 1930, Mr. Allen was transferred to field work and during the next twelve months served as resident engineer in charge of the construction of a cantilever bridge across the Ohio River at Ashland, Ky. This bridge, with a main span of 739 ft and anchor arms of 431 ft, presented an interesting construction problem since pneumatic steel caissons were used in placing the main river piers.

Upon completion of this bridge, Mr. Allen went to Cumberland, Md., where for the next six months he acted as assistant resident engineer on the construction of the Thomas W. Koon Dam near that city. This dam was built to supplement the existing water supply of the City of Cumberland and was the first dam upon which, to compensate for the varying moisture content of the sand and rock, adjustments in the amount of water used for concrete mixing were continuously made by mechanical means.

When he returned to Baltimore in March, 1932, Mr. Allen was promoted to chief draftsman. In this position, which he held until March, 1936, he was in responsible charge of the design of all structures. Many of the reports which the firm made in connection with the repairs of existing bridges were also his responsibility.

From March, 1936, to January, 1938, Mr. Allen was resident engineer on the construction of the Twenty-ninth Street Bridge over Jones Falls in Baltimore, the complete design for which he had previously made. This bridge is a large highway structure of multiple reinforced concrete arches and is faced throughout with masonry. Its general appearance received much favorable comment.

Following the construction of the Twenty-ninth Street Bridge, Mr. Allen resumed the duties of chief draftsman for a few months. In May, 1938, he was appointed project engineer on the Susquehanna River Bridge, at Havre de Grace, Md.—one of the four included in the "Primary Bridge Program" of the State Roads Commission of Maryland. This bridge is a four-lane highway structure 7,613 ft long between abutment bearings and carries the Governor Nice Highway over both the east and west channels of the Susquehanna River. Since the bridge was to be a toll structure and financed by the sale of revenue bonds, the engineering report on the project preliminary to financing was of greater scope than would have been required for a toll-free crossing. When the engineering report had been completed, Mr. Allen prepared the contract, plans, and specifications; and, after contracts had been let, he supervised construction. The bridge, completed in October, 1940, was awarded first prize by the A.I.S.C. for the most beautiful steel bridge built in the United States in 1940. Mr. Allen's part in the conception and successful conclusion of this project was substantial, and his associates and many friends greatly regret that he was not living when the award was made.

Immediately after the completion of the Susquehanna River Bridge, Mr. Allen was placed in full charge of the engineering work for the construction of the Fort George G. Meade Cantonment in Maryland. This project involved the construction of temporary housing, roads, and utilities for approximately 25,000 persons. The defense program was just starting and speed was essential. Mr. Allen gathered together an organization of 214 men and in the four months before his death, in an automobile accident on January 26, 1941, such substantial progress was made that in February troops were quartered at the cantoment in large numbers. His contribution to the success of this vital project was recognized by the erection of a bronze plaque at the foot of General's Hill in the cantonment reading as follows:

"E. Russell Allen
1905–1941
Project Engineer for
Cantonment 1940–1941
In Commemoration of His
Unfaltering Loyalty
& Inspiring Leadership"

Mr. Allen's death at the early age of thirty five ended a career full of promise. He had just completed one large project and was successfully directing another of magnitude and importance. Greater opportunities and achievements were undoubtedly before him. His death was therefore a loss not only to his associates but also to the profession to which he had just begun to contribute significantly.

In 1931 Mr. Allen was married to Frances Somerville Houck of Towson. He was the father of one son, Francis Somerville, and one daughter, Melinda. He was devoted to the children and spent as much time with them as his duties permitted. In addition to his widow and children, Mr. Allen is survived by his mother; two brothers, Herschel H., M. Am. Soc. C. E., and Wendell D.; and one sister, Miriam (Mrs. Roland Wegner).

Mr. Allen was elected a Junior of the American Society of Civil Engineers on November 11, 1929, and an Associate Member on May 13, 1935.

HAROLD JAMES MANNING BAKER, Assoc. M. Am. Soc. C. E.[1]

DIED OCTOBER 2, 1943

The illness that removed Harold James Manning Baker from the Seattle District office, U. S. Engineer Department, terminated a connection begun in July, 1903, which was continued without interruption for forty years. He was the oldest employee of the district in point of service, and it can readily be understood that the loss of one with his strong, fine personality is deeply felt by all his friends and associates. In a sense Harold Baker was the office. His were the long, unbroken years of service; he supplied the thread of continuity to its events and occurrences; and he remembered incidents and recalled details out of the past. District engineers changed with the years and their terms of office. Others in the office sooner or later also moved. Harold Baker was the man who did not change—the steady, persistent, reliable, constant figure who calmly and quietly worked from one season to the next. His first engagement in 1903 was as surveyman. Thereafter he rose by successive steps to his final grade of principal engineer. From 1919 to the time of his death he was the principal civilian engineer in the district.

Mr. Baker was born on April 14, 1878, at Lowell, Mass., the son of the late Rev. Brookes O. Baker, M.D., of Sheerness, Kent, England, and Alice H. (Carleton) Baker, of Lowell and Haverhill, Mass. Through his mother, he was descended from John Carleton who settled in Haverhill in 1643. Nine generations of this pioneer's descendants are known to have lived on Lowell Avenue in Haverhill where John Carleton made a home three centuries ago.

Mr. Baker spent his early childhood in Honolulu, Hawaii; his boyhood in San Francisco, Calif., and in Port Townsend, Wash., where his father was on the medical staff of the Marine Hospital and also rector of St. Paul's Church for several years. He was graduated from the University of Washington at Seattle in 1900, receiving the degree of Bachelor of Science in Civil Engineering. He continued there in postgraduate work the following year and in 1901 and 1902 was a special student in electrical and hydraulic engineering at Cornell University in Ithaca, N. Y. His first engineering work from July, 1902, to January, 1903, was as rodman and instrumentman with the Constructing Quartermaster's office at Port Townsend, in charge of the topographical survey for the location of the post buildings at Fort Casey and Fort Worden in Washington. For a few months he was with the Spring Valley Water Company of Port Townsend as levelman and transitman. Then, in July, 1903, began the long engagement with the U. S. Engineer Department, during which Mr. Baker spent several years on fortification work. Later he was in responsible charge of all river and harbor work in the Puget Sound, Grays Harbor, Willapa Harbor, Columbia River, and Alaskan areas.

---

[1] Memoir prepared by a Committee consisting of Homer M. Hadley, Assoc. M. Am. Soc. C. E., Samuel De Moss, M. Am. Soc. C. E., and E. I. Pease, Asst. Chf., Civ. Works Div., Seattle Dist. Office, U. S. Eng. Div., Seattle, Wash.

In 1928 Mr. Baker was detached from regular river and harbor work and placed in charge of the preparation of a series of reports covering improvements—power, irrigation, flood control, and navigation—of the principal rivers in the Seattle Engineer District. By far the most difficult part of this assignment was the report on the Columbia River, which has been widely used by engineers throughout the United States, producing much favorable comment. Typical of such comment is the following excerpt from a paper by Henry Earle Riggs, Past-President and Hon. M. Am. Soc. C. E., in referring to the necessity for sound engineering reports prior to government expenditures: "No better example of such a study can be found than that on the Columbia River made by the Corps of Engineers after four years of study.[2]

Harold Baker was a man of high principles and firm convictions and governed his life according to these standards, quietly and undeviatingly. His relationships with subordinates were always friendly, cordial, and courteous. His few corrections and criticisms were always impersonal and were voiced because "we are trying to accomplish best results." Egotism and petty vanity had no part in his make-up. For his parents he had a great love and respect, and it was undoubtedly due to his father's influence that he developed the keen interest he had in medicine. He always found delight and pleasure in mathematics and the niceties of its accomplishments. A book that he treasured was an autographed copy of "The Lowell Hydraulic Experiments,"[3] by the late J. B. Francis,[4] Hon. M. Am. Soc. C. E., given him when he was a student at Cornell University by Mr. Francis' sister. Alertness and vigor always characterized his mind. He was a man of fine spirit and character whose loss is deeply regretted by a host of friends in all walks of life.

Mr. Baker was a member of Sigma Nu fraternity and was a Scottish Rite Mason.

He is survived by his widow, Ella M. Baker, and by two cousins, Marjorie Carleton Pratt and Brenda Carleton Simmons.

Mr. Baker was elected a Junior of the American Society of Civil Engineers on October 7, 1902, and an Associate Member on March 4, 1908. He became a Life Member in January, 1943.

---

[2] *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 687.

[3] "The Lowell Hydraulic Experiments," by J. B. Francis, D. Van Nostrand Co., Inc., New York, N. Y., 1883.

[4] For memoir, see *Transactions*, Am. Soc. C. E., Vol. XIX (1893), p. 74.

EDWARD CROSBY BEBB, Assoc. M. Am. Soc. C. E.[1]

DIED AUGUST 7, 1942

Edward Crosby Bebb was born in Seward, Ill., on October 28, 1872, the son of Edward and Harriot Chase (Crosby) Bebb. He was graduated from the University of Wisconsin, at Madison, in the class of 1896 with the degree of Bachelor of Science in Civil Engineering.

In 1906 he was married to Fay Kent of Washington, D. C. He is survived by his widow, a son, Capt. Edward Kent Bebb, Jun. Am. Soc. C. E., and two daughters, Caroline (Mrs. John Williams), and Louise Harriot Bebb.

After graduation from college, Mr. Bebb entered Government Service in the U. S. Geological Survey, transferring in 1903 to the U. S. Bureau of Reclamation, where he served, with distinction, on many important western projects, until 1920.

During World War I he served as a Captain in the armed forces.

In 1920 he entered the service of the Federal Power Commission, where he remained until his death. As engineer for this Commission he passed on many of the largest power developments of the United States.

Ed Bebb was a very modest and retiring man; a kinder or more considerate man never lived. He had a tremendous fund of good "horse sense," with plenty of courage and an exceptional sense of justice for fellow workers and contractors under his supervision. These qualifications, plus his well-trained engineering mind, made him one of the truly great civil engineers of his time.

Mr. Bebb was elected an Associate Member of the American Society of Civil Engineers on November 6, 1907. He became a Life Member in 1942.

JULIUS MONTGOMERY BISCHOFF, Assoc. M. Am. Soc. C. E.[2]

DIED DECEMBER 5, 1943

Julius Montgomery Bischoff, son of Julius G. D. and Helen (Cronenbold) Bischoff, was born at St. Louis, Mo., on February 15, 1881. He was graduated from Washington University at St. Louis in 1904 with the degree of Bachelor of Science in Civil Engineering. During the summers of 1902 and 1903, he worked as a draftsman with the Terminal Railroad Association of St. Louis and with the Louisiana Purchase Exposition in St. Louis.

Upon graduation in June, 1904, Mr. Bischoff spent about one year as inspector and draftsman for the City of St. Louis. Thereafter, his career was identified with railway engineering:

---

[1] Memoir prepared by Francis T. Crowe, Hon. M. Am. Soc. C. E.

[2] Memoir prepared by H. Austill, M. Am. Soc. C. E.

1905—rodman for the St. Louis Southwestern Railway Company at Tyler, Tex.;

July, 1905, to August, 1907—transitman and resident engineer for Morey-Faulhaber Construction Company on the construction of the Apalachicola Northern Railroad, in charge of all trestle construction on 20 miles of line;

August, 1907, to January, 1909—assistant engineer for Edward Flad, M. Am. Soc. C. E., consulting engineer, of St. Louis, on the construction of a steel viaduct with reinforced concrete approaches for the Manufacturers Railway Company;

January, 1909—assistant engineer for the Terminal Railroad Association of St. Louis;

May, 1911—resident engineer with the Cuban Central Railways, Ltd., with headquarters at Sagua la Grande, Santa Clara Province, Cuba;

June, 1912—chief construction engineer for Cuban Central Railways, Ltd.;

September, 1914—assistant engineer for the Terminal Railroad Association of St. Louis;

March, 1918—principal assistant engineer of the St. Louis-East St. Louis Terminal District for the U. S. Railroad Administration; and

March, 1920, until his death—office engineer with the Terminal Railroad Association of St. Louis.

Mr. Bischoff was married to Elizabeth Butler in Tyler, on June 27, 1908. He is survived by his widow and three children, Julius Wiley, Elizabeth, and Eugene Butler.

He was a member of Kappa Sigma fraternity, the Railway Club of St. Louis, Missouri Society of Professional Engineers, and an enthusiastic supporter of the Railway Young Men's Christian Association.

Mr. Bischoff was particularly fond of tennis and regularly joined his friends on the court where he played a splendid game. In fact, he died suddenly while standing on the tennis court.

Mr. Bischoff was elected an Associate Member of the American Society of Civil Engineers on January 4, 1910.

ARTHUR BONIFACE, Assoc. M. Am. Soc. C. E.[1]

DIED JULY 18, 1943

Arthur Boniface was born at Hastings, England, on September 6, 1878. After attending public school and preparatory school there, he completed a course in the British Naval School at Portsmouth, majoring in higher mathematics. He served with the British Navy from 1898 to 1902. Interested in engineering work, he realized the limitations of his naval service and in 1902 resigned and came to the United States.

---

[1] Memoir prepared by Fred Lavis, M. Am. Soc. C. E. (former Trustee and Mayor of Scarsdale, N. Y.).

He was employed as a draftsman by the Western Electric Company in 1902 and thereafter served in various capacities with the Rapid Transit Subway Company of New York, N. Y., as draftsman and designing engineer. He later became assistant engineer, then resident engineer in charge of the office. Following the opening of the first subway he was engaged for several years in designing and preparing plans and estimates for many of the new routes subsequently built in New York City. His studies included the development of plans for a belt line subway for passenger and freight traffic entering and leaving New York City, and for a large union freight yard in the Newark (N. J.) Meadows.

In 1914 he was made resident engineer in charge of construction work in lower Manhattan of Section I of the Seventh Avenue Subway. The work on this section—one of the most difficult along the route—included the underpinning of the elevated railroad, the underpinning of approximately 4,000 lin ft of buildings, many of them high, relocating and rebuilding all of the subsurface structures, as well as the construction of the subway proper involving excavation both through rock and in some places through quicksand.

Arthur Boniface came to Scarsdale, N. Y., in 1907 when the population of the Town was slightly more than 1,000. He became interested in civic matters and on March 19, 1918, was elected a Village Trustee. He was elected Village President in 1921, and in 1922 he resigned as President of the Village and was appointed Village Engineer. His principal work had been his service as Engineer and Manager of the Village of Scarsdale, a service which extended over twenty years until his death deprived the community of a faithful and competent servant.

He served under changing Boards of Trustees (which included women as well as men) and under various and varying Presidents and Mayors, through the period when a rapidly developing suburban community expanded and grew from a population of 3,000 to more than 13,000. He built a new efficient municipal plant for these people.

Although at first his title was Village Engineer, he was actually Village Manager from the time of his appointment, and later his title was changed to that of Village Manager. His work involved not only solving important engineering problems of street construction, sewers, drainage, water supply, and waste and garbage disposal in a tightly restricted residential community but also dealing with many different people—many interested only in the development of some particular section and others from communities whose background, training, customs, and personal idiosyncrasies were different from the Scarsdale tradition of deep-rooted civic consciousness.

At one time he set forth his philosophy with respect to public work:

> "If a citizen presents a request, never turn it down, no matter what its nature. Investigate every complaint however trivial its character. Endeavor always to recognize the other man's viewpoint in all matters of public service, and never assume an arbitrary position without having a very good reason for so doing. Always remember the men in the various departments whose loyalty and service are just as important as the man's who may be directing them."

Scarsdale has over 95% of its area zoned for one-family residences, and problems of zoning were at times complicated and troublesome. The proper proportioning of assessments for street construction, sewers, and water supply in the new developments required the continuous exercise of good judgment.

Waste and garbage disposal in a wholly residential community with no waste land (a good proportion developed with high-class properties) presented difficult problems in which the human element was an important factor. These have been solved satisfactorily. Arthur Boniface went to Italy in 1926 to study the Beccari System of Garbage Disposal, and after his return he spent several years in research work to ascertain why the Beccari System was not entirely successful in the United States. He discovered that the difficulty was with the different composition of American garbage as compared with that produced in Italy. He then concentrated his efforts on the development of the "Boniface Method of Treating Garbage" and received Letters Patent for this method of treating garbage on August 4, 1936.

He dealt as successfully with the Mayors, Trustees, and people as he did with the technical engineering problems. In this he was a true engineer, using the human forces with which he had to deal for the benefit of the community. He brought his engineering knowledge to bear on all these problems with such good judgment and wise planning that Scarsdale has a low funded debt, low costs of maintenance, an efficient municipal plant, and a well organized operating personnel.

With the entry of the United States in the present war and the immediate need for adequate and trained civilian defense forces to meet emergencies, he turned, with characteristic energy, to the organization of the Scarsdale War Council and, as Deputy County Director of Civilian Protection, to the training and establishment of all the Civilian Protection Units within the provisions and framework of the New York State War Emergency Act. These forces were quickly and effectively created, and their smooth functioning has been commended by the County of Westchester, New York State, and U. S. Army authorities.

Although defense problems consumed a great part of his time during the period of war emergency, he was also able to make a splendid beginning on preliminary studies of Scarsdale postwar problems. A tentative schedule of Postwar Public Works for Scarsdale was prepared by him and, with the approval of the Village Board, was filed with the Temporary State Commission for Postwar Public Works Planning.

Author Boniface was never afraid to say "No" when occasion required, but he made few enemies and had many friends. He eschewed politics. Perhaps the greatest tribute that can be paid to him is that among those who knew him he was universally respected. He was a servant of the community and a wise counselor.

Among the organizations to which he belonged were the New England Water Works Association, the Westchester County Water Commission (chairman), the National Society of Professional Engineers, the New York State Society of Professional Engineers, and the Engineers Club of New York.

He was married to S. Marlene Talmage in New York City on September 5, 1907. They had four children—Arthur, Gwendolyn, Marlette, and John, all of whom survive.

Mr. Boniface was elected a Junior of the American Society of Civil Engineers on January 2, 1906, and an Associate Member on October 4, 1910.

DALTON MUNROE BROWN, Assoc. M. Am. Soc. C. E.[1]

Died May 16, 1943

Dalton Munroe Brown was born in Nashua, N. H., on January 13, 1900. He attended public schools in Milford, N. H., and Dartmouth College in Hanover, N. H., being graduated in 1923 with the degree of Bachelor of Science. In 1925, after studying for two years in the Thayer School of Civil Engineering at Dartmouth College, he received the degree of Civil Engineer. During summer vacations, Mr. Brown worked for the Illinois State Highway Department on inspection work.

For the greater part of his engineering career, Mr. Brown was on the engineering staffs of contractors' organizations. With Kenn-Well Contracting Company of New York, N. Y., he was assistant construction engineer on the erection of the East River Power Station for the New York Edison Company. He was employed by Thomas Crimmins Contracting Company as field engineer on construction for the Hunt's Point Gas Plant and additions to the Hell Gate Power Plant. Turning to subway construction, he worked for the Marcus Contracting Company as field engineer on the building of the northerly section of the Nassau Street Subway and later on similar engineering construction for the Marcy-Lafayette Avenue section of the Independent Subway in Brooklyn, N. Y. After a year with the Work Projects Administration as assistant to the project engineer on the development of the New York City park system, he joined the field organization staff of Spencer, White and Prentis, Inc., as field engineer. In this capacity he was engaged on the construction of the Sixth Avenue Subway from Eighth Street to Eighteenth Street in Manhattan, New York, and on the installation of deep foundations for the New York City Criminal Courts Building.

When the national defense program was begun in 1940, Mr. Brown joined the staff of Dry Dock Contractors, builders of the Philadelphia and Norfolk naval dry docks, and was assigned to field work at Norfolk Dock No. 8, which was completed shortly before his death.

Dalton Brown was extremely modest, a hard working and loyal engineer, and a staff man who exhibited efficiency in construction. In addition to his devotion to his family and his profession, Mr. Brown gave much of his talent to the Boy Scouts of America (B.S.A.). As a child he attained the grade of

---

[1] Memoir prepared by Herbert M. Hale, M. Am. Soc. C. E.

Eagle Scout. While he was in New York, he was associated with the B.S.A., and for several years before his death he was chairman, Troop Committee, Troop No. 8, B.S.A., in Brooklyn.

On October 27, 1939, at Brooklyn, N. Y., Mr. Brown was married to Alice E. Gunnerson, who survives him, together with a son, Lawrence D. Brown.

Mr. Brown was elected a Junior of the American Society of Civil Engineers on April 18, 1927, and an Associate Member on February 27, 1933.

KNOX FOLSOM BURNETT, Assoc. M. Am. Soc. C. E.[1]

Died August 13, 1943

Knox Folsom Burnett was born on August 19, 1903, at Lincoln, Nebr., the only son of Edgar Albert and Nellie E. (Folsom) Burnett. His father was associated with the faculty of the University of Nebraska, at Lincoln, from 1899 until his death in 1941, and for the last fourteen years of his life was Chancellor of the University.

Knox F. Burnett was educated in the public schools of his native city. He attended the University of Nebraska where he majored in architectural engineering, being graduated in 1924 with the degree of Bachelor of Arts. Immediately after graduation, he obtained a position with John Latenser and Sons, Architects, at Omaha, Nebr., as a structural draftsman and thus started on a brief, but eventful and successful engineering career.

After staying one-half year on his first job, and another eight months with Engineering Service Company of Omaha, where he gained experience in mechanical and electrical work, in 1925 Mr. Burnett became structural engineer for Davis and Wilson, Architects and Engineers of Lincoln. It was soon discovered, however, that, besides his ability as a structural designer, Mr. Burnett also had an aptitude as a specification writer and as an inspector and supervisor of field work. He learned how the efforts of several contractors on the same project can be coordinated for best results. Consequently, he was entrusted with the execution of several important contracts both by the firm and by others. He supervised the construction of the $500,000 First Plymouth Church for the Church Building Committee and acted as superintendent for the City of Lincoln on the construction of a large pumping plant.

His association with Davis and Wilson lasted until 1932. During those seven years, Mr. Burnett collaborated in the design, and in the supervision of the construction of numerous important building projects, among which the best known are Morrill Hall, Andrews Hall, and Women's Dormitories of the University of Nebraska, Stuart Theatre and Office Building, and Gold and Company Store Building, all at Lincoln.

---

[1] Memoir prepared by Eugene E. Halmos, M. Am. Soc. C. E.

During 1932 and 1933, Mr. Burnett was superintendent for the Olson Construction Company of Lincoln, on the construction of an overhead viaduct at Falls City, Nebr.

Mr. Burnett was engineer inspector with the government on Public Works Administration (PWA) work in Nebraska from November, 1933, until July, 1934, when he joined the engineering staff of the Platte Valley Public Power and Irrigation District at North Platte, Nebr. This District was organized to construct a ten-million-dollar irrigation and hydroelectric project on the North Platte River. In the course of two years, Mr. Burnett advanced from structural designer to office engineer of the organization, coordinating the work of the several departments as well as that of the numerous contractors on the project. The design of the project was prepared under the direction of Parsons, Klapp, Brinckerhoff and Douglas, Consulting Engineers of New York, N. Y., and the contact which Mr. Burnett made with this firm and particularly with John P. Hogan, Past-President and M. Am. Soc. C. E., had a profound effect on his future.

Early in 1937, Colonel Hogan, who at that time was chief engineer of the New York World's Fair of 1939, engaged Mr. Burnett as exhibit engineer on the engineering staff of the Fair. In this capacity, Mr. Burnett conducted all dealings between the Fair Corporation and the exhibitors with reference to space occupancy, type and construction of buildings and displays, use of utilities, etc. This assignment required considerable technical and diplomatic skill, both of which he possessed and successfully applied. After the completion of the construction work, Mr. Burnett remained for two years with the operating organization of the Fair as chief exhibit engineer and general manager of utilities. In recognition of his tactful help to the Rumanian delegation at the Fair, he was made a Knight of the Crown of Rumania by King Carol and also received a decoration from the Lebanese Government.

In December, 1940, Mr. Burnett joined the staff of Caribbean Architect-Engineer, composed of Voorhees, Walker, Foley and Smith, architects, and Parsons, Klapp, Brinckerhoff and Douglas, engineers, to whom the government of the United States entrusted the planning of Army bases at Trinidad and at several of the British Windward Islands. Mr. Burnett first served as liaison engineer between the field and the New York office and later as resident engineer at Antigua, B. W. I. Upon completion of this assignment, he returned to the United States in December, 1942, and shortly thereafter became seriously ill. He lingered for several months, even trying to work for brief periods, but never recovered and passed away on August 13, 1943. His career was thus abruptly terminated when it already gave promise of future distinction. He was buried in the family plot at Lincoln.

Knox F. Burnett was of medium height, robustly built, and indefatigable in both physical exercise and office work. He knew how to take orders from his superiors and how to execute them. For his engineering and executive ability, resourcefulness, and dependability, he was held in high regard by his employers and by literally hundreds of exhibitors at the World's Fair. He demanded hard and loyal work from his subordinates but never asked them to do more than he was willing to do himself; in this manner, he acquired their admiration and respect. While he was intensely devoted to his duties, Mr. Burnett was a very pleasant and sociable man in his private life; he was a gracious host and a much sought-for companion. He was a member of the University Club of Lincoln.

He was married to Lela Mae Randall in 1929, who survives him. Also surviving are his mother, and one son, Knox Robert Burnett.

Mr. Burnett was elected an Associate Member of the American Society of Civil Engineers on October 29, 1934.

DEWITT CLINTON FENSTERMAKER, Assoc. M. Am. Soc. C. E.[1]

DIED APRIL 6, 1943

DeWitt Clinton Fenstermaker was born in Basil, Ohio, on December 27, 1873, the son of Samuel Fenstermaker and Barbara (Hoshor) Fenstermaker.

He was graduated from high school, and, in addition, obtained a technical education by night courses and private instruction while working as a draftsman and engineer in Columbus, Toledo, and Cleveland, Ohio.

He entered railroad service in 1890 as a rodman on the Toledo and Ohio Central Railway, serving until 1898 as rodman, instrumentman, drafstman, and assistant engineer on construction and maintenance work.

From July, 1898, to July, 1899, during the Spanish-American War, he served in Company A, Second U. S. Volunteer Engineers, and in Company 15, U. S. Volunteer Signal Corps. From October, 1899, to April, 1901, he was an assistant engineer in the Department of Havana, Cuba, and the Department of Pinar del Rio, Cuba, on highway construction and topographical surveys.

From April, 1901, to May, 1902, he served as assistant engineer on construction for the Lake Erie, Alliance and Wheeling Railroad Company. From May, 1902, to January, 1903, he was draftsman for the Forest City Steel and Iron Company of Cleveland on design and detail structural work. From January, 1903, to 1908 he was employed as resident engineer, division engineer, and chief engineer of the Louisiana Railway and Navigation Company on the location and construction of 191 miles of new line. During 1909 he was city engineer of Tulsa, Okla. In 1910 and 1911 he served as designing engineer for the Lehigh and New England Railroad Company on construction work in eastern Pennsylvania. From 1912 to 1921 he was resident engineer, assistant engineer, and district engineer for the Chicago, Milwaukee, St. Paul and Pacific Railroad Company in responsible charge of construction and maintenance work.

In April, 1921, he was granted a leave of absence to act as chief engineer for the contracting firm of Peterson, Shirley and Gunther, which was constructing 52 miles of railroad for the Atlantic Fruit Company in Oriente Province, Cuba. After completing this work, he resumed service with the

---

[1] Memoir prepared by W. H. Penfield, M. Am. Soc. C. E.

Chicago, Milwaukee, St. Paul and Pacific Railroad Company as principal assistant engineer on February 1, 1922. In 1923 he was granted a leave of absence to become chief engineer of the Montana Railroad and the Wyoming North and South Railroad companies in charge of the construction of 320 miles of railroad for these companies in Montana and Wyoming. He then returned to the Chicago, Milwaukee, St. Paul and Pacific Railroad Company as district engineer on April 1, 1929, continuing in this capacity until November 30, 1937, when he retired because of ill health.

Mr. Fenstermaker was always very active in civic matters in Itasca, Ill., working for the betterment of the village by giving it the benefit of his engineering ability and experience. He prepared a zoning ordinance which was accepted by the village, and also served as building commissioner—all without compensation.

He was married to Elsie Buckingham of Hopedale, Ohio, on December 23, 1901, and is survived by his widow, one brother, and four sisters.

The McKinley Camp, Spanish War Veterans, conducted the funeral services. He was cremated at Acacia Cemetery, Chicago, Ill., and the ashes were interred at the Greenwood Cemetery near Hopedale.

Mr. Fenstermaker was elected an Associate Member of the American Society of Civil Engineers on January 8, 1908. He became a Life Member in January, 1943.

GEORGE ADDISON FIELD, Assoc. M. Am. Soc. C. E.[1]

Died September 3, 1943

George Addison Field, the son of Harry and Virginia (Townsend) Field, was born on November 8, 1899, in Calvert, Robertson County, Tex.

He was educated in the public schools of Calvert and attended the School of Civil Engineering of the University of Texas at Austin.

In 1922 Mr. Field was employed by the Texas Highway Department as equipment engineer and in 1925 was made division engineer at Lubbock, Tex. In 1929, in association with the writer, he formed the contracting firm of Field Brothers. This company built numerous highways, bridges, and irrigation projects in west and southwest Texas. One important achievement was a 90-mile canal in Maverick County, constructed in conjunction with the W. E. Callahan Construction Company.

Wishing to aid the national defense effort in 1940 Mr. Field gave up his private business to become superintendent of construction on the Naval Air Base at Corpus Christi, Tex., for Brown and Root, W. S. Bellows Construction Company, and Columbia Construction Company. In 1941 he went to Houston, Tex., as project manager for Brown and Root on construction of shipyard facilities for the Houston Shipbuilding Corporation, virtually building the Irish Bend Shipyard. In 1942 he planned the construction organization of the Cactus Ordnance Works in Dumas, Tex. During the same year he directed construction on the Big Spring (Tex.) Bombardier School and the Concho and Goodfellow airfields at San Angelo, Tex. In 1943 he organized construction and operating personnel for the San Jacinto Water Project in Harris County, Texas. In less than three years he supervised more than $150,000,000 worth of construction work.

---

[1] Memoir prepared by Hugh T. Field, Assoc. M. Am. Soc. C. E.

Mr. Field was a member of Sigma Alpha Epsilon fraternity, and a member and former director of the Texas Highway Branch of the Associated General Contractors of America.

On January 4, 1938, in San Antonio, Tex., he was married to Margaret Myrick Morris. He is survived by his widow and a son, George, Jr.

Mr. Field was elected an Associate Member of the American Society of Civil Engineers on December 22, 1930.

IRVIN GITTLESON, Assoc. M. Am. Soc. C. E.[1]

DIED JUNE 11, 1943

Irvin Gittleson was born in New York, N. Y., on December 14, 1902, the son of Philip and Maria (Melisov) Gittleson. He attended Virginia Polytechnic Institute at Blacksburg.

For the greater part of his professional life, Mr. Gittleson was a structural draftsman. His early engineering training was in the drafting room of the Virginia Bridge and Iron Company at Roanoke, where he spent the four years from 1922 to 1926. From 1926 to 1931 he worked in the office of Waddell and Hardesty in New York, and, thereafter for shorter periods, he was a member of the engineering staff for Port of New York Authority; Triborough Bridge Authority; Ash, Howard, Needles and Tammen; and Parsons, Klapp, Brinckerhoff and Douglas. In this work he came in contact with many leaders in the profession.

His many friends were genuinely shocked by his death at such an early age. He was a neat and fast workman, and in all of his associations he left the impression of industry and congeniality. Undoubtedly, many of the large bridges in the New York area contain numerous details of his devising or suggesting.

Among Mr. Gittleson's hobbies were gardening and the collection of original oil paintings.

On February 24, 1929, in New York, Mr. Gittleson was married to Emily Schoham. He is survived by his widow and a son, Laurance.

Mr. Gittleson was elected a Junior of the American Society of Civil Engineers on December 26, 1933, and an Associate Member on October 14, 1935.

---

[1] Memoir prepared by E. L. Macdonald, M. Am. Soc. C. E.

DAN A. HULICK, Assoc. M. Am. Soc. C. E.[1]

DIED MAY 4, 1943

Dan A. Hulick was born in Lyons, N. J., on March 22, 1882, the son of John V. and Anna (Manning) Hulick.

He was graduated from the Summit, N. J., high school in 1898. In 1900 he was employed by F. S. Tainter,[2] M. Am. Soc. C. E., consulting engineer, as axman. So great was his enthusiasm and ambition that twelve years from that time he was made assistant engineer on the construction of country estates, roads, bridges, dams, and water and sewer systems. Two projects on which he was employed were Carnegie Lake in Princeton, N. J., and Peachtree Heights Park in Atlanta, Ga.

From 1912 to 1916 Mr. Hulick was engaged in private practice, chiefly on surveys, subdivisions, general construction of homes, development of estates, and water and sewer systems. In 1916 he helped to lay out and build the town of Kingsport, Tenn. As resident engineer, he directed the building of the Payne Aviation Field at West Point, Miss., in 1918. Upon completion of this project, he became field engineer for Westinghouse, Church, Kerr and Company, working on the construction of a nitrate plant and on the village plan for Muscle Shoals, Ala. He was commended by the chief engineer for this work. In 1919 Mr. Hulick returned to private practice in Atlanta and Greenville, S. C., doing general engineering work on business buildings, private homes, roads, bridges, and sewer and water systems.

Mr. Hulick was appointed city engineer of Greenville in 1925, and served in this capacity for ten years. During this time he directed all municipal improvements, including a $500,000 paving program, design and construction of bridges, sewer extensions, etc. Energetic by nature, he accomplished a great deal during his tenure of office, completing projects of which Greenville may well be proud. He was honest and dependable, and his records prove his meticulous observance of detail.

In 1935 Mr. Hulick became affiliated with the Works Progress Administration, first in Greenville County, then in Walterboro, S. C., and later in Charleston, S. C. He returned to Greenville County in 1938 as county engineer, rebuilding bridges, roads, etc., and preparing plans for a 110-mile road surfacing program. In 1939 he went to Washington, D. C., as sanitary engineer for the United States Housing Authority. Because of failing health, he returned to the South, hoping to regain his strength. However, he never recovered, and died at his home in Gladstone, N. J., four years later.

He is survived by two sisters, Molly (Mrs. D. M. Wolfe), and Georgia (Mrs. J. D. Stantial).

---

[1] Memoir compiled from information supplied by the family, by friends, and from data on file at the Headquarters of the Society.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 107 (1942), p. 1849.

Except for his high school course, Mr. Hulick received no formal education, but he was a prolific reader, completing the *Encyclopædia Britannica*, making notes in the volumes, and cross-referencing them. Intensely interested in old Indian trails, much of his knowledge of terrain—which served him well in engineering—was a result of his frequent long walks in search of paths, fords, etc., referred to in Indian song and legend. He had a noteworthy collection of Bibles, an entire shelf of his bookcase being filled with various editions. An eager student of South Carolina history, he was better informed on this subject than many a native South Carolinian.

He was a member of the South Carolina Society of Engineers, the National Society of Professional Engineers, and the Society of American Military Engineers.

Mr. Hulick was elected an Associate Member of the American Society of Civil Engineers on March 11, 1940.

ALEXANDER ANDREW LAIRD, Assoc. M. Am. Soc. C. E.[1]

DIED MAY 18, 1943

Alexander Andrew Laird was born at Topeka, Kans., on August 16, 1884, the son of Alexander and Mary (Lowrie) Laird. His parents were born and married in Scotland. His preliminary education was received in the public schools of Topeka, and he was graduated from the local high school.

Following his graduation from high school, Mr. Laird was employed in September, 1902, by the engineering department of the Atchison, Topeka and Santa Fe Railway Company, successively as rodman, chainman, transitman, apprentice in the mechanical department, draftsman, and bridge inspector. While with this company, he enrolled in a civil engineering course under a private tutor and also pursued, diligently, correspondence and extension work in this field.

In November, 1908, Mr. Laird left the railway company to accept a position as assistant engineer with Burns and McDonnell, Consulting Engineers, of Kansas City, Mo., in charge of surveys for, and design and construction of, water works, sewers, and electric light plants. In March, 1914, he was employed in a similar capacity for four months by Black and Veatch, Consulting Engineers, also of Kansas City. He then became assistant engineer on the valuation of railroad properties for the Kansas City Southern Railway Company and the Texas and Pacific Railway Company. This work was terminated in May, 1917, shortly after the entry of the United States into World War I.

In February, 1917, Mr. Laird was commissioned a First Lieutenant in the Engineer Officers Reserve Corps of the United States Army and was ordered to active duty in May, 1917. He was promoted to Captain in the Corps of

---

[1] Memoir prepared by L. R. Dail, Assoc. M. Am. Soc. C. E.

Engineers in August, 1917, and assigned as Topographical Officer with the 315th Engineers, 90th Division, and served during all operations of his regiment in the United States, France, and Germany, including the major engagements at Saint-Mihiel and Meuse-Argonne in France. This period of active service terminated in July, 1919. His military service had a profound influence on him, and for the remainder of his life he was a keen student of military engineering. On February 5, 1924, he was commissioned Major, Engineer Officers Reserve Corps, and, on February 4, 1933, was promoted to the rank of Lieutenant-Colonel in the Reserve Corps.

In July, 1919, Mr. Laird accepted a position as resident engineer for the State Highway Commission of Kansas, in charge of federal aid road projects in Allen County, Kansas. In April, 1924, he became chief engineer and general superintendent for a contracting firm on a project which included 8 miles of grading, structures, and approximately 35,000 sq yd of concrete paving.

From December, 1925, to April, 1931, he was field engineer for the Portland Cement Association. He then was appointed engineer with the Road Supply and Metal Company in charge of design, promotion, and sales for drainage structures and water conduits.

From November, 1935, to January, 1936, he was consulting engineer to the Works Progress Administration on designs and estimates for water, sewer, and swimming pool projects, and on emergency airports. In January, 1936, he assumed full charge on the construction of a number of earth dams for the Soil Conservation Service of the U. S. Department of Agriculture. This work was sponsored by the Kansas Fish and Game Commission and involved the moving of approximately 10,000,000 cu yd of earth and the placing of 150,000 sq yd of rock riprap and 15,000 lin ft of sheet piling. The work was performed by enrollees of the Civilian Conservation Corps. An average of 4,000 men including supervisory personnel was engaged on these projects.

From December, 1937, to March, 1938, he worked on the design and construction of an office and warehouse building in Oklahoma City, Okla. In March, 1939, he moved to Phoenix, Ariz., where he entered private practice, investigating mining and industrial properties. In February, 1940, he became industrial engineer for the Arizona Tractor and Equipment Company of Phoenix.

In September, 1940, Mr. Laird was ordered to active duty as Lieutenant-Colonel, U. S. Army, and was assigned to the Arizona State Selective Service Headquarters as Liaison Officer for the Undersecretary of War as adviser on occupational deferments. He was promoted to Colonel in December, 1940, and served efficiently in this capacity until striken with the short illness which terminated in his death on May 18, 1943.

Mr. Laird had a splendid and upright character. Although he was a man of exemplary habits, reserved and reticent, as his associates came to know him they esteemed him highly and learned to value his sound judgment. He was not a man to be shaken from what he thought was the right course. He was an exceptionally diligent and energetic man and his refusal to ease up when his health became impaired undoubtedly shortened his life.

Mr. Laird was married on June 19, 1912, in Kansas City, Mo., to Lottie Defenbaugh. He is survived by his widow and a daughter, Mary E. He was a devoted husband and father. In later years his main outside interests centered around his home. He loved to work in the yard, principally growing flowers. Much of his time, however, was devoted to studying military engineering in connection with his standing in the Engineer Officers Reserve Corps.

He was a member of the Masonic Order, a Shriner, and belonged to the Society of American Military Engineers.

Mr. Laird was elected an Associate Member of the American Society of Civil Engineers on July 6, 1920.

JAMES HENRY MINER, Assoc. M. Am. Soc. C. E.[1]

Died May 31, 1943

James Henry Miner was born in Phillipston, Mass., on November 24, 1877, the son of Frank Henry Miner and Ellen (White) Miner. He was a descendant of Thomas Miner, who came to America in 1628, and later founded the town of Stonington, Conn. When Mr. Miner was five years old, the family moved to Warrensville, Ohio, where he received his education in the district school. In 1896, he was graduated from the University School of Cleveland, Ohio. In the fall of the same year, he entered Cornell University at Ithaca, N. Y., being graduated from Cornell with the degree of Bachelor of Science in Civil Engineering in 1900. As editor and business manager of the *Cornell Era* and other college papers, he practically paid for his college education.

In 1904 Mr. Miner entered the Bureau of Reclamation as an assistant engineer on the Uncompahgre Project (Colorado), advancing to field engineer on the construction of the Gunnison tunnel (six miles in length) and then to office engineer. In 1910 he was assigned as project manager in local charge of construction on the Grand Valley Project. Diversion works in the Grand River for this project included the largest rolling crest installation in the United States at that time. In 1917 the Bureau of Reclamation appointed Mr. Miner project manager on the investigation and reconstruction of the King-Hill Carey Act Project in Idaho.

During World War I he served with the American International Shipbuilding Corporation at Hog Island, Pa., as inspector and expediter on the construction of steel hulls. Following this, he joined Dwight P. Robinson and Company as engineer on estimates for new work, cost control of jobs, and studies of hydroelectric projects on the Hudson, Genessee, Santee, Des Moines, Ottawa, and St. Lawrence rivers; as structural engineer on the Marblehead Lime Company plant; and as supervising engineer in the New York (N. Y.) office on the construction of the thirty-six-story Warwick Hotel, the American

---

[1] Memoir prepared by Fred J. Sharkey, Assoc. M. Am. Soc. C. E.

Consulate at Seville, Spain, and five dams in Ceara, Brazil, for the Brazilian Bureau of Reclamation.

From 1928 to 1932, Mr. Miner was supervising engineer for Dwight P. Robinson in Argentina on the construction of the five-and-one-half-mile Lacroze subway in Buenos Aires. From 1932 to the early part of 1934, he was resident engineer for United Engineers and Constructors, Inc. This firm acted as agent for the Treasury Department in building a central heating plant and distribution system to replace independent plants in some fifty public buildings in Washington, D. C.

In April, 1934, Mr. Miner returned to the Bureau of Reclamation as office engineer. He later became assistant supervising engineer on the Columbia Basin Project, remaining until his death.

Mr. Miner is survived by his widow, Olga (Lacher) Miner, to whom he was married in 1906; four children, Helene (Mrs. Thomas W. Hopper), Jean (Mrs. H. A. O'Connell), Florence (a nurse in the U. S. Army), and James H., Jr. (Aviation Cadet, U. S. Naval Aviation); six grandchildren; two sisters, Ethel (Mrs. Fred Muggleston) and Grace (Mrs. Allen Dicks); and one brother, Warren Miner. Mr. Miner's eldest son, Warren, died in 1919.

His kindly humor, his innate courtesy, his sound judgment, and his deep and constructive interest in the problems and details of his work will be sorely missed by a host of friends and associates.

Mr. Miner was elected a Junior of the American Society of Civil Engineers on March 31, 1903, and an Associate Member on November 8, 1909.

ARTHUR LELAND RICHARDSON, Assoc. M. Am. Soc. C. E.[1]

Died March 11, 1943

Arthur Leland Richardson was born in Goldendale, Wash., on April 21, 1879. He was the son of the late Jacob Richardson and Anna (Bell) Richardson. His father was county surveyor of Klickitat County, Washington, for several years. Previous to that time, he was a deputy government surveyor.

Mr. Richardson spent his early life in Klickitat County. The first school he attended was in a log cabin. Later he completed the course in the grade school at Goldendale and in the Academy at the same location. He decided to be an engineer and continued his studies, tutored by his uncle, Edwin Richardson, who at one time was surveyor general of the State of Washington. Mr. Richardson's first job, in engineering, was as a rodman with the Union Pacific Railroad Company, surveying for a railroad location in the vicinity of Madras, Ore.

In April, 1898, Mr. Richardson offered his services to his government and was accepted in Company H, Oregon Volunteers, Second Infantry. He served as a private in the Philippines during the Spanish-American War and received an honorable discharge in September, 1899.

---

[1] Memoir prepared by F. W. Panhorst, M. Am. Soc. C. E.

From 1900 to 1908 he was county engineer of Klickitat County, in charge of road and bridge work. As an engineer in private practice from 1909 to 1911, he designed and built water systems for Forest Grove, Willamina, Toledo, and Joseph, Ore. Continuing the same type of work, from 1911 to 1913 he was associated with the late J. L. Stannard,[2] M. Am. Soc. C. E., on water works systems at Carlton, Cornelius, Beaverton, Falls City, and Hillsboro, Ore., and at Woodland and Olympia, Wash., and constructed many other similar projects in the Northwest. As a general contractor, in 1914 and 1915 he engaged in the construction of bridges and roads. In 1915 he returned to his chosen profession and until 1924 was assistant engineer, Maintenance of Way Department, Southern Pacific Railroad Company.

The latter part of Mr. Richardson's life was spent with the Bridge Department of the Division of Highways, State of California. From 1924 until his retirement in 1941 he was in charge of construction of many and various bridges throughout the State of California, leaving many monuments to his ability as a bridge builder.

The greatest monuments and reminders left by Mr. Richardson are not of stone and steel, but rather the many young engineers whose knowledge and character were greatly increased and influenced by association with him and by training received from him. He took a great interest and pride in assisting, teaching, and encouraging the many young construction engineers who embarked on their engineering careers under his tutelage. The greatest compliment to be paid a man is to state that he was truly unselfish. The many young engineers fortunate enough to have been associated with him and who gained such information and advice not found in books can testify to his great unselfishness. He will be missed greatly by his many associates but, due to his influence, his character will be perpetuated in many engineers.

Continual failing health caused Mr. Richardson's retirement in January, 1941, and, after almost twenty years of the unsettled life of the construction engineer, he settled down on a beautiful ranch near Yamhill, Ore., to enjoy the remaining years in thoughtful and peaceful reminiscence of his many engineering travels and attainments; but, as with most active engineers, the time allotted to retirement was short and ended with his death on March 11, 1943.

In November, 1902, Mr. Richardson was married to Delia V. Laughlin of Yamhill. He is survived by his widow and by a daughter, Ferhn C. (Mrs. R. J. Muckle).

Mr. Richardson was elected an Associate Member of the American Society of Civil Engineers on January 14, 1929.

---

[2] For memoir, see *Transactions*, Am. Soc. C. E. Vol. 96 (1932), p. 1558.

WILLIAM SHERMAN VAN LOAN, Assoc. M. Am. Soc. C. E.[1]

Died February 24, 1943

William Sherman Van Loan, the son of William and Angeline (Sherman) Van Loan, was born in Poughkeepsie, N. Y., on November 30, 1879. He received his early education in the public schools of that city and his college education at the University of West Virginia in Morgantown.

Mr. Van Loan was employed as draftsman with the firm of Alden and Harlow, architects, of Pittsburgh, Pa., from 1899 to 1901. From 1901 to 1903 he was inspector on the erection of a malleable steel plant at McKees Rocks, Pa., and of a foundry at Swissvale, Pa., under Armin Schotts of Pittsburgh. From 1903 to 1906 he served as an inspector for the U. S. Naval Academy in Annapolis, Md., in charge of building foundation construction.

After completing this work, Mr. Van Loan was employed, successively, on several large public building projects, including the Public Library in Utica, N. Y., for Carrare and Hastings, architects, and on apartment house and residence construction for William Crawford, builder, of New York, N. Y. During the period 1910 to 1917, he was construction engineer for the Supervising Architect, Treasury Department, Washington, D. C., directing the construction and repairs of public buildings in the eastern part of the United States.

During World War I, Mr. Van Loan was Captain in the 7th Regiment of Engineers, Fifth Division. He served sixteen months in France, taking part in the Saint-Mihiel and Meuse-Argonne offensives. He was promoted to the rank of Major, Engineer Reserve Corps, on December 3, 1919.

After the war he returned to the office of the Supervising Architect at Washington, D. C., and was again engaged in supervising the construction and repairs of public buildings. In 1924 he joined the staff of Frank A. Spangenberg, architect, of Buffalo, N. Y., on the construction of buildings, churches, and schools in and around Buffalo until 1927. From 1927 until his death, Major Van Loan was employed by the Board of Education, City of Buffalo, as Supervisor of Construction of all Buffalo public school buildings and in charge of all maintenance and repairs.

Major Van Loan was a great lover of the out of doors—an ardent fisherman and an enthusiastic golfer. He was interested in the boy scout movement and, after acting for several years as scoutmaster of Troop 83, Church of Good Shepherd in Buffalo, he was made chairman of the Camp Committee for the Buffalo Council, Boy Scouts of America. In 1937 he was awarded the Silver Beaver "for distinguished service to boyhood," by the Buffalo Council, Boy Scouts of America.

On January 14, 1903, he was married at Annapolis to Katherine Mason Hodges, who survives him. Also surviving are two children, Capt. William

---

[1] Memoir prepared by William T. Huber and William G. Seyfang, Members, Am. Soc. C. E.

H. Van Loan and Katharine Mason Van Loan (Mrs. Lawrence Moses), and four grandchildren.

Major Van Loan was elected an Associate Member of the American Society of Civil Engineers on May 25, 1931.

ALBERT WILLARD WALKER, Assoc. M. Am. Soc. C. E.[1]

DIED JUNE 15, 1943

Albert Willard Walker was born at Marlboro, Mass., on March 17, 1882, the son of Joseph and Francena (Woods) Walker, and reared on a farm in the vicinity. He attended grade and high school for the normal periods, and was graduated from the Massachusetts Institute of Technology in Boston in 1905, with the degree of Bachelor of Science in Sanitary Engineering.

During intermittent periods from 1899 to 1904, he was with the Metropolitan Water and Sewage Board of Boston, as rodman and instrumentman.

On June 7, 1905, through civil service examination, Mr. Walker entered the service of the Bureau of Reclamation as an engineering aide. He was employed continuously in that branch of the federal service until his death at Great Falls, Mont. He was first assigned to the Belle Fourche Project in South Dakota, where he soon was placed in charge of surveys and estimates and also served as inspector on the construction of the Belle Fourche Dam—an earth-fill structure built by contract at a cost of $1,250,000. Upon completion of this work he was resident engineer in charge of location and construction of many parts of the irrigation system of this project.

Transferred to the Milk River Project in Montana, in June, 1912, Mr. Walker was assistant engineer on the construction of the headquarters office building at Malta, Mont., and on the design of Dodson North Canal structures. In July, 1913, he was transferred to the Huntley Project in Montana, as engineer in charge of investigations, design, and construction by government forces of an extensive drainage system consisting mainly of deep tile drains, costing about $500,000. Thus he entered a field in which much of his future life was to be spent and in which ultimately he excelled by virtue of his understanding of soils and the people who work soils.

On March 14, 1916, he was transferred to the Grand Valley Project, Grand Junction, Colo. From that date until January, 1917, he conducted the investigations and prepared the plans for the drainage of the Grand Valley Drainage District—a cooperative project with an estimated cost of $1,500,000. Thereafter he conducted a similar investigation and made plans, prepared specifications, and supervised the construction of the drainage system for the Grand Valley Project. This program cost about $300,000.

From August, 1921, until February, 1925, Mr. Walker was employed principally on the Newlands Project in Nevada, as engineer in charge of all phases of a $700,000 drainage program involving deep open drain construction with heavy dragline equipment. He was also engaged at odd times as consultant on drainage for other reclamation projects and on special investigations in the San Luis Valley in Colorado. During the remainder of 1925 he was special assistant on soil and drainage matters to reclamation adjustment boards examining the Minidoka, King Hill, Boise, Klamath, and Newlands projects. When this work was completed, he returned to the Newlands Project to work on a small drainage program and to make the investigations, plans, and estimates for the Spanish Forks extension of the project, a 36,000-acre development. In addition, he assumed the duties of project superintendent in December, 1926, retaining this position until May, 1929. During this latter period he directed further drainage work costing $250,000 and the $150,000 Truckee Canal reconstruction, and made a series of investigations for reservoir sites in the Truckee River Basin.

---

[1] Memoir prepared by Irwin B. Hosig, Engr., Bureau of Reclamation, Denver, Colo., and H. P. Wangen, Secretary, Greenfields Irrig. Dist., Fairfield, Mont.

He was transferred in May, 1929, to the position of construction engineer on the Sun River Project, Montana, and in December of that year also assumed the duties of superintendent. Operation and maintenance of much of this project were transferred to the Greenfields Irrigation District in 1931, and, under a cooperative arrangement with the Bureau of Reclamation, Mr. Walker also served as manager of the district. He retained both positions until his death. During this period the project was extended from 56,000 to 99,000 irrigable acres, the principal existing canals and reservoirs were enlarged and improved, and drainage work was performed as necessary and possible—all at a total cost of about $2,500,000. As the canal system was extended to large areas of virgin land, qualified farm families were selected under his direction and permitted to establish homestead residences on the land. The project grew from 400 to 1,050 farms; and its population, from 1,400 to 3,700 persons. To be known as a guiding hand in such growth is much.

Although diligently devoted to the important official tasks with which he was entrusted, Mr. Walker at all times maintained a participating interest in the civic and social activities of the community. His sound judgment and solution of the perplexing problems of his fellow men were respected and accepted by the many who turned to him for advice. He was a man of simple tastes, exercising extreme patience and a calm demeanor under the most trying situations.

To those in the Bureau of Reclamation who knew him, and to the people of the community in which he resided, he was a person rich in character. That character obviously had its beginnings in the habits of sobriety, thrift, and industry necessary to a New England farm home and in the simplicity, honesty, and directness of approach existing in a solid rural community. His life was a beautiful demonstration of the application of such a character without change to a professional career in the public service. For it his associates admired and loved him.

He was married on December 2, 1908, at Belle Fourche, S. Dak., to Grace Eva Wilkinson, who died on December 8, 1926. Three children of that marriage, Russell W., Leland J., and Katherine M. (Mrs. L. R. Jourdonnais) survive him. On September 5, 1932, he was married at Seattle, Wash., to Esther McArdle who also survives him.

Mr. Walker was a member of Fairfield Montana lodge No. 127, A. F. and A. M. and a charter member and first president of the Fairfield Lions Club.

Mr. Walker was elected an Associate Member of the American Society of Civil Engineers on May 3, 1910.

CARL ROBERT WEIDNER, Assoc. M. Am. Soc. C. E.[1]

Died August 20, 1941

Carl Robert Weidner was born on March 21, 1883, at Buffalo, N. Y., the son of Karl Gustav and Clara Francis (Neuman) Weidner. He attended Cornell University at Ithaca, N. Y., and was graduated in 1904 with the degree of Civil Engineer.

During college vacations Mr. Weidner gained a varied experience. In 1901 he was employed by F. K. Wing, M. Am. Soc. C. E., of Buffalo, on water works and sewerage construction. In 1902 he was rodman on maintenance of way for the Erie Railroad Company. In 1903 he served for two months as assistant engineer with D. Fairchild, civil engineer, of Buffalo, in charge of construction of 2 miles of electric railway. In 1904 he worked for several months as draftsman at the Bureau of Filtration, Pittsburgh, Pa.

After his graduation from Cornell, from October, 1904, to October, 1908, Mr. Weidner was assistant engineer for the Pipe Line Department of The Prairie Oil and Gas Company at Independence, Kans. He was in charge of surveys for, and at times directed, construction of pipe lines, pumping stations, reservoirs, and steel tanks in Kansas and Oklahoma for the transportation and storage of crude petroleum. This was pioneer work in a pioneer section of the United States.

From October, 1908, to March, 1909, he traveled and studied in Europe.

During the spring of 1909 he was engaged as instructor in civil engineering at Pennsylvania State College at State College. For the next seven years, as instructor in hydraulic engineering, he taught at the University of Wisconsin in Madison, conducting research and writing several bulletins for the university. These bulletins included "Theory and Test of an Overshot Water Wheel"[2] and "The Diaphragm Method for the Measurement of Water in Open Channels of Uniform Cross-Section."[3] He was also joint author of a bulletin on "An Investigation of the Air Lift Pump."[4]

---

[1] Memoir prepared by L. E. Davis, Engr., Sinclair Refining Co., Pipe Line Dept., Independence, Kans.

[2] "Theory and Test of an Overshot Water Wheel," by Carl R. Weidner, *Bulletin No. 529,* Univ. of Wisconsin, Madison, 1913.

[3] "The Diaphragm Method for the Measurement of Water in Open Channels of Uniform Cross-Section," by Carl R. Weidner, *Bulletin No. 672,* Univ. of Wisconsin, Madison, 1914.

[4] "An Investigation of the Air Lift Pump," by G. J. Davis, Jr., and Carl R. Weidner, *Bulletin No. 450,* Univ. of Wisconsin, Madison, 1911.

During summer vacations, Mr. Weidner accept various positions. In 1912 he served as chief hydrographer for the Knoxville Power Company in charge of stream gaging and stream flow computations for a 400,000-hp water power project. In 1915 he was with the Miami Conservancy District at Dayton, Ohio, on flood control work.

Leaving the academic field, in 1916 Mr. Weidner was engaged to make an inventory and appraisal of the property of The Prairie Pipe Line Company, which had been formed in 1915. In the same year he was made chief engineer of the company, and he continued to serve in this capacity with this company and its successor, Sinclair Refining Company, Pipe Line Department. During these years he had charge of surveys for, and design of, many miles of pipe lines. The organization expanded its facilities from approximately 6,000 miles of laid pipe of all sizes in 1915 to approximately 14,000 miles in 1931. During this time 274 pumping stations were built, and many of the trunk line stations rebuilt and enlarged.

The first major project of the company was an inventory of equipment to adjust investment records in accordance with the Uniform System of Accounts of the Interstate Commerce Commission. This work was completed in 1922, in spite of the interruption of World War I and the heavy volume of construction. During these years Mr. Weidner assisted in developing pipe line accounting procedure in accordance with the Uniform System of Accounts prescribed by the Interstate Commerce Commission. For many years he studied the depreciation of pipe line property, and participated in the settlement of several tax cases involving depreciation.

Carl Weidner was privileged to be identified with oil pipe line transportation during one of its rapid stages of development. He fostered many technical advances, among them: Welding in pipe line construction in 1921; and prevention of corrosion of buried pipe lines by use of protective coatings in 1925.

An active member of the American Petroleum Institute (A.P.I.), he belonged to the original Corrosion Committee; he was the author of a paper on "Protecting and Reconditioning Underground Pipe Lines"[5] (presented at a Group Session Symposium on Corrosion at the annual meeting of the A.P.I. in 1926); and he was joint author of a paper on "Relation of Pipe Line Currents and Soil Resistivity to Corrosion"[6] (presented at the 1931 meeting). In addition, he was active in organizing cooperative tests on pipe coatings, conducted between 1930 and 1940 by the Pipe Coating Manufacturers and the A.P.I. under the direction of the Bureau of Standards, and he supervised the installation of several cathodic units for pipe protection by electrical drainage. From 1934 to 1937 the valuation of the oil pipe lines of the Sinclair Refining Company by the Interstate Commerce Commission demanded much of his time and effort. From 1934 until his death he served on the Engineers-Accountants Committee on Valuation of Pipe Lines of the A.P.I. and made important contributions to the solution of valuation and depreciation problems. In 1939 he edited a report on the history, construction, and operation of oil pipe lines for the Committee on Uniform Methods of Oil Accounting of the A.P.I. Mr. Weidner contributed generously to the standardization and research program of the A.P.I. His work on the committees on Corrosion, Standardization of Line Pipe, Evaporation Losses, and Valuation of Pipe Lines was notable. A clear thinker and writer, he is remembered by fellow committee members for his capacity for work, for his obvious ability, and for his eagerness to cooperate with others. He was held in high esteem and his death was a great loss.

---

[5] "Protecting and Reconditioning Underground Pipe Lines," by C. R. Weidner, *Bulletin*, Am. Petroleum Inst., Vol. VIII, No. 6, January 31, 1927, p. 352.

[6] "Relation of Pipe Line Currents and Soil Resistivity to Corrosion," by C. R. Weidner and L. E. Davis, *Proceedings*, Am. Petroleum Inst., Section IV, December, 1931, p. 36.

The following Resolution in Memoriam was adopted by the Central Committee on Pipe Line Transportation of the Division of Production of the A.P.I. at the Annual Convention on November 5, 1941:

> "Mr. Weidner was very active in the American Petroleum Institute work and at the time of his death was a member of the Committee on Valuation of Pipe Lines; the Central Committee on Pipe Line Transportation; the Topical Committee on Pipe Line Technology; the Correlating Committee on Measuring, Sampling, and Testing Crude Oil; the Central Committee on District Activities; the Topical Committee on Vocational Training; Engineer's Sub-Committee on Tanks; Mid-Continent District Committee on Pipe, as well as chairman of the Mid-Continent District of Group 3, Regional Sub-Committee on Pipe Lines and chairman of the Mid-Continent Sub-Committee on Tanks. Mr. Weidner was also Chairman of a Special Reviewing Committee for the vocational training course, 'Pipe Line Practices,' and had practically completed writing the text at the time of his passing.
>
> "His constructive leadership and kindly personality will be greatly missed in Institute work and by those privileged to know him."

In addition to his technical ability, Mr. Weidner had other talents. In his early years, he was an excellent violinist. A strong man physically, he excelled in swimming, tennis, and golf. He was a considerate employer and encouraged those working under his direction to study and advance. Although he was dignified and reserved, he was a very pleasant companion with a wide range of interesting conversational topics, and he was tolerant of the views and opinions of others. At a meeting of pipe line executives he once gave a fine address on "The Spirit of the Organization."

In addition to the Society and A.P.I., Mr. Weidner belonged to Sigma Xi; Oklahoma Society of Professional Engineers; Independence Lodge No. 780, Benevolent and Protective Order of Elks; and Fortitude Lodge No. 107, A. F. and A. M., affiliated Masonic bodies of the York rite in Independence, and Mirza Temple Shrine in Pittsburg, Kans. He was a member of the Independence Country Club and had served as president. He contributed liberally to many civic causes.

Carl Weidner was never married. He is survived by his mother, Mrs. Clara Francis Weidner; a sister, Martha Emma (Mrs. G. E. Reister); and a brother, Paul G.

Mr. Weidner was elected a Junior of the American Society of Civil Engineers on February 28, 1905, and an Associate Member on April 5, 1910.

ROBERT LEE WHITEHEAD, JR., Assoc. M. Am. Soc. C. E.[1]

Died January 16, 1943

Robert Lee Whitehead, Jr., was born in Amherst, Va., on October 23, 1890. A family biography reveals the following:

> "He was a son of Robert Lee Whitehead of Amherst County, Virginia, and Fanny Lea Zogbaum of Germantown, Pa.
>
> "The Whitehead family is an old Virginia family. Edgar, the emigrant, came to Virginia from England during the reign of Charles II and settled on a tract of land granted him near York River. A descendant was a soldier in the Revolution.
>
> "The family later moved to Lynchburg and Amherst and Nelson Counties, Virginia, where they were prominent in the welfare and development of their community. Robert Lee Whitehead, Sr., was educated at Lehigh University [Bethlehem], Pa., and at the time of his marriage was Chemist and Manager for a Baltimore Electric Refining Company."

Mr. Whitehead was graduated from the Episcopal High School in Alexandria, Va., and received his college training at Washington and Lee University at Lexington, Va. He was an active member of the Episcopal Church, serving as a Vestryman at the time of his death. During World War I, he was a Second Lieutenant in the Field Artillery, U. S. Army.

After World War I until 1920, Mr. Whitehead was employed as an instrumentman by Larson and Fox at Perth Amboy, N. J. From 1920 to 1921, he served as instrumentman for the late C. F. Mebus,[2] M. Am. Soc. C. E., consulting engineer of Philadelphia, Pa. From 1921 to 1922, he was assistant superintendent for F. L. Grant, Inc., contractor, of Clarksburg, W. Va. In 1922 he went to work as instrumentman for the North Carolina State Highway Commission, remaining with the Highway Commission continuously until his death in January, 1943. From 1924 to 1943, Mr. Whitehead was resident engineer and senior resident engineer on all types of highway construction.

Mr. Whitehead was married to Janie Jackson of Dunn, N. C., in 1926. In addition to his widow, he is survived by his mother, one sister, and one brother.

Mr. Whitehead was a capable engineer and will be missed in the Highway Department. Well liked by the men with whom he worked, he had a pleasing manner and a pleasant approach. Those who came in close contact with him cherish the memory of his friendship.

Mr. Whitehead was elected an Associate Member of the American Society of Civil Engineers on November 27, 1933.

---

[1] Memoir prepared by Berrien W. Davis, M. Am. Soc. C. E.

[2] For memoir, see *Transactions*, Vol. 106 (1941), p. 1620.

GUY SMITH WOOD, Assoc. M. Am. Soc. C. E.[1]

Died January 30, 1943

Guy Smith Wood was born at Altona, Clinton County, N. Y., on August 8, 1888, the son of Eugene and Florence (Mott) Wood. During his early childhood his parents moved to Indian Lake, N. Y., where he received his grammar school education. He first attended high school at North Creek, N. Y., and later, when a high school was started in Indian Lake, he went there, being graduated with the first class in 1908.

He was graduated from Rensselaer Polytechnic Institute in Troy, N. Y., with the degree of Civil Engineer in 1912. At the Institute he was elected to both the Tau Beta Pi and Sigma Xi honor societies.

Immediately after graduation Mr. Wood entered the service of the New York State Public Service Commission as junior engineer and assistant engineer—first, on preliminary and location surveys and later on construction of subways in New York, N. Y., until May, 1917. From May, 1917, to November, 1918, he served as assistant engineer for the Degnon Contracting Company on subway construction work in New York City. After this he was employed for a short period by Ford, Bacon and Davis on the construction of a wartime manufacturing plant with an accompanying housing development in the State of Virginia.

In June, 1919, he entered the employ of the International Paper Company, remaining with this company until his death. For the first two years of his service with the company he was resident engineer on the construction of boiler houses and extensive paper mill alterations at Palmer, N. Y., and Glens Falls, N. Y., and also at Berlin, N. H. He was then called to the New York City office, where—with the exception of about a year as resident manager on the construction of a paper mill at Three Rivers, Quebec, Canada—he was in charge of layout, designs, and specifications for three of the largest newsprint mills ever constructed in Canada.

Mr. Wood's practical experience at the mills, together with a natural aptitude for layout and design, made him a particularly valuable man to his employers during this period of expansion. His ability to impart his knowledge to others and his patience with the younger designers made him well liked by those with whom he worked.

The period of newsprint mill expansion in Canada was completed about 1931, and, from 1931 to 1935, Mr. Wood was assistant manager of a subsidiary of the International Paper Company, the Montague Machine Company with shops at Turners Falls, Mass. Besides doing a general foundry and machine shop jobbing business on paper mill and water power machinery, this company built a very successful new type of pulpwood grinder which was sold to outside firms.

---

[1] Memoir prepared by Harry M. Nelson, Assoc. M. Am. Soc. C. E.

In the fall of 1935, Mr. Wood became manager of the Herkimer Mill of the International Paper Company at Herkimer, N. Y., manufacturing leather board and molded pulp products. He continued as manager of this plant until late in 1942 when it was temporarily closed.

Mr. Wood was a member of the Masons and also took an active interest in his college alumni society and in local civic affairs. His hobbies were fishing and hunting in the Adirondack Mountains.

On June 4, 1913, Mr. Wood was married to Edna Stansfield. He is survived by his widow and a daughter, Dorothy (Mrs. Harold Waldron).

Mr. Wood was elected an Associate Member of the American Society of Civil Engineers on May 19, 1924.

EDWIN PARK ARNESON, Jun. Am. Soc. C. E.[1]

DIED JANUARY 1, 1943

Edwin Park Arneson, son of the late Edwin P. Arneson[2], M. Am. Soc. C. E., and Anita (Park) Arneson, was born in San Antonio, Tex., on June 6, 1917.

He attended the public schools of San Antonio, being graduated from high school at the age of fifteen. After finishing high school, he took special work at Westmoreland College, San Antonio, for a year. In September, 1934, he entered the Agricultural and Mechanical College of Texas, at College Station, and was graduated in June, 1938, with the degree of Bachelor of Science in Civil Engineering. He held the rank of Captain in Field Artillery in the Cadet Corps at the time of his graduation, and was commissioned a Second Lieutenant in the Reserve Corps of the U. S. Army.

After graduation, Mr. Arneson was employed by the State Highway Department of Texas, Bridge Division, on tracing, detailing, designing, estimating, and checking work. In August, 1939, he went into the field as instrumentman on the construction of a bridge across the Colorado River. In April, 1940, he became cartographer for the Pan American Airways, with headquarters at Brownsville, Tex. While on this assignment, much of his work was in the Spanish-American countries of North America and Central America. His knowledge of the Spanish language, and his ability to translate, write, and speak it, enabled him to render valuable service. In June, 1941, Mr. Arneson left Pan American Airways, and later reentered the employ of the State Highway Department of Texas as resident engineer. Thus, he returned to his mother's home in San Antonio. He continued with the State Highway Department until he was called into the armed service of the United States.

---

[1] Memoir prepared by A. P. Rollins, M. Am. Soc. C. E.

[2] For memoir see *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 1878.

Mr. Arneson was called to service as a First Lieutenant in the Field Artillery of the U. S. Army in October, 1941. In February, 1942, he was transferred to the Signal Corps and assigned to duty in Alaska. In March, 1942, at his own request, he was transferred to the Army Air Corps and qualified as a pilot in October, 1942. His first assignment was as instructor pilot of multiengine planes. On January 1, 1943, he was directing a cross-country flight of students near Stockton, Calif., when one of the students made a forced landing along a highway. Lieutenant Arneson, feeling responsible for the safety of his pupils, undertook to land in an open space near where the student landed, but far enough from the highway to safeguard other traffic. The open space proved to be a peat bog into which his P-38 immediately sank. He was killed instantly, and another life was placed upon the altar of patriotism as a sacrifice of war.

Lieutenant Arneson came from a notable lineage. His father was an outstanding engineer, being a Director of the Society at the time of his death in 1938, and an esteemed citizen. His mother, highly accomplished in music and reading, continues to be a leader in church and civic affairs in San Antonio, giving freely of her talents.

Lieutenant Arneson was gifted and versatile. He was skilled in music and art. He was proficient in research and possessed, in full measure, the essential fundamentals of engineering. His life, finished so soon, promised much, and his talents, so needed in the times to come, would have been of great benefit to his country. His death leaves an almost unbearable sorrow in the hearts of the loved ones who survive him, but the thought that father and son are reunited is comforting.

He is survived by his mother, Mrs. Anita Park Arneson; a sister, Lily Anita; and a brother, Richard Owen.

Lieutenant Arneson was elected a Junior of the American Society of Civil Engineers on February 13, 1940.

RICHARD ALESTER COLEMAN, Jun. Am. Soc. C. E.[1]

Died December 16, 1942

Richard Alester Coleman was born on May 6, 1920, at Savannah, Ga., and died from complications following an appendectomy on December 16, 1942, at Newport News, Va. He attended grade school in Baltimore, Md., junior high school in Washington, D. C., and the McKinley Technical High School of Washington, D. C., from which he was graduated when he was sixteen. He then entered Worcester Polytechnic Institute at Worcester, Mass., on a competitive scholarship awarded by the Washington alumni of Worcester Polytechnic Institute.

---

[1] Memoir prepared by E. F. Hewins, Chargeman, Eng. Technical Div., Newport News Shipbuilding and Dry Dock Co., Newport News, Va.

During his freshman year at Worcester Polytechnic Institute, he was secretary of his class. In 1938 he won the Class of 1879 prize for the best technical essay presented by an undergraduate. He organized the Debating Society, served as its president for two years, and in 1939 won the Wilfred Peel prize for the presentation and defense of an idea. Throughout his four years in college he achieved first honors, and, although barely twenty when he was graduated in 1940, he was the top ranking member of his class. He received the degree of Bachelor of Science "with high distinction" and was a recipient of the Graduates' Aid prizes. He was elected to Tau Beta Pi and Sigma Xi fraternities and was also a member of Masque and of Lambda Chi Alpha fraternity.

After graduation Mr. Coleman took a special short course in ship construction at Massachusetts Institute of Technology in Cambridge, before accepting a position as hull draftsman for the Newport News Shipbuilding and Dry Dock Company. Early in 1941 he entered partnership with Robert F. M. Pyle, M. Am. Soc. C. E., specializing in engineering surveys and construction. In June, 1941, he returned to the Newport News shipyard as a member of the technical division of the Engineering Department. Although a newcomer in the field of marine engineering, his excellent foundation in, and grasp of, mathematics and engineering fundamentals soon brought him in contact with some of the most interesting and difficult problems connected with shipbuilding. In addition to his regular work, he taught a night class in marine engineering for the University of Virginia extension course. So favorable was the impression he had made that, at the time of his death, Charles F. Bailey, formerly engineering director at the shipyard, said, "He came to be one of the outstanding younger men in the Engineering Department. The Institute [Worcester] has lost one of her brilliant and fine young graduates."

Mr. Coleman is survived by his father and mother, Mr. and Mrs. D. P. Coleman; his wife, Taimi Swan, to whom he was married on May 23, 1941, in South Hill, N. C.; and infant son, Richard Alester Coleman, Jr. (born on July 8, 1943).

Mr. Coleman was elected a Junior of the American Society of Civil Engineers on October 9, 1940.

NATHAN ELIAS ELKIN, Jun. Am. Soc. C. E.[1]

Died June 22, 1943

Nathan Elias Elkin was born in New York, N. Y., on April 15, 1911, the son of Joseph J. Elkin and Mary (Goodman) Elkin. His education was obtained in New York City—at Public School No. 11 (Queens); Stuyvesant High School; and New York University. He received the degree of Bachelor of Science in Civil Engineering from the latter institution in 1932, and then took postgraduate work at Columbia University.

---

[1] Memoir prepared by Joseph J. Elkin, President, Woodcrest Construction Co., Inc., New York, N. Y.

He followed the tradition of his family by entering the civil engineering profession, since his father and his uncle, Charles Goodman, M. Am. Soc. C. E., are both civil engineers. Nathan Elkin's apprenticeship was served with the Woodcrest Construction Company, Inc., on three sections of the Triborough Bridge, on much of the Grand Central Parkway in New York City, on Floyd Bennett Airport on Long Island, N. Y., and on the Mamaroneck Sewage Treatment Plant at Mamaroneck, N. Y.

His progress after graduation was extremely rapid, based upon his quick grasp of engineering construction. He became partner in the firm of M. D. Lieb, Inc., and while thus associated built some of the most difficult construction jobs in the East. Among them were intricate bridge repairs to the Manhattan Bridge; Pelham Bay Elevated line underpinning, for the Westchester Avenue Bronx underpass on the Hutchinson River Parkway Extension; barracks and mess halls for the United States Army; and Public Markets for the City of New York.

His work stands today as a monument to him among all those who knew him, from simple worker to section engineer. His keen executive ability and quick engineering eye led to decisions of sterling worth. He was a young man of the highest character and integrity, and his passing is deeply felt by all who knew him. In his profession his fine reputation far surpassed his years and will long be remembered. He was not married.

Mr. Eikin was elected a Junior of the American Society of Civil Engineers on November 28, 1932.

ROLLAND FRANCIS LANG, Jun. Am. Soc. C. E.[1]

DIED OCTOBER 7, 1943

Rolland Francis Lang was born in Kranzburg, S. Dak., on September 27, 1914, the son of Frank Eugene Lang and Luella (Hughes) Lang. He completed his high school training at Brookings, S. Dak., and entered South Dakota State College, at Brookings, in 1933. He enjoyed an active and productive undergraduate period and was graduated with the degree of Bachelor of Science in Civil Engineering in 1937. He made a superior record as a student and at the same time found time for many extracurricular activities, being active in the Student Chapter of the Society, Scabbard and Blade (national military fraternity), Blue Key (national campus leadership fraternity), and Delta Pi Chi (a local honorary engineering fraternity).

Upon graduation from college, Rolland Lang accepted employment in the vicinity of Brookings and served in various capacities on surveying operations and on some highway research under way at his alma mater. In the fall of 1937 he accepted a half-time instructorship in the Civil Engineering Department of South Dakota State College and devoted the remainder of his time to graduate work in civil engineering. In 1939 he became a full-time instructor. His graduate work was complete except for the final draft of his thesis, and he would have made outstanding contributions to the literature of engineering if he had had the opportunity to complete his investigations of the many problems which interested him. During summer vacations he served in a professional capacity in connection with street improvements and building operations in the City of Brookings.

---

[1] Memoir prepared by H. B. Blodgett, Assoc. M. Am. Soc. C. E.

In the fall of 1940 Rolland Lang accepted a position of greater responsibility with the Michigan College of Mining and Technology at Houghton, where he served as an instructor in civil engineering.

During his undergraduate days he had been active in the Reserve Officers Training Program and had maintained his commission after his graduation. In July, 1942, he was called to active duty as a Second Lieutenant and was subsequently assigned to an Engineer Amphibian Regiment. He received special training in the United States and was then sent to Australia and later to New Guinea. On October 7, 1943, Rolland Francis Lang was instantly killed in action, at the age of 29. A posthumous award of the order of the Purple Heart was made to his parents in November, 1943. He is survived by his parents, Mr. and Mrs. Frank E. Lang; and three sisters, Luella, Marjorie, and Geraldine.

Lieutenant Lang was an accomplished amateur photographer, a skilful draftsman, an inspiring teacher, and an able engineer. In addition to his Society membership, he belonged to the American Road Builders' Association.

Lieutenant Lang was elected a Junior of the American Society of Civil Engineers on May 13, 1940.

THOMAS ALBERT McTEER, Jun. Am. Soc. C. E.[1]

DIED JUNE 25, 1943

Thomas Albert McTeer was born on September 23, 1920, at McClellanville, S. C., the son of Clyde M. and Caroline (Morrison) McTeer.

Mr. McTeer attended South Carolina public schools at Bluffton, Summerton, and McClellanville, and was graduated from the McClellanville High School. He then studied civil engineering at Clemson College, in Clemson, S. C., being graduated in 1942. At Clemson he received honors during his sophomore year and was given high honors as a junior. He was elected to Tau Beta Pi fraternity, and was a member and vice-president of the Society's Student Chapter. As a member of the advanced Reserve Officers Training Corps, he was rated expert at the summer camp. During his senior year he was a member of the crack Senior Platoon, which gave exhibition drills at all football games and other celebrations.

---

[1] Memoir prepared by Clyde M. McTeer, Appeals Referee for the South Carolina Unemployment Compensation Commission, Columbia, S. C.

After receiving his degree in civil engineering and being commissioned a Reserve Officer in the United States Army, he was called for active duty on June 16, 1942. He entered training at Camp Blanding, Florida, with the 111th Engineer Battalion. Soon afterward he moved with this unit to Camp Edwards, Massachusetts, and passed the winter in New England on maneuvers. After five months of service he was promoted to First Lieutenant.

In March, 1943, Lieutenant McTeer was sent overseas to North Africa with his training unit—the 111th U. S. Engineer Battalion, 36th Division, Fifth Army. On June 25, 1943, he died from a gunshot wound. Of him his Commanding Officer wrote as follows: "He was a splendid officer, a brilliant engineer and the possessor of a winsome and loyal nature, which endeared him to all his associates, both officers and men."

He is survived by his father, a veteran of World War I; his mother; a brother, Harry; and his grandparents, Mr. and Mrs. Henry T. Morrison.

Lieutenant McTeer was elected a Junior of the American Society of Civil Engineers on September 9, 1942.

ERNEST FREDERICK HARTMAN, Affiliate Am. Soc. C. E.[1]

Died September 30, 1942

With the death of Ernest Frederick Hartman, a lifelong worker and advocate of conservation of lumber and timber resources through wood preservative treatment was lost to the building industry. Before his death at Chittenden, Vt., when he was sixty three, Mr. Hartman realized his ambition to obtain general acceptance of fireproofed wood as a building material through improved processes of chemical pressure treatment. In the wartime expansion program, millions of board-feet of treated lumber and timber are under fabrication and construction as well as millions more already incorporated in defense plants. Fire-retarded wood as a building material is especially useful for the protection of long span timber trusses, roof-deck planking, scaffolding, and accessory construction units, in order to conserve the use of more critical materials in essential defense work and as a fire-resistive substitute for unprotected steel construction where fire hazard is involved.

In cooperation with other pioneer workers and technical consultants, including Rudolph P. Miller, William J. Krefeld, and the late Albin H. Beyer,[2] Members, Am. Soc. C. E., T. R. Truax, Henry Klein, and Ira H. Woolson, in the development of processes and adaptations of old methods of treating lumber and timber to render it fire-resistive, he devoted his life to the establishment of definite specification standards and commercial values for fire-retarding, preservation, and consequent conservation of this important building material. Largely through his efforts, national recognition finally was accorded to fireproofed and flameproofed wood as a construction material by fire underwriter and other insurance authorities.

---

[1] Memoir prepared by George E. Strehan, M. Am. Soc. C. E.

[2] For memoir, see *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 1499.

About 1891, when he was twelve years old, Mr. Hartman came to the United States from Germany and settled in Milwaukee, Wis., with his parents. About this time the U. S. Naval authorities adopted the use of fireproofed wood decking on warships, treated by the original process of the Bachert Electric Fireproofing Company of New York (N. Y.). Before this time, similar processes had been advocated by the navies of England, France, Sweden, Denmark, and Russia. In 1899, based on the work of Messrs. Woolson and Miller, the use of fireproofed wood was extended to the building requirements of the New York City code for the treatment of combustible wood trim and finished flooring in building structures. The requirements and specification-acceptance tests then developed by these pioneers are still the basis of present New York code regulations, and the application of fireproofed wood has been expanded to include the treatment of structural units.

Mr. Hartman was educated in the Milwaukee public schools and, as a young man, saw service with the Milwaukee National Guard in the Spanish-American War. Early in the present century he became associated with Max Bachert in the study of fireproofing processes and later served as midwestern representative of the Carbolineum Wood Preserving Company on the manufacture and sale of high-boiling creosotes and anthracene oils. In 1906, he moved east to open a New York office for that concern, and his progressive studies and efforts resulted in the establishment of a successor to that company under the name of the Protexol Corporation of which he was president. By acquiring all the United States patent rights to the Bachert process and by introducing refined improvements, he succeeded in combining fireproofing and preservative treatments for many practical and commercial uses.

Primarily through overzealous commercial promotion of competing companies, the fireproofed wood industry had been experiencing a rather haphazard and questionable existence. Mr. Hartman practiced extensive commercial and research activities, studied all foreign developments diligently, and maintained active correspondence with leading authorities on the subject. By such persistent efforts, he kept alive an interest in the true possibilities of fireproofed wood which had, up to the past decade, failed to receive recognition from American building and insurance supervising authorities. Originating in the laboratory of the Protexol Corporation, aided by research work of the Columbia University (New York) Department of Civil Engineering and the laboratories of the U. S. Bureau of Standards, the Forest Products Service, and the National Board of Fire Underwriters, this work eventually resulted in the acceptance of fireproofed wood as an approved building material.

Simultaneously with commercial activities, Mr. Hartman devoted much time to general research and study of the properties of wood and methods of wood preservation, fire-retardation, and flameproofing; and he developed many of his own formulas and processes. He accumulated what is probably the most complete and extensive library available on these subjects. Among other activities, the Protexol Corporation conducts a fire testing station operated under the auspices of New York building authorities for official investigation of new materials and devices and methods of fire-resistive building construction. A considerable part of these investigations concern the use of fireproofed wood. Continuing the work begun by Mr. Klein in the development of the "Flaimproof" fire door of one-hour and one-and-one-half-hour fire resistance under standard time-temperature control, the Protexol Testing Laboratories have applied treated wood successfully in fire-retarding partitions, doors, and fire stops in building construction to meet a wide range of standard time-temperature test requirements of building code and insurance regulations. This work is being continued by his surviving sons at the Kenilworth (N. J.) plant, assisted by Rollin C. Bastress as technical expert.

Mr. Hartman was an active member of the American Wood Preservers Association from 1911 until his death in 1942, serving as a member of the committee on "Preservatives" for twenty years. In 1936, he was elected chairman of the newly-established "Fireproofing Committee" (committee No. 9) and continued in that capacity during the last years of his life. He belonged to committee C–5 of the American Society for Testing Materials and was interested especially in the subcommittee for developing standards and test specifications for "Fireproofed Wood," under the general chairmanship of Mr. Miller. Also, he was a member of the National Fire Protection Association and The American Electric Railway Engineering Association.

During the last thirty years much of his leisure was devoted to the hobby of flower, shrub, and tree cultivation, and he became an expert botanist and authority on plant life—particularly on trees and their by-products. He was also a pteridologist of some repute and maintained extensive gardens at both his home in Amityville, Long Island, N. Y., and at the Kenilworth plant. In the wild-flower garden at his home he successfully grew fifty-six species of wild Vermont ferns of which he was quite proud. Visitors to either place were rewarded by the floral displays and never failed to carry away gift specimens of some favorite species for enjoyment and propagation. In addition to being a member of the Park Department at Amityville, he also was interested in local Boy Scout activities and, for many years, served as chairman of Troop 83, Boy Scouts of America. Holding membership in the Green Mountain Club, in Rutland, Vt., his love of flowers frequently drew him to that state, where, in later years, he spent his summers and where he eventually died from a chronic heart ailment. It was fitting that he was laid to rest in a little cemetery in the hills of Vermont with a simple white oak cross preserved and fireproofed by the process he himself had perfected.

Mr. Hartman is survived by his widow, Florence (Nelke) Hartman, to whom he was married on February 1, 1914; by two sons, Carl F. and Frederick A. Hartman; and by his mother, Mrs. Lydia Eirmann. A third son, Richard Hartman, was killed in combat with the Japanese in December, 1941, at Manila, Philippine Islands, in the first action of World War II.

Mr. Hartman was elected an Affiliate of the American Society of Civil Engineers on January 4, 1910.

Dames, Chairman, Frederick J. Converse, Sterling S. Green, and Paul Baumann—and A. Casagrande and R. E. Fadum. 417.

"Pendleton Levee Failure." Kenneth E. Fields and William L. Wells. (With Discussion.) 1400.

"Relation of Undisturbed Sampling to Laboratory Testing." P. C. Rutledge. 1155. Discussion: Benjamin K. Hough, Jr., F. M. Van Auken, Jacob Feld, Raymond F. Dawson, Hamilton Gray, Karl Terzaghi, D. P. Krynine, D. M. Burmister, and P. C. Rutledge. 1184.

SPILLWAYS

"Aeration of Spillways." G. H. Hickox. 537. Discussion: Joe W. Johnson, J. W. Howe and Claud C. Lomax, Jr., J. C. Stevens, and G. H. Hickox. 557.

"Conformity Between Model and Prototype." A Symposium. (With Discussion.) 1.

STEEL

"Physical Properties that Affect the Behavior of Structural Members." Wilbur M. Wilson. 279. Discussion: Jonathan Jones, A. B. Kinzel, Almon H. Fuller, C. F. Goodrich, R. L. Moore, Leon S. Moisseiff, Fred L. Plummer, A. A. Eremin, and Wilbur M. Wilson. 290.

"Riveted and Pin-Connected Joints of Steel and Aluminum Alloys." Leon S. Moisseiff, E. C. Hartmann, and R. L. Moore. (With Discussion.) 1359.

STRAIN

See **STRESS AND STRAIN**

STREAM FLOW

See **WATER, FLOW OF, IN OPEN CHANNELS**

STRENGTH OF MATERIALS

"Physical Properties that Affect the Behavior of Structural Members." Wilbur M. Wilson. (With Discussion.) 279.

"Riveted and Pin-Connected Joints of Steel and Aluminum Alloys." Leon S. Moisseiff, E. C. Hartmann, and R. L. Moore. (With Discussion.) 1359.

STRESS AND STRAIN

"Physical Properties that Affect the Behavior of Structural Members." Wilbur M. Wilson. (With Discussion.) 279.

"Riveted and Pin-Connected Joints of Steel and Aluminum Alloys." Leon S. Moisseiff, E. C. Hartmann, and R. L. Moore. (With Discussion.) 1359.

"Simplified Analysis of Skewed Reinforced Concrete Frames and Arches." Richard M. Hodges. (With Discussion.) 913.

"Strains, Stresses, and Shear in Engineering Problems." Silas H. Woodard. 491. Discussion: C. M. Goodrich, Maurice P. van Buren, Joseph A. Wise, David B. Hall, Roberto Contini, I. Nelidov, Bernard L. Weiner, Richard W. Albrecht, Duff A. Abrams, C. A. P. Turner, Mark W. Huggins, A. A. Eremin, and Silas H. Woodard. 501.

"Strength of Slender Beams." George Winter. (With Discussion.) 1321.

STRUCTURAL STEEL

See **STEEL**

STRUCTURES, THEORY OF

"A Symmetrically Loaded Base Slab on an Elastic Foundation." Stanley U. Benscoter. (With Discussion.) 763.

"Simplified Analysis of Skewed Reinforced Concrete Frames and Arches." Richard M. Hodges. (With Discussion.) 913.

"Strains, Stresses, and Shear in Engineering Problems." Silas H. Woodard. (With Discussion.) 491.

"Strength of Slender Beams." George Winter. (With Discussion.) 1321.

TESTS

Sample disturbance and consolidation test results for soils. 1157.

Triaxial compression test. 1174.

Unconfined compression test. 1169.

TRAFFIC

Tunnel highways, connections, and traffic, Queens Midtown Tunnel. 683.

TUNNEL LINING

"The Queens Midtown Tunnel." Ole Singstad. 679.

TUNNELS

"The Queens Midtown Tunnel." Ole Singstad. 679. Discussion: Thomas W. Fluhr, Howard L. King, Francis V. Wagner, William J. Wilgus, S. A. Thoresen, H. G. Cruthers, Leo Geenens, Charles E. Conover, Edward Levy, Robert F. Legget, Orrin L. Brodie, A. A. Eremin, Arthur S. Tuttle, and Ole Singstad. 716.

TURBULENCE

"Effect of Turbulence on Sedimentation." William E. Dobbins. (With Discussion.) 629.

VENTILATION

Queens Midtown Tunnel. 699.

WATER, FLOW OF, IN OPEN CHANNELS

"Conformity Between Model and Prototype (Symposium): Grand Tower, Mississippi River." Frederick R. Brown. 100.

"Effect of Turbulence on Sedimentation." William E. Dobbins. (With Discussion.) 629.

"Flow Around Bends in Stable Channels." C. A. Mockmore. 593. Discussion: J. M. Robertson, Joe W. Johnson and M. A. Selim, I. Nelidov, S. M. Woodward and J. W. Howe and C. J. Posey, and C. A. Mockmore. 619.

"Flow Characteristics at Rectangular Open-Channel Junctions." Edward H. Taylor. 893. Discussion: Harold K. Palmer, G. H. Hickox, J. C. Stevens, C. J. Posey, I. B. Hosig, L. Standish Hall, Brooks T. Morris, and Edward H. Taylor. 903.

"Rôle of the Land During Flood Periods." W. W. Horner. (With Discussion.) 1269.

"The Hydraulic Jump in Sloping Channels." Carl E. Kindsvater. (With Discussion.) 1107.

WATER, FLOW OF, IN PIPES

"Determination of Kutter's *n* for Sewers Partly Filled." C. Frank Johnson. (With Discussion.) 223.

WATER, FLOW OF, OVER DAMS AND WEIRS

"Aeration of Spillways." G. H. Hickox. (With Discussion.) 537.

WATER POLLUTION

"Illinois Water Litigation, 1940–1941." Langdon Pearse. 799. Discussion: Willem Rudolfs, L. R. Howson, A. M. Buswell, Lloyd M. Johnson, H. P. Ramey, and Langdon Pearse. 824.

WATERPROOFING

Surface waterproofing of concrete reservoirs. 587.

WATER STORAGE

"Concrete Reservoirs of the Vertical-Beam Type." C. Maxwell Stanley. (With Discussion.) 567.

WATER SUPPLY

"Illinois Water Litigation, 1940–1941." Langdon Pearse. (With Discussion.) 799.

WATERWAYS

"Illinois Water Litigation, 1940–1941." Langdon Pearse. (With Discussion.) 799.

WATER WORKS

"Illinois Water Litigation, 1940–1941." Langdon Pearse. (With Discussion.) 799.

WEIRS

AUTHOR INDEX

ABRAMS, DUFF A.
Strains, stresses, shear. 520.

ADAMS, MILTON P.
Sewage treatment finace. 264.

ALBRECHT, RICHARD W.
Strains, stresses, shear. 517.

ALLEN, EDWARD RUSSELL
Memoir of. 1558.

ALLIN, THOMAS DAVID
Memoir of. 1459.

ALVORD, JOHN WATSON
Memoir of. 1447.

ARNESON, EDWIN PARK
Memoir of. 1587.

AYERS, JAMES R., JR.
Base slab. 793.

BAILEY, FRANK S.
Sloping channels. 1141.

BAILEY, THOMAS WARD
Memoir of. 1461.

BAKER, HAROLD JAMES MANNING
Memoir of. 1561.

BARRON, MAURICE
Skewed rigid frames. 962.

BAUMANN, PAUL
Building foundations. 459.

BEARD, L. R.
Meteorology and flood estimating. 361.

BEBB, EDWARD CROSBY
Memoir of. 1563.

BECKER, DONALD N.
"Development of the Chicago Type Bascule Bridge." 995.

BELL, HUGH STEVENS
Sedimentation. 1088.

BENFIELD, BERNARD
Memoir of. 1464.

BENSCOTER, STANLEY U.
"A Symmetrically Loaded Base Slab on an Elastic Foundation." 763.

BERNARD, MERRILL
"Primary Rôle of Meteorology in Flood Flow Estimating." 311.

BISCHOFF, JULIUS MONTGOMERY
Memoir of. 1563.

BLAISDELL, FRED W.
Model-prototype conformity. 157.

BLANEY, HARRY F.
Sedimentation. 1089.

BOLTON, REGINALD PELHAM
Memoir of. 1465.

BONIFACE, ARTHUR
Memoir of. 1564.

BOWRON, CHARLES EDWARD
Memoir of. 1470.

BRODIE, ORRIN L.
Queens tunnel. 737.

BROWN, CARL B.
Sedimentation. 1080.

BROWN, DALTON MUNROE
Memoir of. 1567.

BROWN, FREDERICK R.
"Conformity Between Model and Prototype (Symposium): Grand Tower, Mississippi River." 100.

BURMISTER, D. M.
Building foundations. 444.
Undisturbed sampling. 1204.

BURNETT, KNOX FOLSOM
Memoir of. 1568.

BUSWELL, A. M.
Illinois litigation. 828.

CAMP, THOMAS R.
Kutter's *n* for sewers. 240.
Turbulence and sedimentation. 660.

CANNON, SYLVESTER QUAYLE
Memoir of. 1472.

CARSON, A. BRINTON
Sewage treatment finance. 271.

CASAGRANDE, A.
"Application of Soil Mechanics in Designing Building Foundations." 383.

CAYE, WOOLSEY MOORMAN
Memoir of. 1474.

COCHRANE, R. B.
"Conformity Between Model and Prototype: A Symposium: Pressure Heads on Bonneville Dam." 77.

COCHRANE, VICTOR H.
Vertical-beam reservoirs. 577.

COLEMAN, RICHARD ALESTER
Memoir of. 1588.

CONOVER, CHARLES E.
Queens tunnel. 729.

CONSTANCE, EDWARD CARTWRIGHT
Memoir of. 1477.

CONTINI, ROBERTO
Strains, stresses, shear. 509.

CONVERSE, FREDERICK J.
Building foundations. 459.

COOK, PAUL DARWIN
Memoir of. 1478.

COULTER, RICHARD G.
Kutter's *n* for sewers. 243.

COX, GLEN N.
Model-prototype conformity. 127.

CRUTHERS, H. G.
Queens tunnel. 727.

CUMMINGS, A. E.
Base slab. 787.

DAMES, TRENT R.
Building foundations. 459.

DAVENPORT, R. W.
New Mexico and Arizona. 877.

DAVISON, GEORGE STEWART
Memoir of. 1437.

DAWSON, RAYMOND F.
Undisturbed sampling. 1190.

DEWEY, H. G., JR.
"Conformity Between Model and Prototype (Symposium): Hydraulic Structures." 3.

DICKSON, A. J.
New Mexico and Arizona. 868.

DOBBINS, WILLIAM E.
"Effect of Turbulence on Sedimentation." 629.

DOUMA, J. H.
Model-prototype conformity. 170.

DUNSTAN, GILBERT H.
Model-prototype conformity. 168.

EIFFERT, C. H.
Meteorology and flood estimating. 369.

EINSTEIN, H. A.
Model-prototype conformity. 134.
Turbulence and sedimentation. 660.

ELKIN, NATHAN ELIAS
Memoir of. 1589.

EPSTEIN, HARRIS
Base slab. 793.

EREMIN, A. A.
Base slab. 785.
Building foundations. 443.
Queens tunnel. 747.
Skewed rigid frames. 968.
Strains, stresses, shear. 533.
Structural properties. 302.

FADUM, R. E.
"Application of Soil Mechanics in Designing Building Foundations." 383.

FEE, JEROME
Sloping channels. 1138.

FELD, JACOB
Building foundations. 417.
Undisturbed sampling. 1189.

FENSTERMAKER, DEWITT CLINTON
Memoir of. 1570

FIELD, GEORGE ADDISON
Memoir of. 1571.

FIELDS, KENNETH E.
"Pendleton Levee Failure." 1400.

FLUHR, THOMAS W.
Queens tunnel. 716.

FOSTER, EDGAR E.
New Mexico and Arizona. 876.

FREEMAN, GEORGE L.
Building foundations. 454.

FULLER, ALMON H.
Structural properties. 295.

GALBREATH, WILLIAM OTTO
Memoir of. 1481.

GALLOWAY, JOHN DEBO
Memoir of. 1451.

GAUDIN, A. M.
Turbulence and sedimentation. 657.

GEARHART, J. C.
Vertical-beam reservoirs. 580.

GEENENS, LEO
Queens tunnel. 728.

GEISLER, C. D.
Skewed rigid frames. 942.

GILARDI, A. J.
Model-prototype conformity. 154.

GILMAN, EDGAR DOW
Meteorology and flood estimating. 352.

GIRAND, JAMES
New Mexico and Arizona. 871.

GITTLESON, IRVIN
Memoir of. 1572.

GOODRICH, C. F.
Structural properties. 296.

GOODRICH, C. M.
Slender beams. 1350.
Strains, stresses, shear. 501.

GORDON, C. W.
Sludge drying. 988.

GRANGER, ARMOUR T.
Chicago bridges. 1031.

GRAY, HAMILTON
Undisturbed sampling. 1193.

GREELEY, SAMUEL A.
"Organizing and Financing Sewage Treatment Projects." 248.

GREEN, STERLING S.
Building foundations. 459.

GRIER, ARTHUR J.
Subsurface exploration. 214.

GRIMM, C. I.
Model-prototype conformity. 119.

HAINES, REUBEN M.
"Seismic Subsurface Exploration on the St. Lawrence River Project." 194.

HALL, DAVID B.
Strains, stresses, shear. 506.

HALL, L. STANDISH
Flow at channel junctions. 908.
Meteorology and flood estimating. 376.
Model-prototype conformity. 150.
Sedimentation. 1093.
Turbulence and sedimentation. 677.

HALLIHAN, JOHN PHILIP
Memoir of. 1483.

HAMMOND, ALONZO J.
Chicago bridges. 1026.

HANOVER, CLINTON D., JR.
Chicago bridges. 1028.

HANSEN, PAUL
Sludge drying. 989.

HAPP, STAFFORD C.
Sedimentation. 1078.

HARROLD, L. L.
New Mexico and Arizona. 868.

HARTIGAN, JAMES J.
"Conformity Between Model and Prototype (Symposium): Pickwick, Wheeler, and Guntersville Locks." 35.

HARTMAN, ERNEST FREDERICK
Memoir of. 1592.

HARTMANN, E. C.
"Riveted and Pin-Connected Joints of Steel and Aluminum Alloys." 1359.

HATHAWAY, GAIL A.
Meteorology and flood estimating. 370.

HAWLEY, GEORGE PRINCE
Memoir of. 1484.

HAYDEN, ARTHUR G.
Skewed rigid frames. 944.

HAYS, JOHN COFFEE
Memoir of. 1486.

HERZBERG, WILLIAM
Memoir of. 1489.

HICKOX, G. H.
"Aeration of Spillways." 537.
"Conformity Between Model and Prototype (Symposium): Spillway Coefficients, Norris Dam." 68.
Flow at channel junctions. 904.
Sloping channels. 1141.

HICKS, W. I.
"A Method of Computing Urban Runoff." 1217.

HODGES, PAUL V.
New Mexico and Arizona. 874.

HODGES, RICHARD M.
"Simplified Analysis of Skewed Reinforced Concrete Frames and Arches." 913.

HOLMES, ROBERT LESLIE
Memoir of. 1490.

HOPKINS, WILLIAM J.
"Conformity Between Model and Prototype (Symposium): Hydraulic Conditions to Lock and Dam No. 4." 103.

HORNER, W. W.
"Rôle of the Land During Flood Periods." 1269.
Urban runoff. 1260.

HOSIG, I. B.
Flow at channel junctions. 906.

HOUGH, BENJAMIN K., JR.
Undisturbed sampling. 1184.

HOUK, IVAN E.
Meteorology and flood estimating. 359.

HOWE, J. W.
Spillway aeration. 559.
Stable channels. 626.

HOWSON, L. R.
Illinois litigation. 826.

HOYT, W. G.
Meteorology and flood estimating. 360.
Rôle of land. 1299.

HUBBARD, WINFRED DEAN
Memoir of. 1492.

HUDSON, CLARENCE WALTER
Memoir of. 1493.

HUGGINS, MARK W.
Strains, stresses, shear. 533.

HUGHES, DAVID EDWARD
Memoir of. 1495.

HULICK, DAN A.
Memoir of. 1573.

HUSSEY, H. D.
Slender beams. 1354.

JAMESON, ROBERT O.
Base slab. 777.

JARVIS, CLARENCE S.
Meteorology and flood estimating. 353.
New Mexico and Arizona. 874.
Rôle of land. 1312.
Sedimentation. 1086.
Urban runoff. 1254.

JASPER, T. McLEAN
Slender beams. 1350.

JENS, S. W.
Urban runoff. 1255.

JOHNSON, C. FRANK
"Determination of Kutter's *n* for Sewers Partly Filled." 223.

JOHNSON, JOE W.
